The Carpentier classification (Fig. 14.75) uses mitral leaflet motion to divide patients into different classes according to the mechanism of regurgitation which can be useful when considering surgical intervention.

Symptoms

Mitral regurgitation can be present for many years and the cardiac dimensions greatly increased before any symptoms occur. The increased stroke volume is sensed as a

(b) Magnified short-axis view showing the mitral valve orifice as seen from the direction of the arrow in (a). The orifice area can be planimtered to assess the severity; in this case it is 1.5 cm², indicating moderately severe disease.

(c) Continuous-wave (CW) Doppler recording showing slow rate of decay of flow velocity from the left atrium to the left ventricle during diastole. It is also possible to derive the valve orifice area from the velocity decay rate. LA, left atrium; LV, left ventricle; AMVL, PMVL, anterior and posterior mitral valve leaflets.

'palpitation'. *Dyspnoea* and *orthopnoea* develop owing to pulmonary venous hypertension occurring as a direct result of the mitral regurgitation and secondarily to left ventricular failure. *Fatigue* and *lethargy* develop because of the reduced cardiac output. In the late stages of the disease

Figure 14.75 Carpentier classification of mitral regurgitation and its causes. (a) Normal leaflet motion; (b) increased leaflet motion/prolapse; (c) restricted leaflet motion. the symptoms of *right heart failure* also occur and eventually lead to congestive cardiac failure. *Cardiac cachexia* may develop. Thromboembolism is less common than in mitral stenosis, but *subacute infective endocarditis* is much more common.

Signs

See Clinical memo in Figure 14.71.

The physical signs of uncomplicated mitral regurgitation are:

- Laterally displaced (forceful) diffuse apex beat and a systolic thrill (if severe)
- Soft first heart sound, owing to the incomplete apposition of the valve cusps and their partial closure by the time ventricular systole begins
- Pansystolic murmur, owing to the occurrence of regurgitation throughout the whole of systole, being loudest at the apex but radiating widely over the precordium and into the axilla
- With a floppy mitral valve (see below) there may be a mid-systolic click, which is produced by the sudden prolapse of the valve and the tensing of the chordae tendineae that occurs during systole. This may be followed by a late systolic murmur owing to some regurgitation.
- Prominent third heart sound, owing to the sudden rush of blood back into the dilated left ventricle in early diastole (sometimes a short mid-diastolic flow murmur may follow the third heart sound).

The signs related to atrial fibrillation, pulmonary hypertension, and left and right heart failure develop later in the disease. The onset of atrial fibrillation has a much less dramatic effect on symptoms than in mitral stenosis.

Investigations

Chest X-ray

The chest X-ray may show left atrial and left ventricular enlargement. There is an increase in the CTR, and valve calcification is seen.

Electrocardiogram

The ECG shows the features of left atrial delay (bifid P waves) and left ventricular hypertrophy (Fig. 14.76) as manifested by tall R waves in the left lateral leads (e.g. leads I and V₆) and deep S waves in the right-sided precordial leads, (e.g. leads V₁ and V₂). (Note that SV₁ plus RV₅ or RV₆ >35 mm indicates left ventricular hypertrophy.) Left ventricular hypertrophy occurs in about 50% of patients with mitral regurgitation. Atrial fibrillation may be present.

Figure 14.76 Left ventricular hypertrophy shown in a 12-lead ECG. Note the size of the S wave seen in V_1 (21 mm); S in $V_1 + R$ in $V_6 = >35$ mm.

Figure 14.77 Mitral regurgitation. (a) Transoesophageal echocardiography with marked prolapse of part of the posterior mitral valve leaflet (PMVL). (b) Transoesophageal echocardiography with colour Doppler demonstrates severe mitral regurgitation (MR) into the left atrium (LA). AMVL, aortic mitral valve leaflet; LV, left ventricle; PISA, proximal isovelocity surface area.

Echocardiogram (Fig. 14.77)

The echocardiogram shows a dilated left atrium and left ventricle. There may be specific features of chordal or papillary muscle rupture. The severity of regurgitation can be assessed with the use of colour Doppler looking at the jet area and the size of the vena contracta and by calculating

the regurgitant fraction, volume or orifice area. Useful information regarding the severity of the condition can be obtained indirectly by observing the dynamics of ventricular function. *Transoesophageal echocardiography* can be helpful to identify structural valve abnormalities before surgery (Fig. 14.77) and intraoperative TOE can aid assessment of the efficacy of valve repair.

Cardiac catheterization

This demonstrates a prominent left atrial systolic pressure wave, and when contrast is injected into the left ventricle it is seen regurgitating into an enlarged left atrium during systole.

Treatment

Mild mitral regurgitation in the absence of symptoms can be managed conservatively by following the patient with serial echocardiograms. Prophylaxis against endocarditis is discussed in Chapter 4 (see p. 87). Any evidence of progressive cardiac enlargement generally warrants early surgical intervention by either mitral valve repair or replacement. The current ESC guidelines recommend surgical intervention in patients with symptomatic severe mitral regurgitation, left ventricular ejection fraction $>30\%$ and end-diastolic dimension of under 55 mm; and in asymptomatic patients with left ventricular dysfunction (end-systolic dimension >45 mm and/or ejection fraction of under 60%). Surgery should also be considered in patients with asymptomatic severe mitral regurgitation with preserved left ventricular function and atrial fibrillation and/or pulmonary hypertension. The advantages of surgical intervention are diminished in more advanced disease. (*Sudden torrential mitral regurgitation, as seen with chordal or papillary muscle rupture or infective endocarditis, necessitates emergency mitral valve replacement.*) In patients who are not appropriate for surgical intervention, or in whom surgery will be performed at a later date, management involves treatment with ACE inhibitors, diuretics and possibly anticoagulants. More recently a percutaneous mitral valve repair (MitraClip) has been compared to cardiac surgery in the EVEREST II trial and appears effective in the short-term at reducing the severity of mitral regurgitation and providing symptomatic relief. It is appropriate in patients unsuitable for cardiac surgery.

Prolapsing (billowing) mitral valve

This is also known as Barlow's syndrome or floppy mitral valve. It is due to excessively large mitral valve leaflets, an

Figure 14.78 Bicuspid aortic valve.

enlarged mitral annulus, abnormally long chordae or disordered papillary muscle contraction. Histology may demonstrate myxomatous degeneration of the mitral valve leaflets. It is more commonly seen in young women than in men or older women and it has a familial incidence. Its cause is unknown but it is associated with Marfan's syndrome, thyrotoxicosis, rheumatic or ischaemic heart disease. It also occurs in association with atrial septal defect and as part of hypertrophic cardiomyopathy. Mild mitral valve prolapse is so common that it should be regarded as a normal variant.

Aortic stenosis

Aortic stenosis is a chronic progressive disease that produces obstruction to the left ventricular stroke volume leading to symptoms of chest pain, breathlessness, syncope and pre-syncope and fatigue.

Aortic valve stenosis includes calcific stenosis of a trileaflet aortic valve, stenosis of a congenitally bicuspid valve, and rheumatic aortic stenosis.

Calcific aortic valvular disease (CAVD) is the commonest cause of aortic stenosis and mainly occurs in the elderly. This is an inflammatory process involving macrophages and T lymphocytes with initially thickening of the subendothelium with adjacent fibrosis. The lesions contain lipoproteins which calcify, increasing leaflet stiffness and reducing systolic opening. This can occur in a tri or bileaflet aortic valve. Risk factors for CAVD include old age, male gender, elevated lipoprotein (a) and low-density lipoprotein (LDL), hypertension, diabetes and smoking.

Bicuspid aortic valve (BAV) (Fig. 14.78) is the commonest form of congenital heart disease occurring in 1–2% of live births and in many cases, is familial. Patients with CAVD of a bicuspid valve tend to present at an earlier age. BAV is associated with aortic coarctation, root dilatation, and potentially aortic dissection and patients should have regular follow-up echocardiography.

Rheumatic fever can produce progressive fusion, thickening and calcification of the aortic valve. In rheumatic heart disease the aortic valve is affected in about 30–40% of cases and there is usually associated mitral valve disease.

Other causes of valvular stenosis include chronic kidney disease, Paget's disease of bone, previous radiation exposure, homozygous familial hypercholesterolaemia.

Valvar aortic stenosis should be distinguished from other causes of obstruction to left ventricular emptying (Fig. 14.79), which include:

- Supravalvular obstruction – a congenital fibrous diaphragm above the aortic valve often associated

Figure 14.79 Several forms of left ventricular outflow tract obstruction.

with mental retardation and hypercalcaemia (Williams' syndrome)

- Hypertrophic cardiomyopathy – septal muscle hypertrophy obstructing left ventricular outflow
- Subvalvular aortic stenosis – a congenital condition in which a fibrous ridge or diaphragm is situated immediately below the aortic valve.

Pathophysiology

Obstructed left ventricular emptying leads to increased left ventricular pressure and compensatory left ventricular hypertrophy. In turn, this results in relative ischaemia of the left ventricular myocardium, and consequent angina, arrhythmias and left ventricular failure. The obstruction to left ventricular emptying is relatively more severe on exercise. Normally, exercise causes a many-fold increase in cardiac output, but when there is severe narrowing of the aortic valve orifice the cardiac output can hardly increase. Thus, the blood pressure falls, coronary ischaemia worsens, the myocardium fails and cardiac arrhythmias develop. Left ventricular systolic function is typically preserved in patients with aortic stenosis (*cf.* aortic regurgitation).

Symptoms

There are usually no symptoms until aortic stenosis is moderately severe (when the aortic orifice is reduced to one-third of its normal size). At this stage, *exercise-induced syncope*, *angina* and *dyspnoea* develop. When symptoms occur, the prognosis is poor – on average, death occurs within 2–3 years if there has been no surgical intervention.

Signs

See Clinical memo in Figure 14.80.

Pulse

The carotid pulse is of small volume and is slow-rising or plateau in nature (see this chapter).

Precordial palpation

The apex beat is not usually displaced because hypertrophy (as opposed to dilatation) does not produce noticeable cardiomegaly. However, the pulsation is sustained and obvious. A double impulse is sometimes felt because the fourth heart sound or atrial contraction ('kick') may be palpable. A systolic thrill may be felt in the aortic area.

Figure 14.80 Features of aortic stenosis and aortic regurgitation. EC, ejection click; EDM, early diastolic murmur; MSM, mid-systolic murmur; S1, first heart sound. LSE, left sternal edge.

	Normal	Mild	Moderate	Severe
Peak velocity (m/s)	<1.7	1.7–2.9	3.0–4.0	>4.0
Peak pressure drop (mmHg)		<36	36–64	>64
Mean pressure drop (mmHg)		<25	25–40	>40
Valve area (cm ²)	>2.0	1.5–2.0	1.0–1.4	<1.0

British Society of Echocardiography.

Auscultation

The most obvious auscultatory finding in aortic stenosis is an ejection systolic murmur that is usually 'diamond-shaped' (crescendo-decrescendo). The murmur is usually longer when the disease is more severe, as a longer ejection time is needed. The murmur is usually rough in quality and best heard in the aortic area. It radiates into the carotid arteries and also the precordium. The intensity of the murmur is not a good guide to the severity of the condition because it is lessened by a reduced cardiac output. In severe cases, the murmur may be inaudible.

Other findings include:

- Systolic ejection click, unless the valve has become immobile and calcified
- Soft or inaudible aortic second heart sound when the aortic valve becomes immobile
- Reversed splitting of the second heart sound (splitting on expiration) (see p. 679)
- Prominent fourth heart sound, which is caused by atrial contraction, is heard unless co-existing mitral stenosis prevents this.

Investigations

Chest X-ray

The chest X-ray usually reveals a relatively small heart with a prominent, dilated, ascending aorta. This occurs because turbulent blood flow above the stenosed aortic valve produces so-called 'post-stenotic dilatation'. The aortic valve may be calcified. The CTR increases when heart failure occurs.

Electrocardiogram

The ECG shows left ventricular hypertrophy and left atrial delay. A left ventricular 'strain' pattern due to 'pressure overload' (depressed ST segments and T wave inversion in leads orientated towards the left ventricle, i.e. leads I, AVL, V₅ and V₆) is common when the disease is severe. Usually, sinus rhythm is present, but ventricular arrhythmias may be recorded.

Echocardiography

Echocardiography readily demonstrates the thickened, calcified and immobile aortic valve cusps, the presence of left ventricular hypertrophy, and can be used to determine the severity of aortic stenosis (Table 14.36, Fig. 14.81a,b). Transthoracic echocardiography is rarely indicated.

Cardiac catheterization

Cardiac catheterization is rarely necessary since all of this information can be gained non-invasively with echocardiography and CMR. Coronary angiography is necessary before recommending surgery.

Cardiac magnetic resonance and cardiac CT

These techniques are indicated for assessing the thoracic aorta for the presence of aneurysm, dissection or coarctation but are rarely necessary.

Treatment

In patients with aortic stenosis, symptoms are a good index of severity and all symptomatic patients should have *aortic valve replacement*. Patients with a BAV and ascending aorta >50 mm or expanding at >5 mm/year should be considered

Figure 14.81 Cardiac echograms. (a) 2-D Echocardiogram (long-axis view) in a patient with calcific aortic stenosis. The calcium in the valve generates abnormally intense echoes. There is some evidence of the associated left ventricular hypertrophy. (b) Continuous-wave (CW) Doppler signals obtained from the right upper parasternal edge, where the high-velocity jet from the stenotic valve is coming towards the transducer. AV, aortic valve; LA, left atrium; MV, mitral valve; LV, left ventricle; IVS, interventricular septum; PVW, posterior ventricular wall.

for surgical intervention. Asymptomatic patients should be under regular review for assessment of symptoms and echocardiography. Surgical intervention for asymptomatic people with severe aortic stenosis is recommended in those with:

- Symptoms during an exercise test or with a drop in blood pressure
- A left ventricular ejection fraction of <50%
- Moderate–severe stenosis undergoing CABG, surgery of the ascending aorta or other cardiac valve.

Antibiotic prophylaxis against infective endocarditis is discussed in Chapter 4 (see p. 87). Provided that the valve is not severely deformed or heavily calcified, critical aortic stenosis in childhood or adolescence can be treated by valvotomy (performed under direct vision by the surgeon or by balloon dilatation using X-ray visualization). This produces temporary relief from the obstruction. Aortic valve replacement will usually be needed a few years later. Balloon dilatation (valvuloplasty) has been tried in adults, especially in the elderly, as an alternative to surgery. Generally results are poor and such treatment is reserved for patients unfit for surgery or as a ‘bridge’ to surgery (as systolic function will often improve).

Table 14.37 Causes and associations of aortic regurgitation

Acute aortic regurgitation	Chronic aortic regurgitation
Acute rheumatic fever	Rheumatic heart disease
Infective endocarditis	Syphilis
Dissection of the aorta	Arthritides:
Ruptured sinus of Valsalva aneurysm	Reactive arthritis
Failure of prosthetic valve	Ankylosing spondylitis
	Rheumatoid arthritis
	Hypertension (severe)
	Bicuspid aortic valve
	Aortic endocarditis
	Marfan's syndrome
	Osteogenesis imperfecta

Percutaneous valve replacement

A novel treatment for patients unsuitable for surgical aortic valve replacement is transcatheter implantation with a balloon expandable stent valve. Valve implantation has been shown to be successful (86%) with a procedural mortality of 2% and 30-day mortality of 12%. Further larger and randomized studies with long-term follow-up are required.

Aortic regurgitation

Aortic regurgitation can occur in diseases affecting the aortic valve e.g. endocarditis and diseases affecting the aortic root, e.g. Marfan's syndrome (Table 14.37).

Pathophysiology

Aortic regurgitation is reflux of blood from the aorta through the aortic valve into the left ventricle during diastole. If net cardiac output is to be maintained, the total volume of blood pumped into the aorta must increase, and consequently the left ventricular size must enlarge. Because of the aortic runoff during diastole, diastolic blood pressure falls and coronary perfusion is decreased. In addition, the larger left ventricular size is mechanically less efficient so that the demand for oxygen is greater and cardiac ischaemia develops.

Symptoms

In aortic regurgitation, significant symptoms occur late and do not develop until *left ventricular failure* occurs. As with mitral regurgitation, a common symptom is *pounding of the heart* because of the increased left ventricular size and its vigorous pulsation. *Angina pectoris* is a frequent complaint. Varying grades of *dyspnoea* occur depending on the extent of left ventricular dilatation and dysfunction. *Arrhythmias* are relatively uncommon.

Signs

See Clinical memo in Figure 14.80. The signs of aortic regurgitation are many and are due to the hyperdynamic circulation, reflux of blood into the left ventricle and the increased left ventricular size.

The pulse is bounding or collapsing (see p. 677). The following signs, which are rare, also indicate a hyperdynamic circulation:

- **Quincke's sign** – capillary pulsation in the nail beds
- **De Musset's sign** – head nodding with each heart beat
- **Duroziez's sign** – a to-and-fro murmur heard when the femoral artery is auscultated with pressure applied distally (if found, it is a sign of severe aortic regurgitation)

- **Pistol shot femorals** – a sharp bang heard on auscultation over the femoral arteries in time with each heart beat.

The apex beat is displaced laterally and downwards and is forceful in quality. On auscultation, there is a high-pitched early diastolic murmur best heard at the left sternal edge in the fourth intercostal space with the patient leaning forward and the breath held in expiration. Because of the volume overload there is commonly an ejection systolic flow murmur. The regurgitant jet can impinge on the anterior mitral valve cusp, causing a mid-diastolic murmur (Austin Flint rumble).

Investigations

Chest X-ray

The chest X-ray features are those of left ventricular enlargement and possibly of dilatation of the ascending aorta. The ascending aortic wall may be calcified in syphilis, and the aortic valve calcified if valvular disease is responsible for the regurgitation.

Electrocardiogram

The ECG appearances are those of left ventricular hypertrophy due to 'volume overload' – tall R waves and deeply inverted T waves in the left-sided chest leads, and deep S waves in the right-sided leads. Normally, sinus rhythm is present.

Echocardiogram

The echocardiogram (Fig. 14.82) demonstrates vigorous cardiac contraction and a dilated left ventricle. The aortic root may also be enlarged. Diastolic fluttering of the mitral leaflets or septum occurs in severe aortic regurgitation (producing the Austin Flint rumble). The severity of aortic regurgitation is assessed with a combination of colour Doppler (extent of regurgitant jet, width of the vena contracta; see Fig. 14.82) and CW Doppler (diastolic flow reversal in the descending thoracic aorta, pressure half time). Transoesophageal echocardiography may provide additional information about the valves and aortic root.

Cardiac catheterization

Cardiac catheterization is required to assess for coronary artery disease in patients requiring surgery. During cardiac catheterization, injection of contrast medium into the aorta (aortography) will outline aortic valvular abnormalities and allow assessment of the degree of regurgitation.

Cardiac magnetic resonance and cardiac CT

These techniques may be indicated for assessing the thoracic aorta in cases of aortic dilatation or dissection. Cardiac MR can be used to quantify regurgitant volume.

Figure 14.82 Aortic regurgitation (colour Doppler).

Treatment

The underlying cause of aortic regurgitation (e.g. syphilitic aortitis or infective endocarditis) may require specific treatment. Patients with acute aortic regurgitation may require treatment with vasodilators and inotropes. ACE inhibitors are useful in patients with left ventricular dysfunction and beta-blockers may slow aortic dilatation in Marfan patients. Because symptoms do not develop until the myocardium fails and because the myocardium does not recover fully after surgery, operative valve replacement may be performed before significant symptoms occur.

Aortic surgery is indicated:

- in acute severe aortic regurgitation e.g. endocarditis
- in symptomatic (dyspnoea, NYHA class II-IV, angina) patients with chronic severe aortic regurgitation
- when asymptomatic with left ventricular ejection fraction is $\leq 50\%$
- when asymptomatic with left ventricular ejection fraction $> 50\%$ but with a dilated left ventricle (end-diastolic dimension > 70 mm or systolic dimension > 50 mm)
- when undergoing CABG, surgery of the ascending aorta or other cardiac valve.

Both mechanical prostheses and tissue valves are used. Tissue valves are preferred in the elderly and when anticoagulants must be avoided, but are contraindicated in children and young adults because of the rapid calcification and degeneration of the valves.

Antibiotic prophylaxis against infective endocarditis (see p. 87) is not recommended.

Tricuspid stenosis

This uncommon valve lesion, which is seen much more often in women than in men, is usually due to rheumatic heart disease and is frequently associated with mitral and/or aortic valve disease. Tricuspid stenosis is also seen in the carcinoid syndrome.

Pathophysiology

Tricuspid valve stenosis results in a reduced cardiac output, which is restored towards normal when the right atrial pressure increases. The resulting systemic venous congestion produces hepatomegaly, ascites and dependent oedema.

Symptoms

Usually, patients with tricuspid stenosis complain of symptoms due to associated left-sided rheumatic valve lesions. The *abdominal pain* (due to hepatomegaly) and swelling (due to ascites), and *peripheral oedema* that occur are relatively severe when compared with the degree of *dyspnoea*.

Signs

If the patient remains in sinus rhythm, which is unusual, there is a prominent jugular venous *a* wave. This pre-systolic pulsation may also be felt over the liver. There is usually a rumbling mid-diastolic murmur, which is heard best at the lower left sternal edge and is louder on inspiration. It may be missed because of the murmur of co-existing mitral stenosis. A tricuspid opening snap may occasionally be heard.

Hepatomegaly, abdominal ascites and dependent oedema may be present.

Investigations

On the chest X-ray there may be a prominent right atrial bulge. On the ECG the enlarged right atrium is shown by

peaked, tall P waves (>3 mm) in lead II. The echocardiogram may show a thickened and immobile tricuspid valve, but this is not so clearly seen as an abnormal mitral valve.

Treatment

Medical management consists of diuretic therapy and salt restriction. Tricuspid valvotomy is occasionally possible, but tricuspid valve replacement is often necessary. Other valves usually also need replacement because tricuspid valve stenosis is rarely an isolated lesion.

Tricuspid regurgitation (Fig. 14.25)

Functional tricuspid regurgitation may occur whenever the right ventricle dilates, e.g. in cor pulmonale, myocardial infarction or pulmonary hypertension.

Organic tricuspid regurgitation may occur with rheumatic heart disease, infective endocarditis, carcinoid syndrome, Ebstein's anomaly (a congenitally malpositioned tricuspid valve) and other congenital abnormalities of the atrioventricular valves.

Symptoms and signs

The valvular regurgitation gives rise to high right atrial and systemic venous pressure. Patients may complain of the symptoms of *right heart failure* (see this chapter).

Physical signs include a large jugular venous 'cv' wave and a palpable liver that pulsates in systole. Usually a right ventricular impulse may be felt at the left sternal edge, and there is a blowing pansystolic murmur, best heard on inspiration at the lower left sternal edge. Atrial fibrillation is common.

An *echo* shows dilatation of the right ventricle with thickening of the valve.

Treatment

Functional tricuspid regurgitation usually disappears with medical management. Severe organic tricuspid regurgitation may require operative repair of the tricuspid valve (annuloplasty or plication). Very occasionally, tricuspid valve replacement may be necessary. In drug addicts with infective endocarditis of the tricuspid valve, surgical removal of the valve is recommended to eradicate the infection. This is usually well tolerated in the short term. The insertion of a prosthetic valve for this condition is sometimes necessary.

Pulmonary stenosis

This is usually a congenital lesion, but it may rarely result from rheumatic fever or from the carcinoid syndrome. Congenital pulmonary stenosis may be associated with an intact ventricular septum or with a ventricular septal defect (Fallot's tetralogy).

Pulmonary stenosis may be valvular, subvalvular or supra-valvular. Multiple congenital pulmonary arterial stenoses are usually due to infection with rubella during pregnancy.

Symptoms and signs

The obstruction to right ventricular emptying results in right ventricular hypertrophy which in turn leads to right atrial hypertrophy. Severe *pulmonary obstruction* may be incompatible with life, but lesser degrees of obstruction give rise to *fatigue*, *syncope* and the symptoms of *right heart failure*. Mild pulmonary stenosis may be asymptomatic.

The physical signs are characterized by a harsh mid-systolic ejection murmur, best heard on inspiration, to the left of the sternum in the second intercostal space. This murmur is often associated with a thrill. The pulmonary closure sound

is usually delayed and soft. There may be a pulmonary ejection sound if the obstruction is valvular. A right ventricular fourth sound and a prominent jugular venous a wave are present when the stenosis is moderately severe. A right ventricular heave (sustained impulse) may be felt.

Investigations

The chest X-ray usually shows a prominent pulmonary artery owing to post-stenotic dilatation. On electrocardiography the ECG demonstrates both right atrial and right ventricular hypertrophy, although it may sometimes be normal even in severe pulmonary stenosis. A Doppler echocardiogram is the investigation of choice.

Treatment

Treatment of severe pulmonary stenosis requires pulmonary valvotomy (balloon valvotomy or direct surgery).

Pulmonary regurgitation

This is the most common acquired lesion of the pulmonary valve. It results from dilatation of the pulmonary valve ring, which occurs with pulmonary hypertension. It is characterized by a decrescendo diastolic murmur, beginning with the pulmonary component of the second sound that is difficult to distinguish from the murmur of aortic regurgitation. Pulmonary regurgitation usually causes no symptoms and treatment is rarely necessary.

Prosthetic valves

There is no ideal replacement for our own normally functioning, native heart valves. There are two options for valve prostheses: mechanical or tissue (bioprosthetic).

The valves consist of two basic components: an opening to allow blood to flow through and an occluding mechanism to regulate the flow. Mechanical prostheses rely on artificial conclusers: a ball and cage (Starr-Edwards), tilting disc (Bjork-Shiley) or double tilting disc (St Jude). Tissue prostheses are derived from human (homograft), or from porcine or bovine (xenograft) origin. A valve replacement from within the same patient (i.e. pulmonary to aortic valve position) is termed an autograft.

Mechanical versus tissue valves

Mechanical valves, being artificial structures, are more durable than their tissue counterparts, which tend to degenerate after 10 years. However, artificial structures are more thrombogenic. Mechanical valves require formal anticoagulation for the lifetime of the prosthesis. The target INR is determined by the type of valve inserted, the position, and whether the patient has additional risk factors for thromboembolism (mitral, tricuspid, pulmonary valve disease; previous thromboembolism; atrial fibrillation; left atrial diameter >50 mm; mitral stenosis; left ventricular ejection fraction $<35\%$; hypercoagulable state) (see Ch. 8):

- Low thrombogenicity valve (Carbomedics (aortic position), Medtronic Hall, St Jude Medical (without silzone)): INR 2.5 without and 3.0 with additional risk factors.
- Medium thrombogenicity valve (Bjork-Shiley, other bi-leaflet valves): INR 3.0 without and 3.5 with additional risk factors.
- Medium thrombogenicity valve (Lillehei-Kaster, Omniscience, Starr-Edwards): INR 3.5 without and 4.0 with additional risk factors.

a

b

c

Prosthetic valves.

- (a) Bjork-Shiley mechanical prosthetic valve.
(b) St Jude double tilting disc.
(c) Aortic valve tissue prosthesis (aortic view).

Tissue valves only require anticoagulation for a limited postoperative period while the suture lines endothelialize (the European Society of Cardiology recommend 3 months with a target INR of 2.5 although some centres use low-dose aspirin 75–100 mg daily); it can then be discontinued unless another risk factor for thromboembolism (e.g. atrial fibrillation) persists. New anticoagulants (direct thrombin inhibitors) do not require monitoring.

On auscultation, tissue valve heart sounds are comparable to those of a native valve. Mechanical valve heart sounds are generally louder and both opening and closing sounds can be heard.

Complications

All prostheses carry a risk of infection. Prosthetic valve endocarditis is associated with significant morbidity and mortality; prevention is the cornerstone of management. Patient education about antibiotic prophylaxis is vital and this should be reinforced at clinic visits. Any procedure which results in a breach of the body's innate defences (i.e. dental treatment, catheter insertion) increases the risk of exposing the prosthesis to a bacteraemia. This must be borne in mind when managing a patient with a prosthetic heart valve and steps taken to minimize the risk involved. The prosthetic valve occluding mechanism can be interrupted by vegetations, but also by thrombosis and calcification, resulting in either stenosis or regurgitation. The prosthesis can become detached from the valve ring resulting in a *para-prosthetic leak*. Evidence of structural failure can be detected by simple auscultation, with echocardiography as the initial investigation of choice. Transthoracic echocardiography is non-invasive, but scattering of echoes by mechanical valves makes their assessment difficult. Transoesophageal echocardiography provides alternative views and higher image resolution, making it the investigation of choice when prosthetic valve endocarditis is suspected.

Interruption of anticoagulant therapy

For minor surgical procedures including dental extraction anticoagulation should not be interrupted although the INR should be reduced to a target of 2.0. Percutaneous arterial puncture is safe with an INR <2.0 although radial catheterization may be possible at higher INR levels. For major surgical procedures anticoagulation should be discontinued 5 days before the procedure and intravenous unfractionated heparin or subcutaneous low-molecular-weight heparin commenced when the INR is below 2.0.

Pregnancy and prosthetic heart valves

The types of valve prosthesis in women of child-bearing age are:

- **Bioprosthetic valves** are preferable during pregnancy as they are less thrombogenic and do not require anticoagulation. However valve degradation in women of child-bearing age has been shown to be as high as 50% at 10 years, and 90% at 15 years and women with a bioprosthetic valve may require redo valve surgery.
- **Mechanical heart valves** have excellent durability but are thrombogenic and require life-long anticoagulation with warfarin. Pregnancy is a hypercoagulable state due to increased levels of fibrinogen, factors VII, VIII, X, decreased levels of protein S activity, venous hypertension and stasis.

Pregnancy in women with a mechanical heart valve is associated with increased maternal mortality (1–4%) due

to valve thrombosis because safe anticoagulation in these patients is complex. Warfarin crosses the placenta and is associated with a 5–12% risk of embryopathy during the 1st trimester. Warfarin also has an anticoagulant effect in the fetus which may lead to spontaneous fetal intracranial haemorrhage. Many women will choose unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) as they do not cross the placenta and do not cause fetal embryopathy. However, UFH may not provide consistent therapeutic anticoagulation during pregnancy and there is a high incidence (25%) of valve thrombosis. LMWH provides a more consistent anticoagulant effect when given twice daily with dose adjustment to maintain anti-Xa levels of 0.8–1.2 U/mL 4 hours after administration.

INFECTIVE ENDOCARDITIS

Infective endocarditis is an endovascular infection of cardiovascular structures, including cardiac valves, atrial and ventricular endocardium, large intrathoracic vessels and intracardiac foreign bodies, e.g. prosthetic valves, pacemaker leads and surgical conduits. The annual incidence in the UK is 6–7/100 000, but it is more common in developing countries. Without treatment the mortality approaches 100% and even with treatment there is a significant morbidity and mortality.

Aetiology

Endocarditis is usually the consequence of two factors: the presence of organisms in the bloodstream and abnormal cardiac endothelium facilitating their adherence and growth.

Bacteraemia may occur due to patient-specific reasons (poor dental hygiene, intravenous drug use, soft tissue infections) or be associated with diagnostic or therapeutic procedures (dental treatment, intravascular cannulae, cardiac surgery or permanent pacemakers). Although bacteraemia may occur there is no good evidence that it leads to infective endocarditis (p. 87).

Damaged endocardium promotes platelet and fibrin deposition which allows organisms to adhere and grow, leading to an infected vegetation. Valvular lesions may create non-laminar flow, and jet lesions from septal defects or a patent ductus arteriosus result in abnormal vascular endothelium. Aortic and mitral valves are most commonly involved in infective endocarditis apart from intravenous drug users in whom right-sided lesions are more common.

Organisms

Common organisms and the sources of infection are shown in Figure 14.83.

Rare causes

These include the HACEK group of organisms which tend towards a more insidious course (Box 14.2).

Culture negative endocarditis

This accounts for 5–10% of endocarditis cases. The usual cause is prior antibiotic therapy (good history taking is vital) but some cases are due to a variety of fastidious organisms that fail to grow in normal blood cultures. These include *Coxiella burnetii* (the cause of Q fever), *Chlamydia* species, *Bartonella* species (organisms that cause trench fever and cat scratch disease) and *Legionella*.

Clinical presentation (Table 14.38)

The clinical presentation of infective endocarditis is dependent on the organism and the presence of predisposing

Figure 14.83 Infective endocarditis – aetiology and sources of infection.

Box 14.2 Modified Duke criteria for endocarditis^a

Major criteria

- A positive blood culture for infective endocarditis, as defined by the recovery of a typical microorganism from two separate blood cultures in the absence of a primary focus (viridans streptococci, *Abiotrophia* species and *Granulicatella* species; *Streptococcus bovis*, HACEK group^b, or community-acquired *Staphylococcus aureus* or enterococcus species) *or*
- A persistently positive blood cultures, defined as the recovery of a microorganism consistent with endocarditis from either blood samples obtained more than 12 h apart or all three or a majority of four or more separate blood samples, with the first and last obtained at least 1 h apart *or*
- A positive serological test for Q fever, with an immunofluorescence assay showing phase 1 IgG antibodies at a titre >1:800 *or*
- Echocardiographic evidence of endocardial involvement:
 - an oscillating intracardiac mass on the valve or supporting structures, in the path or regurgitant jets, or on implanted material in the absence of an alternative anatomical explanation; *or*

- an abscess; *or*
- new partial dehiscence of prosthetic valve; *or*
- New valvular regurgitation.

Minor criteria

- Predisposition: predisposing heart condition or intravenous drug use
- Fever: temperature $\geq 38^{\circ}\text{C}$ (100.4°F)
- Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial haemorrhage, conjunctival haemorrhages, Janeway's lesion
- Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor
- Microbiological evidence: a positive blood culture but not meeting a major criterion as noted above, or serological evidence of an active infection with an organism that can cause infective endocarditis^c
- Echocardiogram: findings consistent with infective endocarditis but not meeting a major criterion as noted above.

^aThe diagnosis of infective endocarditis is definite when: (a) a microorganism is demonstrated by culture of a specimen from a vegetation, an embolism or an intracardiac abscess; (b) active endocarditis is confirmed by histological examination of the vegetation or intracardiac abscess; (c) two major clinical criteria, one major and three minor criteria, or five minor criteria are met.

^bHACEK denotes *Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens* and *Kingella kingae*.

^cExcluded from this criterion is a single positive blood culture for coagulase-negative staphylococci or other organisms that do not cause endocarditis. Serological tests for organisms that cause endocarditis include tests for *Brucella*, *Coxiella burnetii*, *Chlamydia*, *Legionella* and *Bartonella* species.

After Raoult D, Abbara S, Jassal DS et al. Case records of the Massachusetts General Hospital. Case 5–2007. cardiac conditions. Infective endocarditis may occur as an acute, fulminating infection but also occurs as a chronic or subacute illness with low-grade fever and nonspecific symptoms. A high index of clinical suspicion is required to identify patients with infective endocarditis and certain criteria should alert the physician.

High clinical suspicion:

- New valve lesion/(regurgitant) murmur
- Embolic event(s) of unknown origin

- Sepsis of unknown origin
- Haematuria, glomerulonephritis and suspected renal infarction
- 'Fever' plus:
 - Prosthetic material inside the heart
 - Other high predisposition for infective endocarditis, e.g. i.v. drug use
 - Newly developed ventricular arrhythmias or conduction disturbances
 - First manifestation of congestive cardiac failure

- Positive blood cultures (with typical organism)
- Cutaneous (Osler, Janeway) or ophthalmic (Roth) manifestations
- Peripheral abscesses (renal, splenic, spine) of unknown origin
- Predisposition and recent diagnostic/therapeutic interventions known to result in significant bacteraemia.

Low clinical suspicion

Fever plus none of the above.

Diagnostic criteria

The criteria for the clinical diagnosis of endocarditis have been established – the modified Duke criteria (Box 14.1).

Investigations

Investigations are required to confirm the diagnosis of infective endocarditis; to identify the organism to ensure appropriate therapy; and to monitor the patient's response to therapy (Table 14.39). Echocardiography is an extremely useful tool if used appropriately. A negative echocardiogram does not

exclude a diagnosis of endocarditis. It is not an appropriate screening test for patients with just a fever or an isolated positive blood culture, where there is a low pre-test probability of endocarditis.

Treatment

The location of the infection means that prolonged courses of antibiotics are usually required in the treatment of infective endocarditis. The combination of antibiotics may be synergistic in eradicating microbial infection and minimizing resistance. Blood cultures should be taken prior to empirical antibiotic therapy (but this should not delay therapy in unstable patients). Antibiotic treatment should continue for 4–6 weeks. Typical therapeutic regimens are shown in Table 14.40 but specific therapy should be sought from the local microbiology department according to the organism identified and current sensitivities. Serum levels of gentamicin and vancomycin need to be monitored to ensure adequate therapy and prevent toxicity. In patients with penicillin allergy one of the glycopeptide antibiotics, vancomycin or teicoplanin, can be used. Penicillins, however, are fundamental to the therapy of bacterial endocarditis; allergies therefore seriously compromise the choice of antibiotics. It is essential to confirm the nature of a patient's allergy to ensure that the appropriate treatment is not withheld needlessly. Anaphylaxis would be much more influential in antibiotic choice than a simple gastrointestinal disturbance.

Persistent fever

Most patients with infective endocarditis should respond within 48 hours of initiation of appropriate antibiotic therapy. This is evidenced by a resolution of fever, reduction in serum markers of infection and relief of systemic symptoms of infection. Failure of this to occur needs to be taken very seriously. The following should be considered:

- Perivalvular extension of infection and possible abscess formation
- Drug reaction (the fever should promptly resolve after drug withdrawal)
- Nosocomial infection (i.e. venous access site, urinary tract infection)
- Pulmonary embolism (secondary right-sided endocarditis or prolonged hospitalization).

In such cases, samples for culture should be taken from all possible sites and evidence sought for the above causes. Changing antibiotic dosage or regimen should be avoided unless there are positive cultures or a drug reaction is

Table 14.39 Investigations and findings in endocarditis	
Blood cultures	3 sets from different venepuncture sites
Serological tests	Consider in culture negative cases for <i>Coxiella</i> , <i>Bartonella</i> , <i>Legionella</i> , <i>Chlamydia</i>
Full blood count	Reduced haemoglobin, increased white cells, increased or reduced platelets
Urea and electrolytes	Increased urea and creatinine
Liver biochemistry	Increased serum alkaline phosphatase
Inflammatory markers	Increased erythrocyte sedimentation rate and C-reactive protein (CRP reduces in response to therapy and increases with relapse)
Urine	Proteinuria and haematuria
Electrocardiogram	PR prolongation/heart block is associated with aortic root abscess
Chest X-ray	Pulmonary oedema in left-sided disease, pulmonary emboli/abscess in right-sided disease
Transthoracic echocardiography	First-line non-invasive imaging test with sensitivity of 60–75%; demonstrates vegetations, valvular dysfunction, ventricular function, abscesses
Transoesophageal echocardiography (Fig. 16.15)	Second-line invasive imaging test with greater sensitivity (>90%) and specificity; useful in suspected aortic root abscess and essential in prosthetic valve endocarditis

Table 14.40 Antibiotics in endocarditis (adapted from British Society for Antimicrobial Chemotherapy (BSAC) guidelines)

Clinical situation	Suggested antibiotic regimen to start (all given i.v.)
Clinical endocarditis, culture results awaited, no suspicion of staphylococci	Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly
Suspected staphylococcal endocarditis (IVDU, recent intravascular devices or cardiac surgery, acute infection)	Vancomycin 1 g 12-hourly, gentamicin 80–120 mg 8-hourly
Streptococcal endocarditis (penicillin sensitive)	Penicillin 1.2 g 4-hourly, gentamicin 80 mg 12-hourly
Enterococcal endocarditis (no high-level gentamicin resistance)	Ampicillin/amoxicillin 2 g 4-hourly, gentamicin 80 mg 12-hourly
Staphylococcal endocarditis ^a	Vancomycin 1 g 12-hourly, <i>OR</i> Flucloxacillin 2 g 4-hourly, <i>OR</i> Benzylpenicillin 1.2 g 4-hourly, <i>PLUS</i> gentamicin 80–120 mg 8-hourly

Note: 1. Monitor vancomycin and gentamicin levels, and adjust if necessary. 2. Choice of antibiotic for staphylococci depends on sensitivities. 3. Optimum choice of therapy needs close liaison with Microbiology/Infectious Diseases. All antibiotics given i.v. IVDA, intravenous drug abuse.

^aMRSA can affect valves.

suspected. Emergence of bacterial resistance is uncommon. Close liaison with microbiology is recommended and a cardiothoracic surgical opinion should be sought.

Surgery

Decisions about surgical intervention in patients with infective endocarditis should be made after joint consultation between the cardiologist and cardiothoracic surgeon, taking into account patient-specific (age, non-cardiac morbidities, presence of prosthetic material or cardiac failure) and infective endocarditis features (infective organism, vegetation size, presence of perivalvular infection, systemic embolization).

Prevention (p. 87)

Current evidence suggests that antibiotic prophylactic therapy is not required (p. 87). There has been no increase in the number of new cases following implementation of the NICE guidelines.

CONGENITAL HEART DISEASE

A congenital cardiac malformation occurs in about 1% of live births. There is an overall male predominance, although some individual lesions (e.g. atrial septal defect and persistent ductus arteriosus) occur more commonly in females. As a result of improved medical and surgical management, more children with congenital cardiac disease are surviving into adolescence and adulthood. Thus, there is a need for an increased awareness among general physicians and cardiologists of the problems posed by these individuals.

Fetal circulation (Fig. 14.84)

In the developing fetus, oxygenated blood and nutrients are supplied to the fetus via the placenta and the umbilical vein. Half of that blood is directed to the fetal ductus venosus and carried to the inferior vena cava (IVC), the other half enters the liver.

Blood moves from the IVC to the right atrium of the heart. In the fetus, there is an opening between the right and left atrium (the *foramen ovale*), and most of the blood (which is a mixture of oxygenated and de-oxygenated blood) flows from the right into the left atrium, bypassing pulmonary circulation. This blood goes into the left ventricle and is pumped through the aorta into the fetal body. Some of the blood flows from the aorta through the internal iliac arteries to the umbilical arteries and re-enters the placenta, where carbon dioxide and other waste products from the fetus are taken up and enter the woman's circulation.

Some of the blood from the right atrium does not enter the left atrium, but enters the right ventricle and is pumped into the pulmonary artery. In the fetus, there is a connection between the pulmonary artery and the aorta, the *ductus arteriosus*, which directs most of this blood away from the lungs. With the first breath after delivery the vascular resistance in the pulmonary arteries falls and more blood moves from the right atrium to right ventricle and pulmonary arteries and oxygenated blood travels back to the left atrium through the pulmonary veins. The decrease in right atrial pressure and relative increase in left atrial pressure results in closure of the *foramen ovale*.

The *ductus arteriosus* usually closes off within one or two days of birth completely separating the left and right system. The umbilical vein and the *ductus venosus* closes off within 2–5 days after birth, leaving behind the ligamentum teres and the ligamentum venosus of the liver, respectively.

Aetiology

The aetiology of congenital cardiac disease is often unknown, but recognized associations include:

- Maternal prenatal rubella infection (persistent *ductus arteriosus*, and pulmonary valvular and arterial stenosis)
- Maternal alcohol misuse (septal defects)
- Maternal drug treatment and radiation
- Genetic abnormalities (e.g. The familial form of atrial septal defect and congenital heart block)
- Chromosomal abnormalities (e.g. septal defects and mitral and tricuspid valve defects are associated with Down's syndrome (trisomy 21) or coarctation of the aorta in Turner's syndrome (45, XO).

Classification

See Table 14.41.

Symptoms and signs

Congenital heart disease should be recognized as early as possible, as the response is usually better the earlier the

treatment is initiated. Some symptoms, signs and clinical problems are common in congenital heart disease:

- **Central cyanosis** occurs because of right-to-left shunting of blood or because of complete mixing of systemic and pulmonary blood flow. In the latter case, e.g. Fallot's tetralogy, the abnormality is described as cyanotic congenital heart disease.
- **Pulmonary hypertension** results from large left-to-right shunts. The persistently raised pulmonary flow leads to the development of increased pulmonary artery vascular resistance and consequent pulmonary hypertension. This is known as the Eisenmenger's reaction (or the Eisenmenger's complex when due specifically to a ventricular septal defect). The development of pulmonary hypertension significantly worsens the prognosis.
- **Clubbing of the fingers** occurs in congenital cardiac conditions associated with prolonged cyanosis.
- **Paradoxical embolism** of thrombus from the systemic veins to the systemic arterial system may occur when a communication exists between the right and left heart. There is therefore an increased risk of cerebrovascular emboli and also abscesses (as with endocarditis).
- **Polycythaemia** can develop secondary to chronic hypoxaemia, leading to a hyperviscosity syndrome and an increased thrombotic risk, e.g. strokes.
- **Growth retardation** is common in children with cyanotic heart disease.
- **Syncope** is common when severe right or left ventricular outflow tract obstruction is present. Exertional syncope, associated with deepening central cyanosis, may occur in Fallot's tetralogy. Exercise increases resistance to pulmonary blood flow but reduces systemic vascular resistance. Thus, the right-to-left shunt increases and cerebral oxygenation falls.
- **Squatting** is the posture adopted by children with Fallot's tetralogy. It results in obstruction of venous return of desaturated blood and an increase in the peripheral systemic vascular resistance. This leads to a reduced right-to-left shunt and improved cerebral oxygenation.

Presentation

Adolescents and adults with congenital heart disease present with specific common problems related to the long-standing structural nature of these conditions and any surgical treatment:

- Endocarditis (particularly in association with otherwise innocuous lesions such as small VSDs or bicuspid aortic valve that can give up to 10% lifetime risk)
- Progression of valvular lesions (calcification and stenosis of congenitally deformed valves, e.g. bicuspid aortic valve)
- Atrial and ventricular arrhythmias (often quite resistant to treatment)
- Sudden cardiac death
- Right heart failure (especially when surgical palliation results in the right ventricle providing the systemic supply)
- End-stage heart failure (rarely managed by heart or heart-lung transplantation).

Genetic counselling

These conditions necessitate active follow-up of adult patients. Pregnancy is normally safe except if pulmonary

Table 14.41 Classification of congenital heart disease	
Acyanotic	Cyanotic
With shunts	With shunts

Without shunts	Without shunts
Coarctation of the aorta Congenital aortic stenosis	Severe pulmonary stenosis Tricuspid atresia Pulmonary atresia Hypoplastic left heart

hypertension or vascular disease is present, when the prognosis for both mother and fetus is poor.

Table 14.42 lists the most common congenital lesions and their occurrence in first-degree relatives.

Genetic factors should be considered in all patients presenting with congenital heart disease. For example, parents with a child suffering from Fallot's tetralogy stand a 4% chance of conceiving another child with the disease, and so fetal ultrasound screening of the mother during pregnancy is essential. Parents with congenital heart disease are also more likely to have affected offspring. Fathers have a 2% risk, while mothers have a higher risk (around 5%). Individual families can exhibit even higher risks of recurrence.

Ventricular septal defect (VSD) (Fig. 14.85)

VSD is the most common congenital cardiac malformation (1:500 live births). The haemodynamic consequences of this are dependent on the shunt size. Left ventricular pressure is higher than right and blood therefore moves from left to right and pulmonary blood flow increases. In large defects the large volumes of blood flow through the pulmonary vasculature leads to pulmonary hypertension and eventual Eisenmenger's complex when right ventricular pressure becomes higher than left and as a result blood starts to shunt from right to left leading to cyanosis.

Table 14.42 Common congenital lesions

	Percentage of congenital lesions	Occurrence in first-degree relatives (%)
Ventricular septal defect	39	4
Atrial septal defect	10	2
Persistent ductus	10	4
Arteriosus		
Pulmonary stenosis	7	
Coarctation of the aorta	7	2
Aortic stenosis	6	4
Fallot's tetralogy	6	4
Others	15	

Heart sounds and murmurs

Harsh pansystolic murmur heard at the left sternal edge, accompanied by a systolic thrill ± left parasternal heave. May be signs of pulmonary hypertension

Pathophysiology

- Left-to-right shunt
- When the left ventricle contracts, it ejects some blood into the aorta and some across the ventricular septal defect into the right ventricle and pulmonary artery
- **Small** VSDs ('maladie de Roger'): loud and sometimes long systolic murmur
- **Moderate** VSDs: loud 'tearing' pansystolic murmur
- **Large** VSDs: cause pulmonary hypertension and soft murmur Eisenmenger's complex may result

- **Small restrictive VSDs** ('Maladie de Roger') are often found incidentally as patients are asymptomatic. They are associated with a loud pan-systolic murmur. The majority close spontaneously by the age of 10 years.
- **Large (non-restrictive) VSDs** result in significant LA and LV dilatation (due to LV volume overload). Large defects usually present with heart failure symptoms in childhood and eventually lead to pulmonary hypertension and Eisenmenger's complex. As pressures equalize the murmur becomes softer.

Investigations and intervention

A small VSD produces no abnormal X-ray or ECG findings. In larger defects, the chest X-ray may demonstrate prominent pulmonary arteries owing to increased pulmonary blood flow but with pulmonary hypertension there may be 'pruned' pulmonary arteries. Cardiomegaly occurs when a moderate or a large VSD is present and the ECG may show both left and right ventricular hypertrophy. Echocardiography can assess the size and location of the VSD and its haemodynamic consequences. Interventional options are either surgical patch repair or device closure if it is an isolated muscular VSD. Indications for intervention include left atrial and ventricular enlargement with or without early LV dysfunction; reversible pulmonary hypertension (mild) where there is a residual left to right shunt and no significant desaturation with exercise; infective endocarditis. Patients with a restrictive VSD and patients after successful closure have an excellent long term outcome. Prophylaxis of endocarditis is discussed on page 87.

Atrial septal defect (ASD)

This condition is often first diagnosed in adulthood and represents one-third of congenital heart disease. It is two to three times more common in women than in men. There are three main types of ASD (Fig. 14.86):

- **Sinus venosus defects** – located in the superior part of the septum near the SVC (superior sinus venosus defect) or the inferior part of the septum near the IVC (inferior sinus venosus defect) entry point.
- **Ostium secundum defects** (75%) – located in the mid-septum (fossa ovalis). This should not be confused with the patent foramen ovale (PFO), which is a normal

Figure 14.86 Atrial septal defect: pathophysiology and auscultatory findings.

variant and not a true septal defect. PFO is usually asymptomatic but is associated with paradoxical emboli and an increased incidence of embolic stroke.

■ **Ostium primum (atrioventricular septal) defects** (15%) – located in the lower part of atrial septum.

Adult patients with an unrepaired ASD with significant left to right shunt develop right heart overload and dilatation. These patients develop symptoms of dyspnoea and exercise intolerance and may develop atrial arrhythmias from right atrial dilatation. There is also increased pulmonary vascular flow, but significant pulmonary hypertension develops in <5% of patients and it is thought that these patients have additional factors including genetic predisposition to pulmonary hypertension. The physical signs of ASD reflect the volume overloading of the right ventricle (Fig. 14.86). A right ventricular heave can usually be felt.

Investigations and intervention

The chest X-ray may demonstrate prominent pulmonary arteries with pulmonary plethora. Right bundle branch block and right axis deviation may be present on the ECG (because of dilatation of the right ventricle). Ostium primum defects may have left axis deviation on the ECG. Echocardiography may demonstrate hypertrophy and dilatation of the right heart and pulmonary arteries. Subcostal views with 2D and colour Doppler demonstrates the ASD (Fig. 14.87) and allow calculation of the left-right shunt (QP:QS ratio). CMR and CT are helpful to assess for anomalous pulmonary venous drainage which may accompany an ASD. Indications for intervention include: an ASD with significant left to right shunting resulting in right atrial/ventricular enlargement

which should be closed irrespective of symptoms; thromboembolic events including certain patients with a patent foramen ovale. The options for intervention include device closure using a transcatheter clamshell device (Fig. 14.88) for most secundum ASDs (if suitable size) or surgical closure for all other ASD types.

Patent ductus arteriosus (PDA)

This is a persistent communication between the proximal left pulmonary artery and the descending aorta resulting in a continuous left to right shunt (Fig. 14.89). Normally the ductus arteriosus closes within a few hours of birth in response to decreased pulmonary resistance however in some cases (particularly premature babies and in cases with maternal rubella) the ductus persists. Indometacin (a prostaglandin inhibitor) is given to stimulate duct closure. If the shunt is moderate to large it will result in left heart volume overload and in some cases pulmonary hypertension and Eisenmenger's syndrome. The characteristic clinical signs are a bounding pulse and continuous 'machinery murmur' however as pulmonary hypertension develops in a large PDA the murmur becomes softer.

Investigations and intervention

With a large shunt, the aorta and pulmonary arterial system may be prominent on chest X-ray. The ECG may demonstrate left atrial abnormality and left ventricular hypertrophy. The development of Eisenmenger reaction will produce right ventricular hypertrophy. Echocardiography may show a dilated left atrium and left ventricle with right heart changes occurring late. Colour Doppler imaging of the proximal pulmonary

FURTHER READING

Furlan AJ et al. Closure or medical therapy for cryptogenic stroke in patent foramen ovale. *N Engl J Med* 2012; 366:991–999.

arteries may demonstrate the shunt. Indications for intervention (usually with percutaneous devices) include left ventricular dilatation; mild–moderate pulmonary arterial hypertension (not Eisenmenger). Small defects may predispose to endarteritis and should be considered for device closure unless clinically silent.

Figure 14.87 Ostium secundum atrial septal defect (arrows) in a young girl. **(a)** Shown by a 2-D echocardiogram subcostal four-chamber view. **(b)** Colour Doppler can demonstrate the left-to-right shunt. LA, left atrium; RA, right atrium.

Coarctation of the aorta

A coarctation of the aorta is a narrowing of the aorta at or just distal to the insertion of the ductus arteriosus (distal to the origin of the left subclavian artery (Fig. 14.90). Rarely it can occur proximal to the left subclavian. It occurs twice as commonly in men as in women. It is also associated with Turner's syndrome (p. 978). In 80% of cases, the aortic valve is bicuspid (and potentially stenotic or endocarditic). Other associations include patent ductus arteriosus, ventricular septal defect, mitral stenosis or regurgitation and circle of Willis aneurysms. Severe narrowing of the aorta encourages the formation of a collateral arterial circulation involving the periscapular and intercostal arteries. Decreased renal perfusion can lead to the development of systemic hypertension that persists even after surgical correction.

Coarctation of the aorta is often asymptomatic for many years. *Headaches* and *nosebleeds* (due to hypertension), and *claudication* and cold legs (due to poor blood flow in the lower limbs) may be present. Physical examination

Figure 14.88 Angiographic appearance of a fully deployed ASD closure device. The device bridges the ASD and wedges against the surfaces of the right and left atrial septa, occluding flow. The metal object in frame is the distal end of a transoesophageal echocardiography probe. (Courtesy of Dr D Ward, St George's, University of London.)

Heart sounds and murmurs

Continuous 'machinery' murmur best heard below the left clavicle in the first interspace or over the first rib. A thrill can often be felt

Pathophysiology

- Left-to-right shunt
- Some of the blood from the aorta crosses the ductus arteriosus and flows into the pulmonary artery
- Murmur is produced by the turbulent aortic-to-pulmonary artery shunting in both systole and diastole
- Dilatation of the pulmonary artery, left atrium and left ventricle
- As pulmonary hypertension (Eisenmenger's reaction) develops, the murmur becomes quieter, may be confined to systole or may even disappear causing central cyanosis

Figure 14.89 Patent ductus arteriosus: pathophysiology and auscultatory findings.

Figure 14.90 Coarctation of the aorta: pathophysiology and auscultatory findings.

Figure 14.91 Severe aortic coarctation in an adult shown on cardiac magnetic resonance angiography.

reveals hypertension in the upper limbs, and weak, delayed (radiofemoral delay) pulses in the legs. If coarctation is present in the aorta, proximal to the left subclavian artery, there will be asynchronous radial pulses in right and left arms. Poor peripheral pulses are seen in severe cases. For heart sounds and murmurs in coarctation of aorta, see Figure 14.90.

Investigations and intervention

Chest X-ray may reveal a dilated aorta indented at the site of the coarctation. This is manifested by an aorta (seen in the upper right mediastinum) shaped like a 'figure 3'. In adults, tortuous and dilated collateral intercostal arteries may erode the undersurfaces of the ribs ('rib notching'). ECG demonstrates left ventricular hypertrophy. Echocardiography sometimes shows the coarctation and other associated anomalies. CT and CMR (Fig. 14.91) scanning can accurately demonstrate the coarctation and quantify flow.

Intervention is required if there is a peak-peak gradient across the coarctation of >20 mmHg and/or proximal hypertension. In neonates coarctation is treated with surgical repair. In older children and adults, balloon dilatation and stenting is an option although many centres still prefer surgery. Balloon dilatation is preferred for recoarctation.

Cyanotic congenital heart disease

Fallot's tetralogy

Tetralogy of Fallot (Fig. 14.92) consists of:

- A large malaligned VSD
- An overriding aorta
- Right ventricular outflow tract obstruction
- Right ventricular hypertrophy.

Symptoms depend on the degree of pulmonary stenosis. Often this is progressive in the first year of life and cyanosis develops due to increased right-sided pressures, resulting in a right to left shunt. Fallot's spells are episodes of severe cyanosis noted in children due to spasm of the subpulmonary muscle – these can be relieved by increasing systemic resistance by postural manoeuvres, e.g. squatting. In babies with severe pulmonary stenosis systemic-to-pulmonary artery shunts (i.e. Blalock-Taussig – subclavian to pulmonary artery shunt) may be used initially to increase pulmonary blood flow in severe cases of pulmonary stenosis. The majority of adults with tetralogy of Fallot will have undergone complete repair which involves relief of the right ventricular outflow tract obstruction and closure of the VSD. The overall survival of those who have had operative repair is excellent. DiGeorge's syndrome is found in 15% of those with tetralogy of Fallot.

Transposition of the great arteries

Complete transposition of the great arteries (TGA)

In *complete transposition of the great arteries (TGA)*, the right atrium connects to the morphological right ventricle, which gives rise to the aorta and the left atrium connects to the morphological left ventricle, which gives rise to the pulmonary artery (Fig. 14.93). This is incompatible with life as blood circulates in two parallel circuits, i.e. deoxygenated blood from the systemic veins passes into the right heart and then via the aorta back to the systemic circulation. Oxygenated blood from the pulmonary veins passes through the left heart and back to the lungs. Babies with transposition are usually born cyanosed – if there is a significant ASD, VSD or PDA allowing a shunt (i.e. mixing of oxygenated and deoxygenated blood) the diagnosis might be delayed. In those without a shunt an atrial septostomy is performed. A Rashkind's balloon is used to dilate the foramen ovale and is used to maintain saturations at 50–80% until a definitive procedure can be performed. The arterial switch procedure

Figure 14.92 Fallot's tetralogy: pathophysiology and auscultatory findings.

Figure 14.93 Transposition of great arteries.

is now performed in the first 2 weeks of life – the aorta is reconnected to the left ventricle and the pulmonary artery is connected to the right ventricle. The coronary arteries are re-implanted.

Currently, the majority of adult patients with transposition of the great arteries will have had an 'atrial switch' operation. The right ventricle remains the systemic ventricle in this situation. Although most of these patients do well for many years, life expectancy is clearly limited by eventual failure of the systemic right ventricle.

Congenitally corrected transposition of the great arteries (ccTGA)

In *congenitally corrected transposition of the great arteries* (ccTGA), systemic venous return to the right atrium enters a morphological left ventricle, which pumps into the pulmonary artery. Pulmonary venous blood returns to the left atrium and then via the morphological right ventricle to the aorta. The

Figure 14.94 Marfan's syndrome. (a) High arched palate and (b) eye lens dislocation. (From: Forbes CD, Jackson WF. Color Atlas and Text of Clinical Medicine. St Louis: Mosby; 2003: 134, ©Elsevier.)

circulation is physiologically corrected but the systemic circulation is supported by a morphologic right ventricle. ccTGA is often associated with cardiac lesions; systemic (tricuspid) atrio-ventricular valve abnormalities with valve insufficiency; VSD; subpulmonary stenosis; complete heart block; Wolff-Parkinson-White syndrome; dextrocardia. Many patients with ccTGA live a normal life, although other patients require pacemaker insertion (the AV node is abnormal leading to heart block), surgery for a regurgitant tricuspid valve, or develop heart failure from the systemic (right ventricle).

MARFAN'S SYNDROME

Clinical features

Marfan's syndrome (MFS) is one of the most common autosomal dominant inherited disorders of connective tissue, affecting the heart (aortic aneurysm and dissection, mitral valve prolapse), eye (dislocated lenses, retinal detachment) and skeleton (tall, thin body build with long arms, legs and fingers; scoliosis and pectus deformity) (Figs 14.94, 14.95; Table 14.43).

Clinically, two of three major systems must be affected, to avoid overdiagnosing the condition. Diagnosis may be

Figure 14.95 Marfan's syndrome. (a) Photograph of a 63-year-old man. (b) 2-D Longitudinal echocardiogram of the aortic root. (c) Measurements of aortic size.

Table 14.43 Yearly risk (%) of complications based on aortic size in Marfan's syndrome				
	Aortic size (cm)			
	>3.5	>4	>5	>6
Rupture	0.0	0.3	1.7	3.6
Dissection	2.2	1.5	2.5	3.7
Death	5.9	4.6	4.8	10.8
Any of the above	7.2	5.3	6.5	14.1

confirmed by studying family linkage to the causative gene, or by demonstrating a mutation in the Marfan's syndrome gene (*MFS1*) for fibrillin (*FBN-1*) on chromosome 15q21.

MFS affects approximately 1 in 5000 of the population worldwide and 25% of patients are affected as a result of a new mutation. This group includes many of the more severely affected patients, with high cardiovascular risk. Other known associations with early death due to aortic aneurysm and dissection are: family history of early cardiac involvement; family history of dissection with an aortic root diameter of >5 cm; male sex; and extreme physical characteristics, including markedly excessive stature and widespread striae. Histological examination of aortas often shows widespread medial degeneration, described as 'cystic medial necrosis'.

Cardiac investigations

- **Chest X-ray** is often normal but may show signs of aortic aneurysm and unfolding, or of widened mediastinum. Pneumothorax affects 11% and scoliosis is present in 70% of patients.
- **ECG** may be misleadingly normal with an acute dissection. In conjunction with mitral valve prolapse,

40% of patients usually have arrhythmia, with premature ventricular and atrial arrhythmias.

- **Echocardiography** shows mitral valve prolapse, and mitral regurgitation in the majority of patients. High-quality serial echocardiogram measurements of aortic root diameter in the sinuses of Valsalva, at 90° to the direction of flow are the basis for medical and surgical management (Fig. 14.95b).
- **CT or CMR** can detect aortic dilatation and are useful in monitoring.

Management

- **Beta-blocker therapy** slows the rate of dilatation of the aortic root.
- **ACE receptor blockers.** In Marfan's there is upregulation of $\text{TNF-}\beta$, which is specifically inhibited by ACE blockers. A small trial has shown no increase in aortic root diameter on this therapy.
- **Lifestyle alterations** are required because of ocular, cardiac or skeletal involvement. Sports that necessitate prolonged exertion at maximum cardiac output, such as cross-country running, are to be avoided. Sedentary occupations are usually best, as patients tend to suffer from easy fatigability and hypermobile painful joints.
- **Monitoring** with yearly echocardiograms up to aortic root diameter of 4.5 cm, 6-monthly from 4.5 to 5 cm, and then referred directly to a surgeon who is experienced in aortic root replacement in Marfan's syndrome for elective surgery.

Pregnancy is generally well tolerated if no serious cardiac problems are present, but is preferably avoided if the aortic root diameter is over 4 cm, with aortic regurgitation. Echocardiography should be performed every 6–8 weeks throughout

FURTHER READING

Judge DP, Dietz AC. Marfan's syndrome. *Lancet* 2005; 366:1965–1976.

pregnancy and during the initial 6 months postpartum. Blood pressure should be regularly monitored and hypertension treated actively. Delivery should be by the least stressful method; ideally a vaginal delivery. Caesarean section should not be routinely performed. However, if the aortic root is over 4.5 cm, delivery at 39 weeks by induction or caesarean section should be considered. Beta-blocker therapy may be safely instituted or continued throughout pregnancy, to help prevent aortic dissection.

Medical and surgical management have increased the overall survival rate. On average, 13 years of life is added when surgical survival is compared to that reported in the natural history of MFS.

Genetic counselling

The condition is inherited in an autosomal dominant mode, with each child of one affected parent having a 50:50 chance of inheriting the condition. Males and females are equally often affected. In 25% of all cases, the condition arises as the result of a spontaneous mutation in gene 5 of one of the parents. Fibrillin-1 gene mutations can be identified in 80% of those affected, confirming diagnosis and aiding prognosis. The mutation can also be used to screen at-risk family members, including postnatal or prenatal offspring.

PULMONARY HEART DISEASE

The normal mean pulmonary artery pressure (mPAP) at rest is 14 ± 3 mmHg with an upper limit of normal of 20 mmHg. The normal values for mean pulmonary artery pressure (mPAP), mean capillary wedge pressure (mPCWP) and cardiac output (CO) are 12 ± 2 mmHg, 6 ± 2 mmHg and 5 L/min, respectively. The fall in pressure across the lung circulation is known as the transpulmonary gradient and reflects the difference between mPAP and mPCWP. The normal transpulmonary gradient is 6 ± 2 mmHg.

The *pulmonary vascular resistance* (PVR) is calculated by the formula:

$$\frac{\text{mPAP} - \text{mPCWP}}{\text{CO}}$$

It is normally about 1.5 mmHg/L per min (1.5 Wood units). Approximately 60% of the body's endothelial surface is in the lungs and the lungs normally offer a low resistance to blood flow. This is because the media of the precapillary pulmonary arterioles is thin as compared with their more muscular systemic counterparts that have to respond constantly to postural changes under the influence of gravity. The fact that the lung circulation normally offers a low resistance to flow explains the preferential passage of blood through the lungs in specific forms of congenital heart disease, which may eventually lead to remodelling of the lung circulation and pulmonary hypertension.

Pulmonary hypertension**Definition**

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure (mPAP) of >25 mmHg at rest as measured on right heart catheterization. The clinical classification of PH is provided in Table 14.44. (PH can also complicate congenital heart disease as discussed in the ACHD section.)

Pathophysiology

The different groups are characterized by variable amounts of hypertrophy, proliferation and fibrotic changes in distal

Table 14.44 Updated clinical classification of pulmonary hypertension (Dana Point, 2008)

- 1 **Pulmonary arterial hypertension (PAH)**
 - 1.1 Idiopathic pulmonary hypertension
 - 1.2 Heritable
 - 1.2.1 BMPR2
 - 1.2.2 ALK1, endoglin (with or without hereditary haemorrhagic telangiectasia)
 - 1.2.3 Unknown
 - 1.3 Drugs and toxins
 - 1.4 Associated with (APAH)
 - 1.4.1 Connective tissue diseases
 - 1.4.2 HIV infection
 - 1.4.3 Portal hypertension
 - 1.4.4 Congenital heart disease
 - 1.4.6 Schistosomiasis
 - 1.4.5 Chronic haemolytic anaemia
 - 1.5 Persistent pulmonary hypertension of the newborn
- 1' Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary haemangiomatosis
- 2 **Pulmonary hypertension owing to left heart disease**
 - 2.1. Systolic dysfunction
 - 2.2. Diastolic dysfunction
 - 2.3. Valvular disease
- 3 **Pulmonary hypertension owing to lung diseases and/or hypoxia**
 - 3.1. Chronic obstructive pulmonary disease
 - 3.2. Interstitial lung disease
 - 3.3. Other pulmonary disease with mixed restrictive and obstructive pattern
 - 3.4. Sleep-disordered breathing
 - 3.5. Alveolar hypoventilation disorders
 - 3.6. Chronic exposure to high altitude
 - 3.7. Developmental abnormalities
- 4 **Chronic thromboembolic pulmonary hypertension (CTEPH)**
- 5 **Pulmonary hypertension with unclear and/or multifactorial mechanisms**
 - 5.1. Haematological disorders: myeloproliferative disorders, splenectomy
 - 5.2. Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
 - 5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
 - 5.4. Others: tumoural obstruction, fibrosing mediastinitis, chronic kidney disease on dialysis

ALK1, activin receptor-like kinase type 1; BMPR2, bone morphogenetic protein receptor type 2; HIV, human immunodeficiency virus.

pulmonary arteries (pulmonary arterial hypertension PAH, pulmonary veno-occlusive disease PVOD, pulmonary hypertension PH due to left heart disease, PH due to lung disease and/or hypoxia). Pulmonary venous changes are seen in groups PVOD and PH due to left heart disease and the vascular bed may be destroyed in emphysematous or fibrotic areas seen in lung disease. In chronic thromboembolic pulmonary hypertension (CTEPH) organized thrombi are seen in the elastic pulmonary arteries. Patients with PH with unclear and/or multifactorial mechanisms have variable pathological findings.

Patients with progressive PH develop right ventricular hypertrophy, dilatation, failure and death.

Epidemiology of PAH

Pulmonary artery hypertension (PAH)

Data from a recent French registry of 674 patients with pulmonary artery hypertension identified 39.2% with idiopathic pulmonary artery hypertension (IPAH), 3.9% familial (or heritable), 9.5% drugs and toxins (anorexigens), 15.3% connective tissue disorders (autoimmune rheumatic disease), 11.3% congenital heart disease, 10.4% portal hypertension and 6.2% HIV-associated. In familial or heritable PAH, mutations in the bone morphogenetic protein receptor 2 gene *BMPR2* are detected in over 70% of cases; other mutations are seen in patients with hereditary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome). Drugs and toxins known to cause PAH include aminorex, fenfluramine, dexfenfluramine, toxic rapeseed oil and benfluorex.

Diagnosis of PAH

Patients with PAH may present with symptoms of dyspnoea, fatigue, weakness, angina, syncope or abdominal distension. Clinical signs of PAH and right heart hypertrophy include a left parasternal heave, a loud P2 heart sound, a soft pan systolic murmur with tricuspid regurgitation or early diastolic murmur with pulmonary regurgitation. Right heart failure leads to jugular venous distension, ascites, peripheral oedema, and hepatomegaly. Clinical signs of associated diseases, e.g. systemic sclerosis, chronic liver disease, should be sought.

- **Chest X-ray** shows enlargement of the pulmonary arteries and the major branches, with marked tapering (pruning) of peripheral arteries. The lung fields are usually lucent and there may be right atrial and right ventricular enlargement.
- The **ECG** shows right ventricular hypertrophy and right atrial enlargement (P pulmonale). The *chest X-ray* may facilitate the diagnosis of PH due to left heart or chronic lung disease.
- **Echocardiography** (Fig. 14.96) with tricuspid regurgitation can be used for determination of pulmonary artery pressure (PAP) using the simplified Bernoulli equation ($PAP = 4 \times (\text{tricuspid regurgitation velocity})^2 + \text{estimated right atrial pressure}$). Right atrial pressure can be assumed at 5–10 mmHg unless there is significant dilatation of the inferior vena cava with reduced respiratory variation. Mean PAP = $0.61 \times \text{PA systolic pressure} + 2 \text{ mmHg}$ (although the Bernoulli equation may not be accurate in cases of severe tricuspid regurgitation).
- **Cardiac magnetic resonance imaging** may be useful in ACHD and in assessing right ventricular function on serial assessment.
- **Routine blood tests** include full blood count, renal and liver function tests, thyroid function tests, serological assays for underlying connective tissue diseases, HIV and hepatitis.
- **Abdominal liver ultrasound** is useful to exclude liver cirrhosis and portal hypertension.
- **Right heart catheterization.** As part of the clinical assessment right heart catheterization (RHC) may be indicated to confirm the diagnosis (elevated PAP), to determine the pulmonary wedge pressure (PWP), to calculate the cardiac output, and to assess for pulmonary vascular resistance and reactivity. In PAH vasodilator challenge (inhaled nitric oxide, intravenous adenosine or epoprostenol) should be performed to identify patients who may benefit from vasodilator

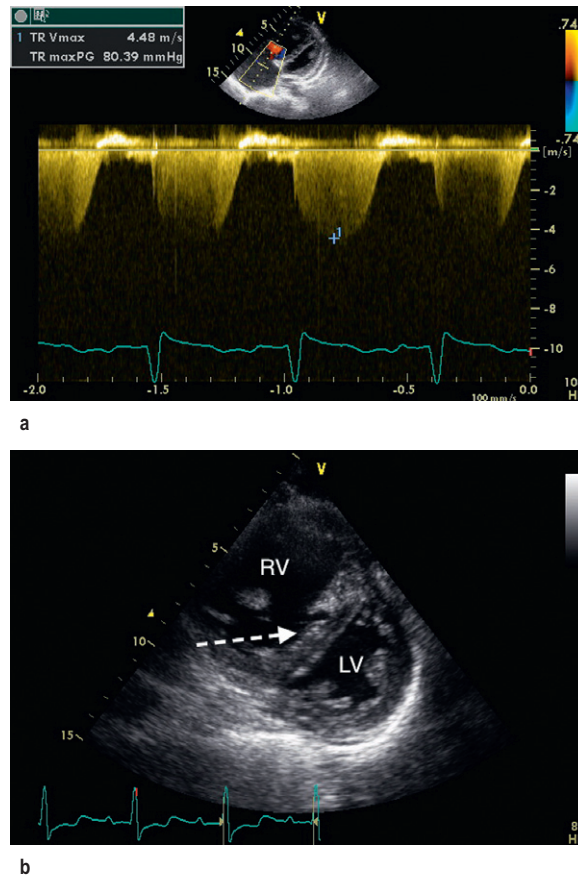

Figure 14.96 Pulmonary hypertension. (a) Continuous wave Doppler echocardiography demonstrates markedly elevated tricuspid regurgitation velocity consistent with pulmonary hypertension. (b) Parasternal short-axis echocardiogram with a dilated right ventricle (RV) and septal flattening (arrows) in a patient with pulmonary hypertension.

therapies. A responder is defined as a reduction in mean PAP of ≥ 10 mmHg to reach an absolute mean PAP of ≤ 40 mmHg with increased or unchanged cardiac output. These vasodilator challenges are not recommended in patients with other types of PH (types 2–5).

Treatment of PAH

- **Physical activity** – patients should be encouraged to remain physically active but avoid exertion that precipitates severe dyspnoea, chest pain or pre-syncope.
- **Pregnancy** – patients with PAH have a very high mortality rate during pregnancy (30–50%) and should be counselled against conception. Contraception may include barrier methods, progesterone-only pill, or the Mirena coil.
- **Travel** – during plane travel supplementary oxygen at 2 L/minute may be appropriate for patients with reduced functional class and with resting hypoxia of < 8 kPa.
- **Vaccination** should be given for influenza and pneumococcal pneumonia.
- **Elective surgery** – epidural anaesthesia may be preferable to a general anaesthetic.
- **Oral anticoagulation** has evidence to support its use in patients with IPAH, heritable PAH and PAH due to anorexigens. The European target INR is 2.0–3.0.

- **Diuretics** – these are used in patients with right heart failure and fluid overload.
- **Digoxin** may be helpful in patients with tachyarrhythmias.
- **Calcium channel blockers** can be effective in high doses in selected patients with IPAH who demonstrate a response to a vasodilator challenge. A right heart catheter should be repeated in 3–4 months to assess response to therapy.
- **Prostanoids** – prostacyclin is a potent vasodilator that also inhibits platelet aggregation and cell proliferation. Synthetic prostacyclins are generally short-acting compounds requiring continuous intravenous or subcutaneous infusion or regular aerosol inhalation. They provide symptomatic relief and can improve exercise capacity and *epoprostenol* can improve survival in patients with IPAH and APAH.
- **Endothelin receptor antagonists** – endothelin-1 is a potent vasoconstrictor and mitogen that binds to endothelin A and B receptors in the pulmonary vasculature. Both dual antagonists (*bosentan*) and selective A receptor antagonists (*sitaxsentan*, *ambrisentan*) can improve symptoms, exercise capacity and haemodynamics in patients with IPAH.
- **Phosphodiesterase type 5 inhibitors** produce vasodilation in pulmonary vasculature and reduce cellular proliferation. *Sildenafil* and *tadalafil* have been demonstrated to provide symptomatic relief and improve exercise capacity in patients with IPAH.
- **Balloon atrial septostomy** may be considered as palliative therapy in severe cases of PH.
- **Cardiac transplantation** is used in patients with adverse prognosis although the 5-year survival following transplantation may be only 40–50%.

Pulmonary hypertension

Left-sided heart disease (systolic and diastolic heart failure) and valvular heart disease is frequently associated with PH as is advanced chronic obstructive pulmonary disease (p. 814), pulmonary fibrosis and emphysema. Following acute pulmonary embolism 0.5–2.0 % of patients will develop CTEPH.

Pulmonary embolism

Thrombus, usually formed in the systemic veins or rarely in the right heart (<10% of cases), may dislodge and embolize into the pulmonary arterial system. Post-mortem studies indicate that this is a very common condition (microemboli are found in up to 60% of autopsies) but it is not usually diagnosed this frequently in life. Of clinical pulmonary emboli, 10% are fatal.

Most clots which cause clinically relevant pulmonary emboli actually come from the pelvic and abdominal veins, but femoral deep venous thrombosis, and even occasionally axillary thrombosis, can be the origin of the clot. Clot forms as a result of a combination of sluggish blood flow, local injury or compression of the vein and a hypercoagulable state. Emboli can also occur from tumour, fat (long bone fractures), amniotic fluid and foreign material during i.v. drug use. Risk factors are shown in Table 8.26 and discussed on page 427.

After pulmonary embolism, lung tissue is ventilated but not perfused – producing an intrapulmonary dead space and resulting in impaired gas exchange. After some hours the non-perfused lung no longer produces surfactant. Alveolar collapse occurs and exacerbates hypoxaemia. The primary

haemodynamic consequence of pulmonary embolism is a reduction in the cross-sectional area of the pulmonary arterial bed which results in an elevation of pulmonary arterial pressure and a reduction in cardiac output. The zone of lung that is no longer perfused by the pulmonary artery may infarct, but often does not do so because oxygen continues to be supplied by the bronchial circulation and the airways.

Clinical features

Sudden onset of *unexplained dyspnoea* is the most common, and often the only symptom of pulmonary embolism. *Pleuritic chest pain* and *haemoptysis* are present only when infarction has occurred. Many pulmonary emboli occur silently, but there are three typical clinical presentations. A clinical deep venous thrombosis is not commonly observed, although detailed investigation of the lower limb and pelvic veins will reveal thrombosis in more than half of the cases.

Small/medium pulmonary embolism

In this situation an embolus has impacted in a terminal pulmonary vessel. Symptoms are pleuritic chest pain and breathlessness. Haemoptysis occurs in 30%, often ≥ 3 days after the initial event. On examination, the patient may be tachypnoeic with a localized pleural rub and often coarse crackles over the area involved. An exudative pleural effusion (occasionally blood-stained) can develop. The patient may have a fever, and cardiovascular examination is normal.

Massive pulmonary embolism

This is a much rarer condition where sudden collapse occurs because of an acute obstruction of the right ventricular outflow tract. The patient has severe central chest pain (cardiac ischaemia due to lack of coronary blood flow) and becomes shocked, pale and sweaty. Syncope may result if the cardiac output is transiently but dramatically reduced, and death may occur. On examination, the patient is tachypnoeic, has a tachycardia with hypotension and peripheral shutdown. The jugular venous pressure (JVP) is raised with a prominent 'a' wave. There is a right ventricular heave, a gallop rhythm and a widely split second heart sound. There are usually no abnormal chest signs.

Multiple recurrent pulmonary emboli

This leads to increased breathlessness, often over weeks or months. It is accompanied by weakness, syncope on exertion and occasionally angina. The physical signs are due to the pulmonary hypertension that has developed from multiple occlusions of the pulmonary vasculature. On examination, there are signs of right ventricular overload with a right ventricular heave and loud pulmonary second sound.

Investigations in pulmonary embolism

Small/medium pulmonary emboli

- **Chest X-ray** is often normal, but linear atelectasis or blunting of a costophrenic angle (due to a small effusion) is not uncommon. These features develop only after some time. A raised hemidiaphragm is present in some patients. More rarely, a wedge-shaped pulmonary infarct, the abrupt cut-off of a pulmonary artery or a translucency of an underperfused distal zone is seen. Previous infarcts may be seen as opaque linear scars.
- **ECG** is usually normal, except for sinus tachycardia, but sometimes atrial fibrillation or another tachyarrhythmia occurs. There may be evidence of right ventricular strain.
- **Blood tests.** Pulmonary infarction results in a polymorphonuclear leucocytosis, an elevated ESR and

increased lactate dehydrogenase levels in the serum. Immediately prior to commencing anticoagulants a thrombophilia screen should be checked.

- **Plasma D-dimer** (see p. 416) – if this is undetectable, it excludes a diagnosis of pulmonary embolism.
- **Radionuclide ventilation/perfusion scanning (\dot{V}/\dot{Q} scan)** is a good and widely available diagnostic investigation. Pulmonary ^{99m}Tc scintigraphy demonstrates underperfused areas (Fig. 14.97) which, if not accompanied by a ventilation defect on a ventilation scintigram performed after inhalation of radioactive xenon gas (see p. 802), is highly suggestive of a pulmonary embolus. There are limitations to the test, however. For example, a matched defect may arise with a pulmonary embolus which causes an infarct, or from emphysematous bullae. This test is therefore conventionally reported as a probability (low, medium or high) of pulmonary embolus and should be interpreted in the context of the history, examination and other investigations.
- **Ultrasound scanning** can be performed for the detection of clots in pelvic or iliofemoral veins (see p. 789).

Figure 14.97 Ventilation (top) and perfusion (bottom) lung scans which demonstrate absence of perfusion in the right upper lobe, i.e. probably pulmonary embolism (arrows).

- **CT scans.** Contrast-enhanced multidetector CT angiograms (CTA) (Fig. 14.98), have a sensitivity of 83% and specificity of 96%, with a positive predictive value of 92%. These values will increase with the use of 64-multislice scanners.
- **MR imaging** gives similar results and is used if CT angiography is contraindicated.

Massive pulmonary emboli

- **Chest X-ray** may show pulmonary oligoemia, sometimes with dilatation of the pulmonary artery in the hila. Often there are no changes.
- **ECG** shows right atrial dilatation with tall peaked P waves in lead II. Right ventricular strain and dilatation give rise to right axis deviation, some degree of right bundle branch block, and T wave inversion in the right precordial leads (Fig. 14.99). The 'classic' ECG pattern with an S wave in lead I, and a Q wave and inverted T waves in lead III (S1, Q3, T3), is rare.
- **Blood gases** show arterial hypoxaemia with a low arterial CO_2 level, i.e. type I respiratory failure pattern.
- **Echocardiography** shows a vigorously contracting left ventricle, and occasionally a dilated right ventricle and a clot in the right ventricular outflow tract.
- **Pulmonary angiography** has now been replaced by CT and MR angiography.

Figure 14.98 CT pulmonary angiographic image at level of the main right and left pulmonary arteries showing a large thrombus (arrow) in the right pulmonary artery.

Figure 14.99 Acute pulmonary embolism shown by a 12-lead ECG. There is an S wave in lead I, a Q wave in lead III and an inverted T wave in lead III (the S1, Q3, T3 pattern). There is sinus tachycardia (160 b.p.m.) and an incomplete right bundle branch block pattern (an R wave in AVR and V1 and an S wave in V6).

Multiple recurrent pulmonary emboli

- **Chest X-ray** may be normal. Enlarged pulmonary arterioles with oligaemic lung fields indicate advanced disease.
- **ECG** can be normal or show signs of pulmonary hypertension (Fig. 14.99).
- **Leg imaging** with ultrasound and venography may show thrombi.
- **V/Q scan** may show evidence of pulmonary infarcts.
- **Multidetector CT scans** can detect small emboli.

Further tests looking for exercise-induced hypoxaemia and catheter studies to estimate pulmonary artery pressures are sometimes required.

Diagnosis

The symptoms and signs of small and medium-sized pulmonary emboli are often subtle and nonspecific, so the diagnosis is often delayed or even completely missed. Pulmonary embolism should be considered if patients present with symptoms of unexplained cough, chest pain, haemoptysis, new-onset atrial fibrillation (or other tachycardia), or signs of pulmonary hypertension if no other cause can be found. Patients that are haemodynamically stable should have their clinical probability of a pulmonary embolus determined with the Revised Geneva Score (Table 14.45).

- High clinical probability patients should proceed to multi-detector contrast-enhanced CT angiography (CTA) (see Fig. 14.98). A positive test confirms the diagnosis. A negative test but with an elevated D-dimer may require venous ultrasonography. (Patients with renal failure or contrast allergy can have ventilation/perfusion V/Q scanning).
- Low or intermediate clinical risk patients should have a D-dimer assay performed. A negative D-dimer rules out a pulmonary embolism. A positive D-dimer requires further investigation with CTA.

Patients who are haemodynamically unstable (shock, systolic blood pressure <90 mmHg, drop in pressure of ≥40 mmHg) may require urgent CTA or if critically ill with a high clinical probability, an echocardiogram should be

performed – right ventricular dysfunction is highly suggestive of a pulmonary embolism – a normal right ventricle should suggest alternative diagnoses.

Treatment**Acute management**

- All patients should receive high-flow oxygen (60–100%) unless they have significant chronic lung disease. Patients with pulmonary infarcts require bed rest and analgesia.
- Patients should be anticoagulated initially with subcutaneous low-molecular-weight heparin or fondaparinux or intravenous unfractionated heparin followed by warfarin therapy.
- **Massive pulmonary emboli.** Intravenous fluids and even inotropic agents to improve the pumping of the right heart are sometimes required, and very ill patients will require care on the intensive therapy unit (see p. 885).
- **Fibrinolytic therapy** such as streptokinase (250 000 units by i.v. infusion over 30 min, followed by streptokinase 100 000 units i.v. hourly for up to 12–72 hours, according to manufacturer's instructions) has been shown in controlled trials to clear pulmonary emboli more rapidly and to confer a survival benefit in massive PE. It should be used in unstable patients and in some stable patients with adverse features, e.g. right ventricular dysfunction.
- **Surgical embolectomy** is rarely necessary, but there may be no alternative when the haemodynamic circumstances are very severe.

Prevention of further emboli

Patients should be anticoagulated with vitamin K antagonists for a period of 3–6 months with a target INR of 2.0–3.0. Patients with cancer or pregnant women should be treated with long-term low-molecular-weight heparin. Occasionally, physical methods are required to prevent further emboli. This is usually because recurrent emboli occur despite adequate anticoagulation, but it is also indicated in high-risk patients in whom anticoagulation is absolutely contraindicated. The most common method by which pulmonary embolism is treated in this situation is by insertion of a filter in the inferior vena cava via the femoral vein to above the level of the renal veins.

Table 14.45 Revised Geneva Score for the clinical prediction of a pulmonary embolism

	Score
Risk factors	
Age >65 years	+1
Previous deep venous thrombosis or pulmonary embolism	+3
Surgery or fracture within 1 month	+2
Active malignancy	+2
Symptoms	
Unilateral leg pain	+3
Haemoptysis	+2
Clinical signs

MYOCARDIAL AND ENDOCARDIAL DISEASE**Atrial myxoma**

This is the most common primary cardiac tumour. It occurs at all ages and shows no sex preference. Although most myxomas are sporadic, some are familial or are part of a multiple system syndrome. Histologically, they are benign. The majority of myxomas are solitary, usually develop in the left atrium and are polypoid, gelatinous structures attached by a pedicle to the atrial septum. The tumour may obstruct the mitral valve or may be a site of thrombi that then embolize. It is also associated with constitutional symptoms: the patient may present with dyspnoea, syncope or a mild fever. The physical signs are a loud first heart sound, a tumour 'plop' (a loud third heart sound produced as the pedunculated tumour comes to an abrupt halt), a mid-diastolic murmur and signs due to embolization. A raised ESR is usually present.

Figure 14.100 Atrial myxoma shown by a 2-D echocardiogram (long-axis view). The myxoma is an echo-dense mass obstructing the mitral valve orifice. It was removed surgically. LV, left ventricle; LA, left atrium.

The diagnosis is easily made by echocardiography because the tumour is demonstrated as a dense space-occupying lesion (Fig. 14.100). Surgical removal usually results in a complete cure.

Myxomas may also occur in the right atrium or in the ventricles. Other primary cardiac tumours include rhabdomyomas and sarcomas.

Myocardial disease

Myocardial disease that is not due to ischaemic, valvular or hypertensive heart disease, or a known infiltrative, metabolic/toxic or neuromuscular disorder may be caused by:

- An acute or chronic inflammatory pathology (myocarditis)
- Idiopathic myocardial disease (cardiomyopathy).

Myocarditis

Acute inflammation of the myocardium has many causes (Table 14.46). Establishment of a definitive aetiology with isolation of viruses or bacteria is difficult in routine clinical practice.

In western societies, the commonest causes of infective myocarditis are Coxsackie or adenoviral infection. Myocarditis in association with HIV infection is seen at post-mortem in up to 20% of cases but causes clinical problems in less than 10% of cases. Chagas' disease, due to *Trypanosoma cruzi*, which is endemic in South America, is one of the commonest causes of myocarditis worldwide. Additionally, toxins (including prescribed drugs), physical agents, hypersensitivity reactions and autoimmune conditions may also cause myocardial inflammation.

Pathology

In the acute phase, myocarditic hearts are flabby with focal haemorrhages; in chronic cases they are enlarged and hypertrophied. Histologically an inflammatory infiltrate is present – lymphocytes predominating in viral causes; polymorphonuclear cells in bacterial causes; eosinophils in allergic and hypersensitivity causes.

Clinical features

Myocarditis may be an acute or chronic process; its clinical presentations range from an asymptomatic state associated with limited and focal inflammation to *fatigue*, *palpitations*,

Table 14.46 Causes of myocarditis

Idiopathic

Infective

- Viral: Coxsackievirus, adenovirus, CMV, echovirus, influenza, polio, hepatitis, HIV
- Parasitic: *Trypanosoma cruzi*, *Toxoplasma gondii* (a cause of myocarditis in the newborn or immunocompromised)
- Bacterial: Streptococcus (most commonly rheumatic carditis), diphtheria (toxin-mediated heart block common)
- Spirochaetal: Lyme disease (heart block common), leptospirosis
- Fungal
- Rickettsial

Toxic

- Drugs: Causing hypersensitivity reactions, e.g. methyl dopa, penicillin, sulphonamides, antituberculous, modafinil
- Radiation: May cause myocarditis but pericarditis more common

Autoimmune

- An autoimmune form with autoactivated T cells and organ-specific antibodies may occur

Alcohol

Hydrocarbons

chest pain, *dyspnoea* and *fulminant congestive cardiac failure* due to diffuse myocardial involvement. An episode of viral myocarditis, perhaps unrecognized and forgotten, may be the initial event that eventually culminates in an 'idiopathic' dilated cardiomyopathy. Physical examination includes soft heart sounds, a prominent third sound and often a tachycardia. A pericardial friction rub may be heard.

Investigations

- **Chest X-ray** may show some cardiac enlargement, depending on the stage and virulence of the disease.
- **ECG** demonstrates ST- and T-wave abnormalities and arrhythmias. Heart block may be seen with diphtheritic myocarditis, Lyme disease and Chagas' disease (see below).
- **Cardiac enzymes** are elevated.
- **Viral antibody titres** may be increased. However, since enteroviral infection is common in the general population, the diagnosis depends on the demonstration of acutely rising titres.
- **Endomyocardial biopsy** may show acute inflammation but false negatives are common by conventional criteria. Biopsy is of limited value outside specialized units.
- **Viral RNA**. DNA can be measured from biopsy material using polymerase chain reaction (PCR). Specific diagnosis requires demonstration of active viral replication within myocardial tissue.

Treatment

The underlying cause must be identified, treated, eliminated or avoided. Bed rest is recommended in the acute phase of the illness and athletic activities should be avoided for 6 months. Heart failure should be treated conventionally with the use of diuretics, ACE inhibitors/AT1 receptor antagonists, beta-blockers, spironolactone ± digoxin. *Antibiotics* should be administered immediately where appropriate. *NSAIDs* are contraindicated in the acute phase of the illness but may be used in the late phase. The use of *corticosteroids* is controversial and no studies have demonstrated an improvement in left ventricular ejection fraction or survival following their use. The administration of high-dose intravenous *immunoglobulin* on the other hand appears to be associated with a more rapid

resolution of the left ventricular dysfunction and improved survival. Novel and effective antiviral, immunosuppressive (e.g. γ -interferon) and *immunomodulating* (e.g. IL-10) agents are available to treat viral myocarditis.

Giant cell myocarditis

This is a severe form of myocarditis characterized by the presence of multinucleated giant cells within the myocardium. The cause is unknown but it may be associated with sarcoidosis, thymomas and autoimmune disease. It has a rapidly progressive course and a poor prognosis. Immunosuppression is recommended.

Chagas' disease

Chagas' disease is caused by the protozoan *Trypanosoma cruzi* and is endemic in South America where upwards of 20 million people are infected. Acutely, features of myocarditis are present with fever and congestive heart failure. Chronically, there is progression to a dilated cardiomyopathy with a propensity towards heart block and ventricular arrhythmias. Treatment is discussed on page 148. Amiodarone is helpful for the control of ventricular arrhythmias; heart failure is treated in the usual way (p. 719).

Cardiomyopathy

Cardiomyopathies are a group of diseases of the myocardium that affect the mechanical or electrical function of the

heart. They are frequently genetic and may produce inappropriate ventricular hypertrophy or dilatation and can be primarily a cardiac disorder or part of a multisystem disease (Table 14.47). Nevertheless, there is considerable heterogeneity and overlap between the conditions (Fig. 14.10). Abnormal myocardial function produces systolic or diastolic heart failure; abnormal electrical conduction results in cardiac arrhythmias and sudden cardiac death.

Hypertrophic cardiomyopathy (HCM)

HCM includes a group of inherited conditions that produce hypertrophy of the myocardium in the absence of an alternate cause (e.g. aortic stenosis or hypertension). It is the most common cause of sudden cardiac death in young people and affects 1 in 500 of the population. The majority of cases are familial autosomal dominant, due to mutations in the genes encoding sarcomeric proteins (Fig. 14.101). The most common causes of HCM are mutations of the β -myosin heavy chain MYH7 and myosin-binding protein C MYBPC3. Other mutations include troponin T and I, regulatory and essential myosin light chains, titin, α tropomyosin, α actin, α myosin heavy chain and muscle LIM protein (although over 400 mutations have been identified.) There are non-sarcomeric protein mutations in genes that control cardiac metabolism that result in glycogen storage diseases (Danon's, Pompe's and Fabry's disease) that are indistinguishable from HCM.

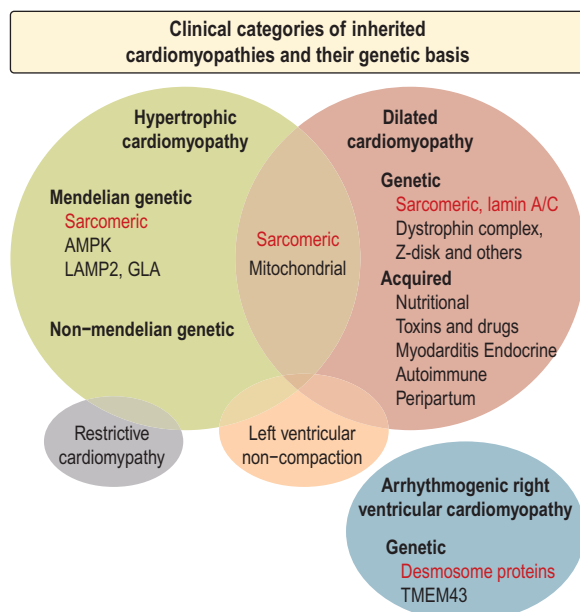

Figure 14.101 Cardiomyopathy – clinical categories and genetic basis. Hypertrophic and dilated cardiomyopathies share the same genes, as do the less common restrictive cardiomyopathy and left ventricular non-compaction. Arrhythmogenic right ventricular cardiomyopathy (ARVC) is genetically different. AMPK, AMP-activated kinase; GLA, galactosidase A; LAMP2, lysosomal assisted membrane protein 2; TMEM43, transmembrane protein 43. (Modified from Watkins H et al. *Inherited cardiomyopathies*. N Engl J Med 2011; 364:1643–1656, with permission.)

Clinical features

HCM is characterized by variable myocardial hypertrophy frequently involving the interventricular septum and disorganization ('disarray') of cardiac myocytes and myofibrils. Some 25% of patients have dynamic left ventricular outflow tract obstruction due to the combined effects of hypertrophy, systolic anterior motion (SAM) of the anterior mitral valve leaflet and rapid ventricular ejection. The salient clinical and morphological features of the disease vary according to the underlying genetic mutation. For example, marked hypertrophy is common with β myosin heavy chain mutations whereas mutations in troponin T may be associated with mild hypertrophy but a high risk of sudden death. The hypertrophy may not manifest before completion of the adolescent growth spurt, making the diagnosis in children difficult. HCM due to myosin-binding protein may not manifest until the sixth decade of life or later.

Symptoms

- Many are asymptomatic and are detected through family screening of an affected individual or following a routine ECG examination.
- Chest pain, dyspnoea, syncope or pre-syncope (typically with exertion), cardiac arrhythmias and sudden death are seen.
- Sudden death occurs at any age but the highest rates (up to 6% per annum) occur in adolescents or young adults. Risk factors for sudden death are discussed below.
- Dyspnoea occurs due to impaired relaxation of the heart muscle or the left ventricular outflow tract obstruction that occurs in some patients. The systolic cavity remains

Figure 14.102 Hypertrophic cardiomyopathy. A 2-D echocardiogram (short-axis view). The grossly thickened interventricular septum is shown, resulting in a small left ventricular cavity. This condition is associated with an abnormal anterior motion of the mitral valve during systole (arrows). LA, left atrium; LV, left ventricle.

small until the late stages of disease when progressive dilatation may occur. If a patient develops atrial fibrillation there is often a rapid deterioration in clinical status due to the loss of atrial contraction and the tachycardia – resulting in elevated left atrial pressure and acute pulmonary oedema.

Signs

- Double apical pulsation (forceful atrial contraction producing a fourth heart sound).
- Jerky carotid pulse because of rapid ejection and sudden obstruction to left ventricular outflow during systole.
- Ejection systolic murmur due to left ventricular outflow obstruction late in systole – it can be increased by manoeuvres that decrease afterload, e.g. standing or Valsalva, and decreased by manoeuvres that increase afterload and venous return, e.g. squatting.
- Pansystolic murmur due to mitral regurgitation (secondary to SAM).
- Fourth heart sound (if not in AF).

Investigations

- **ECG** abnormalities of HCM include left ventricular hypertrophy (see Fig. 14.76), ST and T wave changes, and abnormal Q waves especially in the inferolateral leads.
- **Echocardiography** is usually diagnostic and in classical HCM there is asymmetric left ventricular hypertrophy (involving the septum more than the posterior wall), systolic anterior motion of the mitral valve, and a vigorously contracting ventricle (Fig. 14.102). However, any pattern of hypertrophy may be seen, including concentric and apical hypertrophy.
- **Cardiac MR** can detect both the hypertrophy but also abnormal myocardial fibrosis (Fig. 14.103).
- **Genetic analysis**, where available, may confirm the diagnosis and provide prognostic information for the patient and relatives.

Treatment

The management of HCM includes treatment of symptoms and the prevention of sudden cardiac death in the patient and relatives.

Figure 14.103 Cardiac MR in a patient with hypertrophic cardiomyopathy. (a) Turbo spin-echo demonstrates marked thickening of the basal to mid-anterior wall and septum (*). (b) Inversion recovery image post gadolinium demonstrates regional fibrosis with enhancement (+).

Risk factors for sudden death:

- Massive left ventricular hypertrophy (>30 mm on echocardiography)
- Family history of sudden cardiac death (<50 years old)
- Non-sustained ventricular tachycardia on 24-hour Holter monitoring
- Prior unexplained syncope
- Abnormal blood pressure response on exercise (flat or hypotensive response).

The presence of these cardiac risk factors is associated with an increased risk of sudden death (Table 14.48), and patients with two or more should be assessed for implantable cardioverter-defibrillator (ICD). In patients in whom the risk is less, amiodarone is an appropriate alternative.

Chest pain and dyspnoea are treated with beta-blockers and verapamil either alone or in combination. An alternative agent is disopyramide if patients have left ventricular outflow tract obstruction. In some patients with significant left outflow obstruction and symptoms, dual-chamber pacing is necessary. Alcohol (non-surgical) ablation of the septum has been investigated and appears to give good results in reduction of outflow tract obstruction and subsequent improvement in exercise capacity. This procedure carries risks, including the development of complete heart block and myocardial infarction. Occasionally surgical resection of septal myocardium may be indicated. Vasodilators should be avoided because they may aggravate left ventricular outflow obstruction or cause refractory hypotension.

Arrhythmogenic (right) ventricular cardiomyopathy (AVC)

AVC is an uncommon (1 in 5000 population) inherited condition that predominantly affects the right ventricle with fatty or fibro-fatty replacement of myocytes, leading to segmental or global dilatation (Fig. 14.104). Left ventricular involvement

Figure 14.104 Gross pathological specimen demonstrating thinning and fibro-fatty replacement of right ventricular free wall. (From Basso C, Thiene G, Corrado D et al. *Circulation* 1996; 94:983–991, with permission.)

Table 14.48 Causes of sudden cardiac death

Coronary artery disease

Acute myocardial infarction – STEMI
Chronic ischaemic heart disease
Following coronary artery bypass surgery
After successful resuscitation for cardiac arrest

Coronary artery embolism
Coronary arteritis

Non-coronary artery disease

Hypertrophic cardiomyopathy
Dilated cardiomyopathy (ischaemic or idiopathic)
Arrhythmogenic right ventricular cardiomyopathy
Congenital long QT syndrome
Brugada syndrome
Valvular heart disease (aortic stenosis, mitral valve prolapse) ± infective endocarditis
Cyanotic heart disease (tetralogy of Fallot, transposition)
Acyanotic heart disease (ventricular septal defect, patent ductus arteriosus)

has been reported in up to 75% of cases. The fibro-fatty replacement leads to ventricular arrhythmia and risk of sudden death in its early stages, and right ventricular or biventricular failure in its later stages.

Autosomal dominant AVC has been mapped to eight chromosomal loci within mutations in four genes encoding for desmosomal proteins. These are the cardiac ryanodine receptor RyR2 (also responsible for familial catecholaminergic polymorphic ventricular tachycardia, CPVT), desmoplakin, plakophilin-2 and mutations altering the regulatory sequences of the transforming growth factor- β gene.

There are two recessive forms: *Naxos disease* (associated with palmoplantar keratoderma and woolly hair) that is due to a mutation in junctional plakoglobin, and *Carvajal's syndrome*, due to a mutation in desmoplakin.

Clinical features

Most patients are asymptomatic. Symptomatic ventricular arrhythmias, syncope or sudden death occur. Occasionally presentation is with symptoms and signs of right heart failure, although this is more common in the later stages of the disease. Some patients may be detected through family

screening, although frequently the morphological appearance of the right ventricle is normal, despite significant cardiac arrhythmias.

Investigations

- **ECG** is usually normal but may demonstrate T wave inversion in the precordial leads related to the right ventricle (V_1 – V_3). Small-amplitude potentials occurring at the end of the QRS complex (epsilon waves) may be present (Fig. 14.105) and incomplete or complete RBBB is sometimes seen. Signal averaged ECG may indicate the presence of late potentials, the delayed depolarization of individual muscle cells; 24-hour Holter monitoring may demonstrate frequent extrasystoles of right ventricular origin or runs of non-sustained ventricular tachycardia.
- **Echocardiography** is frequently normal but with more advanced cases may demonstrate right ventricular dilatation and aneurysm formation, and there may be left ventricular dilatation.
- **Cardiac MR** can more accurately assess the right ventricle and in some cases can demonstrate fibro-fatty infiltration (Fig. 14.106).
- **Genetic testing** may soon be the diagnostic 'gold standard'.

Clinical diagnosis is made using Task Force Criteria that include structural abnormalities of the right ventricle and RVOT (dilatation and abnormal wall motion on echocardiography or MRI), fibro-fatty replacement of myocytes on tissue biopsy, repolarization and conduction abnormalities on ECG or signal averaged ECG, ventricular tachycardia or frequent ventricular extrasystoles on Holter monitor, family history of ARVC/D in a first- or second-degree relative or premature sudden death (<35 years) due to ARVC/D.

Figure 14.105 Electrocardiogram from an adult with arrhythmogenic right ventricular cardiomyopathy (ARVC) demonstrating RBBB and precordial T wave insertion with epsilon waves visible at the terminal of the QRS complex (arrow).

Figure 14.106 Arrhythmogenic right ventricular cardiomyopathy (ARVC). Inversion recovery MR image post gadolinium demonstrates marked hyperenhancement (arrows) in the right ventricular free wall and infero-septum consistent with fibro-fatty replacement in right and left ventricles.

Treatment

Beta-blockers are first-line treatment for patients with non-life-threatening arrhythmias. Amiodarone or sotalol are used for symptomatic arrhythmias but for refractory or life-threatening arrhythmias an ICD is required. Occasionally cardiac transplantation is indicated either for intractable arrhythmia or cardiac failure.

Dilated cardiomyopathy (DCM)

DCM has a prevalence of 1 in 2500 and is characterized by dilatation of the ventricular chambers and systolic dysfunction with preserved wall thickness.

Familial DCM is predominantly autosomal dominant and can be associated with over 20 abnormal loci and genes (Fig. 14.107). Many of these are genes encoding cytoskeletal or associated myocyte proteins (dystrophin in X-linked cardiomyopathy; actin, desmin, troponin T, beta myosin heavy chain, sarcoglycans, vinculin and lamin a/c in autosomal dominant DCM) (Fig. 14.108). Many of these have prominent associated features such as skeletal myopathy or conduction system disease and therefore differ from the majority of cases of DCM.

Sporadic DCM can be caused by multiple conditions (Table 14.47):

- Myocarditis – Coxsackie, adenoviruses, erythroviruses, HIV, bacteria, fungus, mycobacteria, parasitic (Chagas's disease)
- Toxins – alcohol, chemotherapy, metals (cobalt, lead, mercury, arsenic)
- Autoimmune
- Endocrine
- Neuromuscular.

a

b

Figure 14.109 Dilated cardiomyopathy. (a) 2-D (apical four-chamber view) and (b) M-mode echocardiograms. The heart has a 'globular' appearance with all four chambers dilated. The extremely impaired left ventricular function can be appreciated from the M-mode recording. Compare the systolic shortening fraction with that of Figure 14.23. LA, left atrium; RA, right atrium; LV, left ventricle.

Clinical features

DCM can present with heart failure, cardiac arrhythmias, conduction defects, thromboembolism or sudden death. Increasingly, evaluation of relatives of DCM patients is allowing identification of early asymptomatic disease, prior to the onset of these complications. Clinical evaluation should include a family history and construction of a pedigree where appropriate.

Investigations

- **Chest X-ray** demonstrates generalized cardiac enlargement.
- **ECG** may demonstrate diffuse nonspecific ST segment and T wave changes. Sinus tachycardia, conduction abnormalities and arrhythmias (i.e. atrial fibrillation, ventricular premature contractions or ventricular tachycardia) are also seen.
- **Echocardiogram** reveals dilatation of the left and/or right ventricle with poor global contraction function (Fig. 14.109).
- **Cardiac MR** may demonstrate other aetiologies of left ventricular dysfunction (e.g. previous myocardial infarction) or demonstrate abnormal myocardial fibrosis (Fig. 14.110).
- **Coronary angiography** should be performed to exclude coronary artery disease in all individuals at risk (generally patients >40 years or younger if symptoms or risk factors are present).

Figure 14.110 Dilated cardiomyopathy. Inversion recovery MR post gadolinium demonstrates septal mid-wall hyperenhancement (arrows) consistent with fibrosis in a patient with dilated cardiomyopathy.

- **Biopsy** is generally not indicated outside specialist care.

Treatment

Treatment consists of the conventional management of heart failure with the option of cardiac resynchronization therapy and ICDs in patients with NYHA III/IV grading. Cardiac transplantation is appropriate for certain patients.

Left ventricular non-compaction (LVNC)

LVNC is associated with a sponge-like appearance of the left ventricle. The condition predominantly affects the apical portion of the left ventricle and may be associated with congenital heart abnormalities. The condition is diagnosed by echocardiography, cardiac MR or left ventricular angiography. The natural history of the condition is unresolved but includes congestive cardiac failure, thromboembolism, cardiac arrhythmias and sudden death. Familial and spontaneous cases have been described.

Conduction system disease

Lenegre's disease (p. 701) is a progressive disease of the cardiac conduction system (His-Purkinje system) that causes broad QRS duration, long pauses and bradycardia which presents with syncope. Sick-sinus syndrome is phenotypically similar.

Ion channelopathies

Features of the ion channelopathies are long QT syndrome (LQTS) (p. 708), Brugada's syndrome (p. 701), catecholaminergic polymorphic ventricular tachycardia (CPVT), short QT syndrome (SQTS) and idiopathic ventricular fibrillation (VF).

Primary restrictive non-hypertrophic cardiomyopathy

This is a rare condition in which there is normal or decreased volume of both ventricles with bi-atrial enlargement, normal wall thickness, normal cardiac valves and impaired ventricular filling with restrictive physiology but near normal systolic function. The restrictive physiology produces symptoms and signs of heart failure. Conditions associated with this form of cardiomyopathy include amyloidosis (commonest), sarcoidosis, Loeffler's endocarditis and endomyocardial fibrosis; in the latter two conditions there is myocardial and endocardial fibrosis associated with eosinophilia. The idiopathic form of restrictive cardiomyopathy may be familial.

Clinical features

Patients with restrictive cardiomyopathy may present with dyspnoea, fatigue and embolic symptoms. On clinical examination there will be elevated jugular venous pressure with

diastolic collapse (Friedreich's sign) and elevation of venous pressure with inspiration (Kussmaul's sign), hepatic enlargement, ascites and dependent oedema. Third and fourth heart sounds may be present.

Investigations

- **Chest X-ray** may show pulmonary venous congestion. The cardiac silhouette can be normal or show cardiomegaly and/or atrial enlargement.
- **ECG** may demonstrate low-voltage QRS and ST segment and T wave abnormalities.
- **Echocardiography** shows symmetrical myocardial thickening and often a normal systolic ejection fraction but impaired ventricular filling. In amyloid patients the myocardium typically appears speckled with absent radial thickening as demonstrated by 'tram-lines' on M-mode echocardiography (Fig. 14.111).
- **Cardiac MR** may demonstrate abnormal myocardial fibrosis in amyloidosis or sarcoidosis.
- **Cardiac catheterization** and haemodynamic studies may help distinguish between restrictive cardiomyopathy and constrictive pericarditis, although volume loading may be required.
- **Endomyocardial biopsy** in contrast with other cardiomyopathies is often useful in this condition and may permit a specific diagnosis, such as amyloidosis, to be made.

Treatment

There is no specific treatment. Cardiac failure and embolic manifestations should be treated. Cardiac transplantation is necessary in some severe cases, especially the idiopathic variety. In primary amyloidosis combination therapy with melphalan plus prednisolone with or without colchicine may improve survival. However, patients with cardiac amyloidosis have a worse prognosis than those with other forms of the disease, and the disease often recurs after transplantation. Liver transplantation may be effective in familial amyloidosis (due to production of mutant pre-albumin) and may lead to reversal of the cardiac abnormalities.

Acquired cardiomyopathies

Myocarditis (see p. 767)

Stress (Tako-tsubo/octopus pot/apical ballooning syndrome) cardiomyopathy

Patients with this condition present acutely with chest pain and breathlessness associated with ECG changes and elevated cardiac biomarkers consistent with acute myocardial infarction. Diagnostic coronary angiography typically demonstrates unobstructed coronary arteries with characteristic akinesia of the mid-apical segments of the left ventricle on ventriculography or echocardiography with preserved basal function (Fig. 14.112). The pathophysiology of the condition is uncertain but may be due to transient catecholamine excess, coronary vasospasm, abnormalities of the coronary microcirculation and hypertrophy of the basal septum. The syndrome is more common in middle-old aged women. Severe cases may have cardiogenic shock and pulmonary oedema. Patients with a significant left ventricular gradient may respond to cautious beta-blockade. Complete recovery of function is normal within 4–6 weeks.

Peripartum cardiomyopathy

This rare condition affects women in the last trimester of pregnancy or within 5 months of delivery. It presents as a

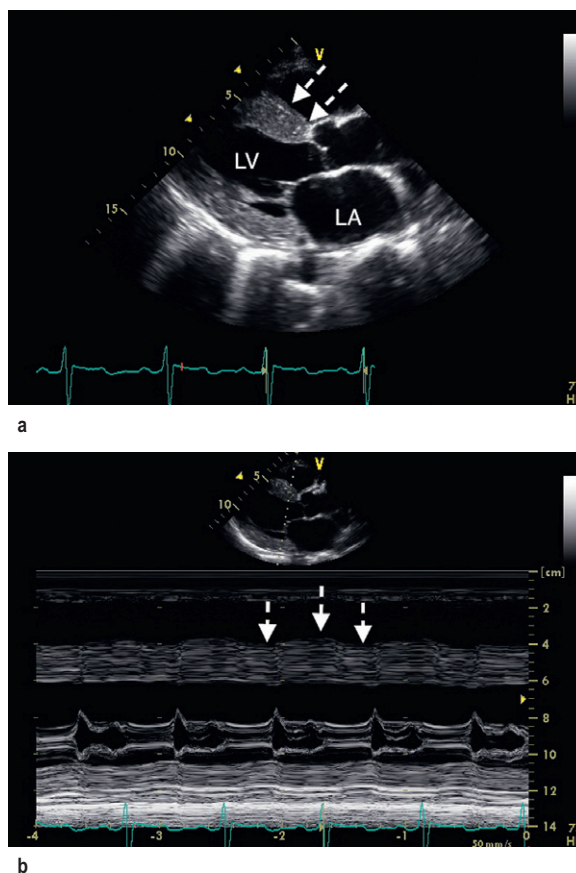

Figure 14.111 Amyloid. (a) Parasternal long-axis echocardiogram demonstrates left ventricular (LV) hypertrophy with reduced systolic function. The septum has a speckled appearance (arrows). (b) M-mode echocardiogram demonstrates reduced septal thickening with 'tram-line' appearance (arrows). These features are suggestive of cardiac amyloid – confirmed on cardiac biopsy. LA, left atrium.

Figure 14.112 Tako-tsubo cardiomyopathy. Left ventricular angiography in a patient admitted with chest pain following emotional stress demonstrates apical ballooning (arrows) consistent with Tako-tsubo cardiomyopathy. Diagnostic coronary angiography showed normal coronary arteries.

dilated cardiomyopathy, is more common in obese, multiparous women over 30 years old and is associated with pre-eclampsia. Nearly half of patients will recover to normal function within 6 months but in some patients it can cause progressive heart failure and sudden death.

Tachycardia cardiomyopathy

Prolonged periods of supraventricular or ventricular tachycardia will lead to dilated cardiomyopathy. Cardioversion and ablation may be necessary to restore sinus rhythm and allow for recovery of cardiac function.

PERICARDIAL DISEASE

The pericardium acts as a protective covering for the heart. It consists of an outer fibrous pericardial sac and an inner serous pericardium made up of the inner visceral epicardium that lines the heart and great vessels and its reflection the outer parietal pericardium that lines the fibrous sac. The normal amount of pericardial fluid is 20–49 mL that lubricates the surface of the heart. Presentations of pericardial disease include:

- Acute and relapsing pericarditis
- Pericardial effusion and cardiac tamponade
- Constrictive pericarditis.

Acute pericarditis

This refers to inflammation of the pericardium. Classically, fibrinous material is deposited into the pericardial space and pericardial effusion often occurs. Acute pericarditis has numerous aetiologies (Table 14.49) although in most cases a cause is not identified (idiopathic).

Viral pericarditis. The most common viral causes are Coxsackie B virus and echovirus. Viral pericarditis is usually painful but has a short time course and rarely long-term effects. Increasingly, HIV is implicated in the aetiology of

pericarditis, both directly and via immunosuppression, which predisposes the subject to infective causes.

Post-myocardial infarction pericarditis occurs in about 20% of patients in the first few days following MI. It occurs more commonly with anterior MI and ST elevation MI with high serum cardiac enzymes, but its incidence is reduced to 5–6% with thrombolysis. It may be difficult to differentiate this pain from recurrent angina when it occurs early (day 1–2 post-infarct) but a good history of the pain and serial ECG monitoring is helpful. Pericarditis may also occur later on in the recovery phase after infarction. This usually occurs as a feature of *Dressler's syndrome*, an autoimmune response to cardiac damage occurring 2–10 weeks' post-infarct. Autoimmune reaction to myocardial damage is the main aetiology, and antimyocardial antibodies can often be found. Recurrences are common. Differential diagnosis includes a new myocardial infarction or unstable angina.

Uraemic pericarditis is due to irritation of the pericardium by accumulating toxins. It can occur in 6–10% of patients with advanced kidney disease if dialysis is delayed. It is an indication for urgent dialysis as it continues to be associated with significant morbidity and mortality.

Bacterial pericarditis may rarely occur with septicaemia or pneumonia, or it may stem from an early postoperative infection after thoracic surgery or trauma, or may complicate endocarditis. *Staphylococcus aureus* is a frequent cause of purulent pericarditis in HIV patients. This form of pericarditis, especially staphylococcal, is fulminant and often fatal.

Other *endemic infectious pericarditis* includes mycoplasmosis and Lyme pericarditis which are often effusive and require pericardial drainage. The diagnosis is based on serological tests of pericardial fluid and identification of organisms in pericardial or myocardial biopsies.

Tuberculous pericarditis usually presents with chronic low-grade fever, particularly in the evening, associated with features of acute pericarditis, dyspnoea, malaise, night sweats and weight loss. Pericardial aspiration is often required to make the diagnosis. Constrictive pericarditis is a frequent outcome. Treatment is as for pulmonary TB (p. 842) but prednisolone 60 mg daily for 2–6 weeks.

Fungal pericarditis is a common complication of endemic fungal infections, such as histoplasmosis and coccidioidomycosis but may be also caused by *Candida albicans*, especially in immunocompromised patients, drug addicts or after cardiac surgery.

Malignant pericarditis. Carcinoma of the bronchus, carcinoma of the breast and Hodgkin's lymphoma are the most common causes of malignant pericarditis. Leukaemia and malignant melanoma are also associated with pericarditis. A substantial pericardial effusion is very typical and is due to the obstruction of the lymphatic drainage from the heart. The effusion is often haemorrhagic. Radiation and therapy for thoracic tumours may cause radiation injury to the pericardium resulting in serous or haemorrhagic pericardial effusion and pericardial fibrosis. Absence of neoplastic cells in the pericardial fluid in these conditions often helps diagnosis.

Clinical features

Pericardial inflammation produces sharp central *chest pain* exacerbated by movement, respiration and lying down. It is typically relieved by sitting forward. It may be referred to the neck or shoulders. The main differential diagnoses are angina and pleurisy. The classical clinical sign is a pericardial friction rub occurring in three phases corresponding to atrial systole, ventricular systole and ventricular diastole. It may also be heard as a biphasic 'to and fro' rub. The rub is heard best with the diaphragm of the stethoscope at the lower left

Table 14.49 Aetiology of pericarditis

I.	Infectious pericarditis
	Viral (Coxsackievirus, echovirus, mumps, herpes, HIV)
	Bacterial (<i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Pneumococcus</i> , <i>Meningococcus</i> , <i>Haemophilus influenzae</i> , <i>Mycoplasmosis</i> , <i>Borreliosis</i> , <i>Chlamydia</i>)
	Tuberculous

XI.	Familial and idiopathic pericarditis

sternal edge at the end of expiration with the patient leaning forward. There is usually a *fever*, *leucocytosis* or *lymphocytosis* when pericarditis is due to viral or bacterial infection, rheumatic fever or myocardial infarction. Features of a pericardial effusion may also be present (p. 776). Large *pericardial effusion* can compress adjacent bronchi and lung tissue and may cause *dyspnoea*.

Investigations

ECG is diagnostic. There is widespread concave-upwards (saddle-shaped) ST elevation (Fig. 14.113), reciprocal ST depression in leads aVR and V₁, and PR segment depression. These changes evolve over time, with resolution of the ST elevation, T wave flattening/inversion and finally T wave normalization. The early ECG changes must be differentiated from the ST elevation found in myocardial infarction which is limited to the infarcted area, e.g. anterior or inferior. Sinus tachycardia may result from fever or haemodynamic embarrassment, and rhythm and conduction abnormalities may be present if myocardium is involved. Cardiac enzymes should be assayed as they may be elevated if there is associated myocarditis (see p. 767). Chest X-ray may demonstrate cardiomegaly (in cases with an effusion) which should be confirmed with echocardiography. CT and cardiac MR may be helpful for in cases with thickened (>4 mm) or inflamed (abnormal delayed enhancement) pericardium.

Treatment

If a cause is found, this should be treated. Bed rest and oral NSAIDs (high-dose aspirin indometacin or ibuprofen) are

effective in most patients. Aspirin is the drug of choice for patients with a recent myocardial infarction. Colchicine is also effective in combination with conventional therapy, as demonstrated in the COPE trial. Corticosteroids should be reserved for patients with a known immune cause as their use is associated with an increased rate of recurrence.

Recurrent or relapsing pericarditis

About 20% of cases of acute pericarditis go on to develop idiopathic relapsing pericarditis which may be incessant (recurs within 6 weeks during weaning of NSAIDs) or intermittent (recurs >6 weeks after the initial presentation). The first-line treatment is again oral NSAIDs. The colchicine as first-choice therapy for recurrent pericarditis trial demonstrated that prolonged colchicine (for 6 months) was more effective than aspirin alone in reducing recurrence. In resistant cases, oral corticosteroids may be effective and in some patients pericardiectomy may be appropriate.

Pericardial effusion and cardiac tamponade

A pericardial effusion is a collection of fluid within the potential space of the serous pericardial sac (Fig. 14.114), commonly accompanying an episode of acute pericarditis. When a large volume collects in this space, ventricular filling is compromised leading to embarrassment of the circulation. This is known as cardiac tamponade.

Clinical features

Symptoms of a pericardial effusion commonly reflect the underlying pericarditis. On examination:

- Heart sounds are soft and distant
- Apex beat is commonly obscured
- A friction rub may be evident due to pericarditis in the early stages, but this becomes quieter as fluid accumulates and pushes the layers of the pericardium apart
- Rarely, the effusion may compress the base of the left lung, producing an area of dullness to percussion below the angle of the left scapula (Ewart's sign)

Figure 14.113 ECGs associated with pericarditis. (a) Acute pericarditis. Note the raised ST segment, concave upwards (arrow). **(b)** Chronic phase of pericarditis associated with a pericardial effusion. Note the T wave flattening and inversion, and the alternation of the QRS amplitude (QRS alternans). **(c)** The same patient after evacuation of the pericardial fluid. Note that the QRS voltage has increased and the T waves have returned to normal.

Figure 14.114 Chest X-ray showing a pericardial effusion; the heart appears globular.

Pericardial disease

Imazio M, Bobbio M, Cecchi E et al. Colchicine as first-choice therapy for recurrent pericarditis: results of the CORE (COLchicine for REcurrent pericarditis) trial. *Arch Intern Med* 2005; 165: 1987–1991.

- As the effusion worsens, signs of cardiac tamponade may become evident:
 - Raised jugular venous pressure with sharp rise and y descent (Friedreich's sign)
 - Kussmaul's sign (rise in JVP/increased neck vein distension during inspiration)
 - Pulsus paradoxus (an exaggeration in the normal variation in pulse pressure seen with inspiration such that there is drop in systolic blood pressure of ≥ 10 mmHg)
 - Reduced cardiac output.

Investigations

- **ECG** reveals low-voltage QRS complexes (<0.5 mV in limb leads) with sinus tachycardia and there may be electric alternans (alteration of QRS amplitude or axis between beats).
- **Chest X-ray** (Fig. 14.114) shows large globular or pear-shaped heart with sharp outlines. Typically, the pulmonary veins are not distended.
- **Echocardiography** (Fig. 14.115) is the most useful technique for demonstrating the effusion and looking for evidence of tamponade – late diastolic collapse of the right atrium, early diastolic collapse of the right ventricle, ventricular septum displacement into the left ventricle during inspiration, diastolic flow reversal in the hepatic veins during expiration, dilated inferior vena cava with $<50\%$ reduction during inspiration.
- **Cardiac CT or MRI** should be considered if loculated pericardial effusions are suspected (post-cardiac surgery).
- **Pericardiocentesis** is the removal of pericardial fluid with aseptic technique under echocardiographic guidance. It is indicated when a tuberculous, malignant or purulent effusion is suspected.
- **Pericardial biopsy** may be needed if tuberculosis is suspected and pericardiocentesis is not diagnostic.

Other tests include looking for underlying causes, e.g. blood cultures, autoantibody screen.

Figure 14.115 2-D Echocardiogram (short-axis view) from a patient with a large pericardial effusion associated with pulmonary tuberculosis. The exudate is seen between the visceral and parietal layers of the pericardium and would give a false impression of cardiomegaly on a chest X-ray. Note the multiple fibrous strands within the effusion, showing that it is consolidating and will probably lead to constriction of cardiac function. LA, left atrium; LV, left ventricle; PE, pericardial effusion; RA, right atrium; RV, right ventricle.

Treatment

An underlying cause should be sought and treated if possible. Most pericardial effusions resolve spontaneously. However, when the effusion collects rapidly, tamponade may result. Pericardiocentesis is then indicated to relieve the pressure – a drain may be left in temporarily to allow sufficient release of fluid. Pericardial effusions may reaccumulate, most commonly due to malignancy (in the UK). This may require pericardial fenestration, i.e. creation of a window in the pericardium to allow the slow release of fluid into the surrounding tissues. This procedure may either be performed transcutaneously under local anaesthetic or using a conventional surgical approach.

Constrictive pericarditis

Certain causes of pericarditis such as tuberculosis, haemopericardium, bacterial infection and rheumatic heart disease result in the pericardium becoming thick, fibrous and calcified. This may also develop late after open heart surgery, and fibrosis also occurs with the use of dopamine agonists, e.g. cabergoline, pergolide. In many cases these pericardial changes do not cause any symptoms. If, however, the pericardium becomes so inelastic as to interfere with diastolic filling of the heart, constrictive pericarditis is said to have developed. As these changes are chronic, allowing the body time to compensate, this condition is not as immediately life-threatening as cardiac tamponade, in which the circulation is more acutely embarrassed.

Constrictive pericarditis should be distinguished from restrictive cardiomyopathy (see p. 772). The two conditions are very similar in their presentation, but the former is fully treatable, whereas most cases of the latter are not. In the later stages of constrictive pericarditis, the subepicardial layers of myocardium may undergo fibrosis, atrophy and calcification.

Clinical features

The symptoms and signs of constrictive pericarditis occur due to:

- reduced ventricular filling (similar to cardiac tamponade, i.e. Kussmaul's sign, Friedreich's sign, pulsus paradoxus)
- systemic venous congestion (ascites, dependent oedema, hepatomegaly and raised JVP)
- pulmonary venous congestion (dyspnoea, cough, orthopnoea, PND) less commonly
- reduced cardiac output (fatigue, hypotension, reflex tachycardia)
- rapid ventricular filling ('pericardial knock' heard in early diastole at the lower left sternal border)
- atrial dilatation (30% of cases have atrial fibrillation).

Investigations

- **Chest X-ray** shows a relatively small heart in view of the symptoms of heart failure. Pericardial calcification may be present in up to 50%. A lateral chest film may be useful in detecting calcification that is missed on an AP film. However, a calcified pericardium is not necessarily a constricted one.
- **ECG** reveals low-voltage QRS complexes with generalized T wave flattening or inversion.
- **Echocardiography** shows thickened calcified pericardium, and small ventricular cavities with

normal wall thickness. Doppler studies may be useful.

- **CT and CMR** are used to assess pericardial anatomy and thickness (≥ 4 mm) (see Fig. 14.28).
- **Endomyocardial biopsy** may be helpful in distinguishing constrictive pericarditis from restrictive cardiomyopathy in difficult cases.
- **Cardiac catheterization.** End-diastolic pressures in the left and right ventricles measured during this procedure are usually equal, owing to pericardial constriction.

Restrictive cardiomyopathy is a close mimic of constrictive pericarditis and all the above tests may not help to distinguish the two conditions.

Treatment

The treatment for chronic constrictive pericarditis is complete resection of the pericardium. This is a risky procedure with a high complication rate due to the presence of myocardial atrophy in many cases at the time of surgery. Thus early pericardiectomy is suggested in non-tuberculous cases, before severe constriction and myocardial atrophy have developed.

In cases of tuberculous constriction, the presence of pericardial calcification implies chronic disease. Current evidence tends to favour early pericardiectomy with antituberculous drug cover in these cases. If there is no calcification, a course of antituberculous therapy should be attempted first. If the patient's haemodynamic state remains static or deteriorates after 4–6 weeks of therapy, pericardiectomy is recommended.

SYSTEMIC HYPERTENSION

Definitions of hypertension

Elevated arterial blood pressure is a major cause of premature vascular disease leading to cerebrovascular events, ischaemic heart disease and peripheral vascular disease. Blood pressure is a characteristic of each individual, like height and weight, with marked interindividual variation, and has a continuous (bell-shaped) distribution. The levels of blood pressure observed depend on the characteristics of the population studied – in particular, the age and ethnic background. Blood pressure in industrialized countries rises with age, certainly up to the seventh decade. This rise is more marked for systolic pressure and is more pronounced in men. Hypertension is very common in the developed world. Depending on the diagnostic criteria, hypertension is present in 20–30% of the adult population. Hypertension rates are much higher in black Africans (40–45% of adults). The definition of an abnormal blood pressure is indicated in Table 14.50.

The risk of mortality or morbidity rises progressively with increasing systolic and diastolic pressures, with each measure having an independent prognostic value; e.g. isolated systolic hypertension is associated with a two- to three-fold increase in cardiac mortality.

A *prehypertension* category has been added to reflect the continuum between normal and abnormal blood pressure.

All adults should have blood pressure measured routinely at least every 5 years until the age of 80 years. Seated blood pressure when measured after 5 minutes' resting with appropriate cuff size and arm supported is usually sufficient, but standing blood pressure should be measured in diabetic and elderly subjects to exclude orthostatic hypotension. The cuff

Table 14.50 Classification of blood pressure levels of the British Hypertension Society

Category	Systolic blood pressure (mmHg)	Diastolic blood pressure (mmHg)
Blood pressure		
Optimal	<120 and	<80
Normal	120–129 and/or	<80–84
High normal ^a	130–139 and/or	85–89
Hypertension		
Grade 1 (mild)	140–159 and/or	90–99
Grade 2 (moderate)	160–179 and/or	100–109
Grade 3 (severe)	≥ 180	≥ 110
Isolated systolic hypertension		
Grade 1	140–149	<90
Grade 2	>160	<90
The European Societies of Hypertension and Cardiology Guidelines 2007 are based on clinical blood pressure and not values for ambulatory blood pressure measurement. Threshold blood pressure levels for the diagnosis of hypertension using self/home monitoring are $>135/85$ mmHg. For ambulatory monitoring, 24-hour values are $>125/80$ mmHg. If systolic blood pressure and diastolic blood pressure fall into different categories, the higher value should be taken for classification.		
^a Equivalent to prehypertension.		

should be deflated at 2 mm/s and the blood pressure measured to the nearest 2 mmHg. Two consistent blood pressure measurements are needed to estimate blood pressure, and more are recommended if there is variation in the pressure. When assessing the cardiovascular risk, the average blood pressure at separate visits is more accurate than measurements taken at a single visit.

Causes

The majority (80–90%) of patients with hypertension have primary elevation of blood pressure, i.e. essential hypertension of unknown cause.

Essential hypertension

Essential hypertension has a multifactorial aetiology.

Genetic factors

Blood pressure tends to run in families and children of hypertensive parents tend to have higher blood pressure than age-matched children of parents with normal blood pressure. This familial concordance of blood pressure may be explained, at least in part, by shared environmental influences. However, there still remains a large, still largely unidentified genetic component.

Fetal factors

Low birth weight is associated with subsequent high blood pressure. This relationship may be due to fetal adaptation to intrauterine undernutrition with long-term changes in blood vessel structure or in the function of crucial hormonal systems.

Environmental factors

Among the several environmental factors that have been proposed, the following seem to be the most significant:

Obesity. Fat people have higher blood pressures than thin people. There is a risk, however, of overestimation if the blood pressure is measured with a small cuff. Adjust the bladder size to the arm circumference. Sleep disordered

Khandaker MH, Espinosa RE, Nishimura RA et al. Pericardial disease: diagnosis and management. *Mayo Clin Proc* 2010; 85(6):572–593.

breathing (see p. 818) often seen with obesity may be an additional risk factor.

Alcohol intake. Most studies have shown a close relationship between the consumption of alcohol and blood pressure level. However, subjects who consume small amounts of alcohol seem to have lower blood pressure level than those who consume no alcohol.

Sodium intake. A high sodium intake has been suggested to be a major determinant of blood pressure differences between and within populations around the world. Populations with higher sodium intakes have higher average blood pressures than those with lower sodium intake. Migration from a rural to an urban environment is associated with an increase in blood pressure that is in part related to the amount of salt in the diet. Studies of the restriction of salt intake have shown a beneficial effect on blood pressure in hypertensives. There is some evidence that a high potassium diet can protect against the effects of a high sodium intake.

Stress. While acute pain or stress can raise blood pressure, the relationship between chronic stress and blood pressure is uncertain.

Humoral mechanisms

The autonomic nervous system, as well as the renin-angiotensin, natriuretic peptide and kallikrein-kinin system, plays a role in the physiological regulation of short-term changes in blood pressure and has been implicated in the pathogenesis of essential hypertension. A low renin, salt-sensitive, essential hypertension in which patients have renal sodium and water retention has been described. However, there is no convincing evidence that the above systems are directly involved in the maintenance of hypertension.

Insulin resistance

An association between diabetes and hypertension has long been recognized and a syndrome has been described of hyperinsulinaemia, glucose intolerance, reduced levels of HDL cholesterol, hypertriglyceridaemia and central obesity (all of which are related to insulin resistance) in association with hypertension. This association (also called the 'metabolic syndrome', p. 218) is a major risk factor for cardiovascular disease.

Secondary hypertension

Secondary hypertension is where blood pressure elevation is the result of a specific and potentially treatable cause (Table 14.51).

Pathophysiology

The pathogenesis of essential hypertension remains unclear. In some young hypertensive patients, there is an early increase in cardiac output, in association with increased pulse rate and circulating catecholamines. This could result in changes in baroreceptor sensitivity, which would then operate at a higher blood pressure level.

In *established hypertension* there are:

- **Cardiac changes:**
 - **Resistance vessels** (the small arteries and arterioles) show structural changes in hypertension with an increase in wall thickness and a reduction in the vessel lumen diameter. It is an increased peripheral resistance that maintains the elevated blood pressure. The cardiac output is normal. There is also some evidence for rarefaction (decreased density) of these vessels. These mechanisms would result in an increased overall peripheral vascular resistance.

Table 14.51 Secondary causes of hypertension

Endocrine	Cardiovascular
Cushing's syndrome	Aortic coarctation
Acromegaly	Drugs
Thyroid disease	NSAIDs
Hyperparathyroid disease	Oral contraceptives
Adrenal	Steroids
Conn's syndrome	Carbenoxalone
Adrenal hyperplasia	Liquorice
Phaeochromocytoma	Sympathomimetics
Renal	Vasopressin
Diabetic nephropathy	Monoamine oxidase inhibitors (with tyramine)
Chronic glomerulonephritis	
Adult polycystic disease	
Chronic tubulointerstitial nephritis	
Renovascular disease	

- **Large vessel changes occur:** there is thickening of the media, an increase in collagen and the secondary deposition of calcium. These changes result in a loss of arterial compliance, which in turn leads to a more pronounced arterial pressure wave.
- **Pulse wave velocity** is a measure of arterial stiffness and is inversely related to distensibility. With each systolic contraction a pulse wave travels down the arterial wall before the flow of blood. Thus, the more rigid the arterial wall, the faster the wave travels. It can be measured but is not in routine use. Atheroma develops in the large arteries owing to the interaction of these mechanical stresses and low growth factors (see p. 725). Endothelial dysfunction with alternations in agents such as nitric oxide and endothelins appear to be involved.
- **Left ventricular hypertrophy**, which results from increased peripheral vascular resistance and increased left ventricular load, is a significant prognostic indicator of future cardiovascular events.
- **Renal changes:** eventually, changes in the renal vasculature lead to a reduced renal perfusion, reduced glomerular filtration rate and, finally, a reduction in sodium and water excretion. The decreased renal perfusion may lead to activation of the renin-angiotensin system (renin converts angiotensinogen to angiotensin I, which is in turn converted to angiotensin II by angiotensin-converting enzyme) with increased secretion of aldosterone and further sodium and water retention.
- **Cerebral changes** in small vessel cause lacunae (small infarcts) and reversible neurological deficits which do not show abnormalities on imaging. This may lead to dementia and stroke.

Complications

Cerebrovascular disease and coronary artery disease are the most common causes of death, although hypertensive patients are also prone to renal failure and peripheral vascular disease (Fig. 14.116).

Hypertensives have a six-fold increase in stroke (both haemorrhagic and atherothrombotic). There is a three-fold increase in cardiac death (due either to coronary events or to cardiac failure). Furthermore, peripheral arterial disease is twice as common.

Malignant hypertension

Malignant or accelerated hypertension occurs when blood pressure rises rapidly and is considered with severe

Figure 14.116 Target organ damage in hypertension.

Figure 14.117 Fundus showing hypertensive changes: Grade 4 retinopathy with papilloedema, haemorrhages and exudates.

hypertension (diastolic blood pressure >120 mmHg) (see p. 784). The characteristic histological change is fibrinoid necrosis of the vessel wall and, unless treated, it may lead to death from progressive renal failure, heart failure, aortic dissection or stroke. The changes in the renal circulation result in rapidly progressive renal failure, proteinuria and haematuria. There is also a high risk of cerebral oedema and haemorrhage with resultant hypertensive encephalopathy. In the retina there may be flame-shaped haemorrhages, cotton wool spots, hard exudates and papilloedema (Fig. 14.117). Without effective treatment there is a 1-year survival of $<20\%$.

Assessment

Management should be considered in three stages: assessment, non-pharmacological treatment and drug treatment. During the assessment period, secondary causes of hypertension should be excluded, target-organ damage from the blood pressure should be evaluated and any concomitant conditions (e.g. dyslipidaemia or diabetes) that may add to the cardiovascular burden should be identified.

History

The patient with mild hypertension is usually asymptomatic. Attacks of sweating, headaches and palpitations point towards the diagnosis of pheochromocytoma. Higher levels of blood pressure may be associated with headaches, epistaxis or nocturia. Breathlessness may be present owing to left ventricular hypertrophy or cardiac failure, while angina or symptoms of peripheral arterial vascular disease suggest the diagnosis of atheromatous renal artery stenosis. This is usually a local manifestation of more generalized atherosclerosis, and patients are often elderly with co-existent vascular disease (Fig. 14.118). Fibromuscular disease of the renal arteries encompasses a group of conditions in which fibrous or muscular proliferation results in morphologically simple or complex stenoses and tends to occur in younger patients (see Ch. 12). Malignant hypertension may present with severe headaches, visual disturbances, fits, transient loss of consciousness or symptoms of heart failure.

Examination

Elevated blood pressure is usually the only abnormal sign. Signs of an underlying cause should be sought, such as renal artery bruits in renovascular hypertension, or radiofemoral delay in coarctation of the aorta. The cardiac examination may also reveal features of left ventricular hypertrophy and a loud aortic second sound. If cardiac failure develops, there may be a sinus tachycardia and a third heart sound.

Figure 14.118 Digital subtraction angiography, showing typical unilateral atheromatous renal artery stenosis with post-stenotic dilatation (arrow).

Funduscopy is an essential part of the examination of any hypertensive patient (Fig. 14.117). The abnormalities are graded according to the Keith-Wagener classification:

- **Grade 1** – tortuosity of the retinal arteries with increased reflectiveness (silver wiring)
- **Grade 2** – grade 1 plus the appearance of arteriovenous nipping produced when thickened retinal arteries pass over the retinal veins
- **Grade 3** – grade 2 plus flame-shaped haemorrhages and soft ('cotton wool') exudates actually due to small infarcts
- **Grade 4** – grade 3 plus papilloedema (blurring of the margins of the optic disc)

Grades 3 and 4 are diagnostic of malignant hypertension.

Ambulatory blood pressure monitoring

Indirect automatic blood pressure measurements can be made over a 24-hour period using a measuring device worn by the patient. The clinical role of such devices remains uncertain, although they are used to confirm the diagnosis in those patients with 'white-coat' hypertension, i.e. blood pressure is completely normal at all stages except during a clinical consultation (Fig. 14.119a). These patients do not have any evidence of target-organ damage, and unnecessary treatment can be avoided. These devices may also be used to monitor the response of patients to drug treatment and, in particular, can be used to determine the adequacy of 24 hours control with once-daily medication (Fig. 14.119b,c).

Ambulatory blood pressure recordings seem to be better predictors of cardiovascular risk than clinic measurements. Analysis of the diurnal variation in blood pressure suggests that those hypertensives with loss of the usual nocturnal fall in blood pressure ('non-dippers') have a worse prognosis than those who retain this pattern.

Investigations

Routine investigation of the hypertensive patient should include:

- Urine stix test for protein and blood
- Fasting blood for lipids (total and HDL cholesterol) and glucose

Figure 14.119 24-Hour ambulatory blood pressure monitoring, showing: (a) white-coat hypertension; (b) pretreatment; (c) after 3 months' treatment.

- Serum urea, creatinine and electrolytes
- ECG.

If the urea or creatinine is elevated, more specific renal investigations are indicated – creatinine clearance, renal ultrasound (in case of polycystic kidney disease, or parenchymal renal artery disease) and a renal isotope scan or renal angiography if renovascular disease (either atheromatous or fibromuscular dysplasia) is suspected. A low serum potassium may indicate an endocrine disorder (either primary hyperaldosteronism or glucocorticoid excess), and aldosterone, cortisol and renin measurements must then be made, preferably prior to initiating pharmacological therapy. Clinical suspicion of pheochromocytoma should be investigated further with measurement of urinary metanephrines and plasma or urinary catecholamines.

If the ECG shows evidence of coronary artery disease the coronary vascular status should be assessed. If left ventricular hypertrophy or aortic coarctation is suspected *echocardiography* (or MRI) should be undertaken.

Treatment

Unless the patient has severe or malignant hypertension, there should be a period of assessment with repeated blood pressure measurements, combined with advice and non-pharmacological measures prior to the initiation of drug therapy (Table 14.52).

The British Hypertension Society provides guidance on when treatment should be commenced (Fig. 14.120).

Target blood pressure

- For most patients, a target of ~140 mmHg systolic blood pressure and ~85 mmHg diastolic blood pressure is recommended. For patients with diabetes, renal impairment or established cardiovascular disease a lower target of ~130/80 mmHg is recommended.
- When using ambulatory blood pressure readings, mean daytime pressures are preferred and this value would be expected to be approximately 10/5 mmHg lower than the clinic blood pressure equivalent for both thresholds and targets. Similar adjustments are recommended for averages of home blood pressure readings.

- The main determinant of outcome following treatment is the level of blood pressure reduction that is achieved rather than the specific drug used to lower blood pressure.
- Most hypertensive patients will require a combination of antihypertensive drugs to achieve the recommended targets.

Table 14.52 Lifestyle modification in borderline and hypertensive patients

Measure	Recommendations
Body weight	Maintain normal body weight (BMI 20–25 kg/m ²)
Aerobic exercise	Perform ≥30 min brisk walk most days of the week
Diet	Reduce intake of fat and saturated fat Reduce salt intake <100 mmol/day (<6 g NaCl or <2.4 g Na/day) Limit alcohol to ≤3 units/day men and ≤2 units/day women Consume ≥5 portions of fresh fruit and vegetables/day
Cardiovascular risk reduction	Avoid cigarette smoking and increase oily fish intake

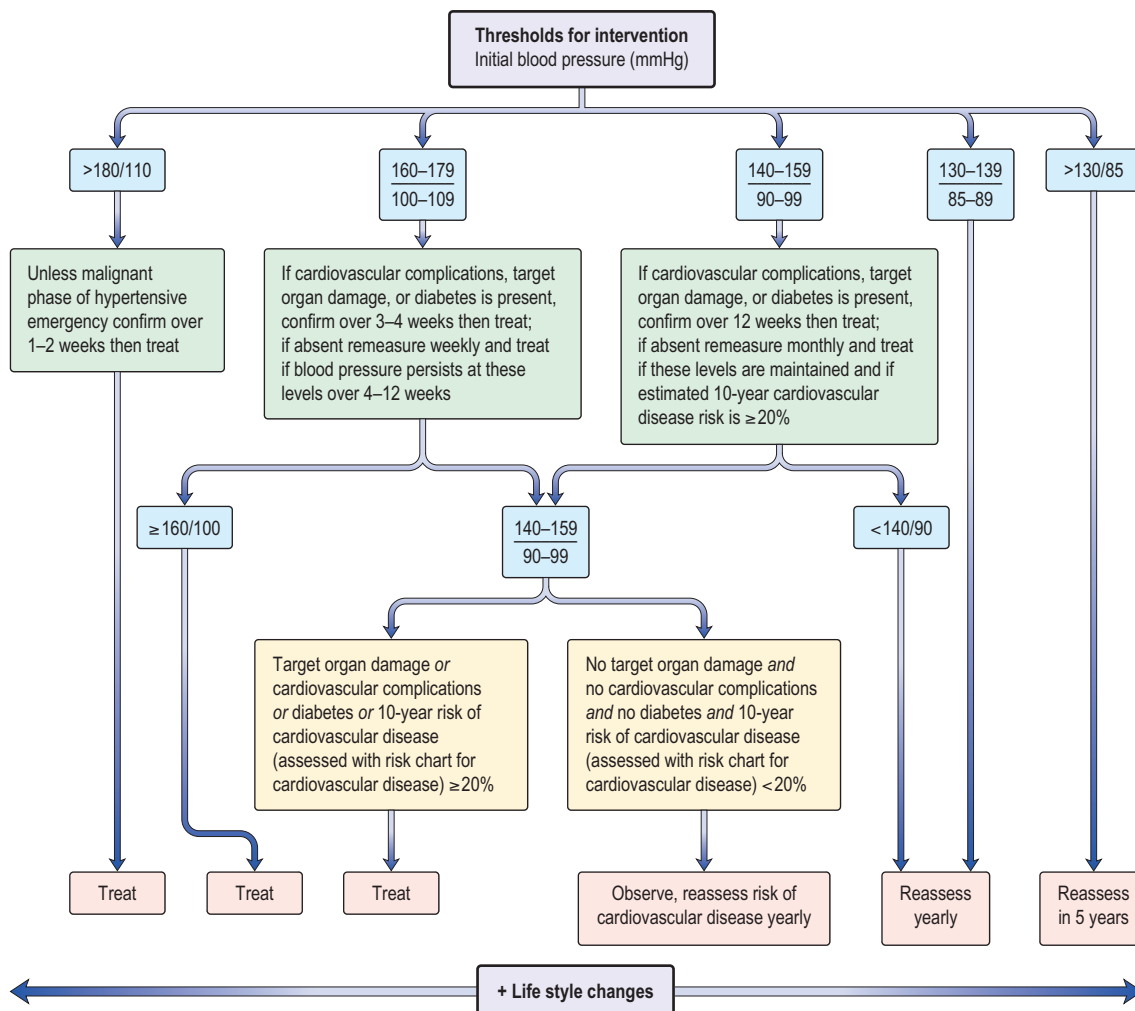

Figure 14.120 When to initiate treatment. (From Williams B, Poulter MR, Brown MJ et al. British Hypertension Society guidelines for hypertension management 2004 (BHS-IV): summary. British Medical Journal 2004; 328:634–640, with permission from the BMJ Publishing Group.)

- In most hypertensive patients therapy with statins and aspirin is added to reduce the overall cardiovascular risk burden. Glycaemic control should be optimized in diabetics ($\text{HbA}_{1c} < 7\%$).

The decision to commence specific drug therapy should usually be made only after a careful period of assessment with lifestyle changes, of up to 6 months, with repeated measurements of blood pressure (Fig. 14.120). The aim of drug treatment to reduce the risk of complications of hypertension should be carefully explained to the patient and a plan for the patient's treatment (drug dose titration, change of drug and combination of drugs) should be agreed with the patient. All of the drugs used to treat hypertension have side-effects and, since the benefits of drug treatment are not immediate, compliance may be a major problem.

Several classes of drugs are available to treat hypertension (Table 14.53). The norm are: (a) ACE inhibitors or angiotensin receptor antagonists; (b) beta-blockers; (c) calcium-channel blockers or (d) diuretics. It is recommended that drugs are chosen according to the scheme laid out in Figure 14.121.

The rationale for **Step 1** in this scheme is that young Caucasians are more likely to have high renin hypertension, and older patients and black patients usually have low renin hypertension. If a drug within each pair is not tolerated, the alternative drug type can be used (e.g. if an ACE inhibitor is not tolerated, an angiotensin receptor antagonist). If a drug is not effective, a drug from the other group should be

selected. Thus, if a calcium-channel blocker is not helpful, an ACE inhibitor/angiotensin receptor antagonist should be tried. Almost all patients will need more than one drug to effectively lower blood pressure.

Step 2 involves combining one drug from each group.

In **Step 3** an ACE inhibitor (or angiotensin receptor antagonist) is combined with a calcium-channel blocker and diuretic. If triple therapy is not sufficient to achieve target blood pressure readings, an alpha-blocker, beta-blocker or spironolactone, or another agent may be used. It is not advised to combine a diuretic with a beta-blocker since both aggravate diabetes.

Diuretics

Thiazide diuretics in low dosage are well-established agents which have been shown to reduce the risk of stroke in patients with hypertension. Chlortalidone is the drug of choice. However, they are ineffective in patients who have glomerular filtration rates below 30 mL/min. The majority of side-effects occur with higher doses but include increased serum cholesterol, impaired glucose tolerance, hyperuricaemia (which may precipitate gout) and hypokalaemia. Loop diuretics do have a hypotensive effect, but are not routinely used in the treatment of essential hypertension. Potassium-sparing diuretics are not effective agents when used alone, with the exception of spironolactone in the treatment of hypertension and hypokalaemia associated with primary hyperaldosteronism.

Beta-adrenoceptor blockers

Beta-blockers are no longer a preferred initial therapy for hypertension but they may be useful in younger people, particularly those with an intolerance or contraindication to ACE inhibitors and angiotensin-II receptor antagonists; women of child-bearing potential; or patients with evidence of increased sympathetic drive. If a second drug is required, add a calcium-channel blocker rather than a thiazide-type diuretic to reduce the patient's risk of developing diabetes. Beta-blockers exert their effects by attenuating the effects of the sympathetic nervous and the renin-angiotensin systems. Atenolol has been shown to reduce brachial arterial pressure but not aortic pressure, which is more significant in causing strokes and heart attacks. The major *side-effects* of this class of agents are bradycardia, bronchospasm, cold extremities, fatigue, bad dreams and hallucinations. These agents are especially useful in the treatment of patients with both hypertension and angina.

Angiotensin-converting enzyme (ACE) inhibitors

These drugs block the conversion of angiotensin I to angiotensin II, which is a potent vasoconstrictor. They also block the degradation of bradykinin, a potent vasodilator. There is evidence that black African patients respond less well to ACE inhibitors unless combined with diuretics. They are particularly useful in diabetics with nephropathy, where they have been shown to slow disease progression, and in those patients with symptomatic or asymptomatic left ventricular dysfunction, where they have been shown to improve survival.

Profound hypotension following the first dose is occasionally seen in sodium-depleted patients or in those on treatment with large doses of diuretics. Renal function should be monitored during therapy as deterioration may occur in patients with severe bilateral renovascular disease (in whom the production of angiotensin II is playing a major role in maintaining renal perfusion by causing efferent arteriolar constriction at the glomerulus). The most common side effect is a mild dry cough due to their effect on bradykinin.

Table 14.53 Pharmacological therapy in hypertension

Drug	Dose	Conditions favouring use	Cautions/contraindications
Alpha-blockers			
Doxazosin	1.0–16 mg daily	Benign prostatic hypertrophy	Postural hypotension, urinary incontinence
Indoramin	25–100 mg ×2 daily	Phaeochromocytoma crisis	Profound hypotension
Phenoxybenzamine	1 mg/kg i.v. over >2 h		
Phentolamine	2.0–5.0 mg i.v.		
Aldosterone antagonists			
Spironolactone	50–400 mg daily	Primary hyperaldosteronism, heart failure	Hyperkalaemia
Eplerenone	50–100 mg daily		
Angiotensin-converting enzyme inhibitors			
Enalapril	5.0–40 mg daily	<55 years old, Caucasian, heart failure or left ventricular dysfunction, myocardial infarction or cardiovascular disease, diabetic nephropathy, chronic renal disease, stroke secondary prevention	Renal failure (monitor electrolytes), peripheral vascular disease (if renovascular disease), pregnancy
Lisinopril	2.5–40 mg daily		
Perindopril	2.0–8.0 mg daily		
Ramipril	1.25–10 mg daily		
Angiotensin II receptor blockers			
Losartan	50–100 mg daily	ACE inhibitor intolerant, <55 years old, Caucasian, hypertension with LVH, heart failure or left ventricular dysfunction, myocardial infarction, diabetic nephropathy, chronic renal disease	Renal failure (monitor electrolytes), peripheral vascular disease (if renovascular disease), pregnancy
Candesartan	2.0–32 mg daily		
Valsartan	40–320 mg daily		
Olmesartan	10–40 mg daily		
Telmisartan	40 mg daily		
Beta-blockers			
Atenolol	25–100 mg daily	Coronary heart disease (post myocardial infarction or angina), heart failure (bisoprolol and carvedilol)	Diabetes, peripheral vascular disease, asthma/COPD, heart block, unstable heart failure
Bisoprolol	1.25–20 mg daily		
Carvedilol	12.5–50 mg daily		
Labetalol	100–200 mg ×2 daily (max. 2.4 g/day)	Hypertension in pregnancy	
Calcium channel blockers			
Amlodipine	5.0–10 mg daily	>55 years, black patients, angina	Bradycardia, heart block, heart failure, beta-blockers (verapamil)
Nifedipine (long acting)	20–90 mg daily		
Diltiazem (long acting)	90–180 mg ×2 daily		
Verapamil	120–240 mg ×2 daily		
Centrally acting			
Methyldopa	250 mg–1 g ×3 daily	Hypertension in pregnancy, breastfeeding	Monitor blood counts and liver function tests
Moxonidine	200–600 µg daily	Resistant hypertension, insulin resistance	Renal or heart failure, glaucoma, angioedema, bradycardia
Diuretics			
Bendroflumethiazide	2.5 mg daily	>55 years, black patients, heart failure, stroke secondary prevention	Gout, diabetes, hypokalaemia
Chlortalidone	25 mg daily		
Furosemide	40–80 mg daily	Heart failure, renal dysfunction	Hypokalaemia
Renin inhibitors			
Aliskiren	150–300 mg daily	Resistant hypertension	Renal failure, pregnancy
Vasodilators			
Hydralazine	25–50 mg ×2 daily	Black patients, heart failure (when combined with nitrates)	SLE
Minoxidil	5.0–50 mg daily	Severe hypertension (with a diuretic and beta-blocker)	Pregnancy
Sodium nitroprusside	0.3–5 µg/kg per min i.v.	Hypertensive crisis	Needs intra-arterial BP monitoring, avoid prolonged use

Angiotensin II receptor antagonists

This group of agents selectively block the receptors for angiotensin II. They share many of the actions of ACE inhibitors but, since they do not have any effect on bradykinin, do not cause a cough. They are used for patients who cannot tolerate ACE inhibitors because of persistent cough.

Angioneurotic oedema and renal dysfunction are encountered less with these drugs than with ACE inhibitors.

Calcium-channel blockers

These agents effectively reduce blood pressure by causing arteriolar dilatation, and some also reduce the force of

cardiac contraction. Like the beta-blockers, they are especially useful in patients with concomitant ischaemic heart disease. The major side-effects are particularly seen with the short-acting agents and include headache, sweating, swelling of the ankles, palpitations and flushing.

Alpha-blockers

These agents cause postsynaptic α_1 -receptor blockade with resulting vasodilatation and blood pressure reduction. Earlier short-acting agents caused serious first-dose hypotension, but the newer longer-acting agents are far better tolerated.

Renin inhibitors

Aliskerin is the first orally active renin inhibitor which directly inhibits plasma renin activity: it reduces the negative feedback by which angiotensin II inhibits renin release. It has been used in combination with ACE inhibitors and angiotensin receptor blockers with a significant reduction in blood pressure. However, a recent FDA warning suggests avoiding these drugs with aliskerin. Side-effects are few but hypokalaemia occurs.

Other vasodilators

Vasodilators are reserved for patients resistant to other forms of treatment. Hydralazine can be associated with tachycardia, fluid retention and a systemic lupus erythematosus-like syndrome. Minoxidil can cause severe oedema, excessive hair growth and coarse facial features.

Centrally acting drugs

Methyldopa acts on central α_2 -receptors, usually without slowing the heart and is usually reserved for patients with hypertension in pregnancy.

Management of severe or malignant hypertension

Patients with severe hypertension (diastolic pressure >140 mmHg), malignant hypertension (grades 3 or 4 retinopathy), hypertensive encephalopathy or with severe hypertensive complications, such as cardiac failure, should be admitted to hospital for immediate initiation of treatment. However, it is unwise to reduce the blood pressure too rapidly, since this may lead to cerebral, renal, retinal or myocardial infarction, and the blood pressure response to therapy must be carefully monitored, preferably in a high-dependency unit. In most cases, the aim is to reduce the diastolic blood pressure to 100–110 mmHg over 24–48 hours. This is usually achieved with oral medication, e.g. amlodipine. The blood pressure can then be normalized over the next 2–3 days.

When rapid control of blood pressure is required (e.g. in an aortic dissection), the agent of choice is intravenous sodium nitroprusside. Alternatively, an infusion of labetalol can be used. The infusion dosage must be titrated against the blood pressure response.

Management of hypertension in pregnancy

There are three types of hypertension seen in pregnant women:

1. Chronic or pre-existing hypertension
2. Gestational hypertension
3. Pre-eclampsia and eclampsia.

During the normal pregnancy there is a reduction in blood pressure due to a reduction in systemic vascular resistance which is maximal by weeks 22–24. Patients with pre-existing hypertension should discontinue ACE inhibitors and ARBs which are associated with abnormalities of the developing fetal renal system. The first-line therapy during pregnancy is methyldopa which has no adverse effects on the fetus although

sedating side-effects may limit up-titration. Second-line agents include nifedipine and labetalol. The target blood pressure should be <150/100 mmHg.

Gestational hypertension is a blood pressure of >140/90 mmHg in the 2nd trimester in a previously normotensive woman. These patients should have twice-weekly BP measurements and urine tested for protein as there is an increased risk of developing pre-eclampsia. Patients with moderate hypertension (159–150/109–100 mmHg) should commence oral labetalol and have blood tests performed (electrolytes, blood count, liver function tests) and those with severe hypertension ($\geq 160/110$ mmHg) should be admitted to hospital.

Pre-eclampsia is a multi-system disorder that occurs after 20 weeks' gestation consisting of:

- Hypertension
- Oedema
- Proteinuria (>0.3 g/24 hours).

These patients should be admitted and treated for hypertension with regular BP measurements (4 times daily) and blood tests 2–3/week. Patients require close fetal monitoring due to the risks of placental insufficiency and intrauterine growth retardation. Patients who progress to eclampsia (convulsions) and/or HELLP (haemolysis, elevated liver enzymes, low platelet count) syndrome should be admitted to a critical care unit and may require intravenous hydralazine, labetalol, and magnesium sulphate (for convulsions) and prompt delivery.

Prognosis

The prognosis from hypertension depends on a number of features:

- Level of blood pressure
- Presence of target-organ changes (retinal, renal, cardiac or vascular)
- Co-existing risk factors for cardiovascular disease, such as hyperlipidaemia, diabetes, smoking, obesity, male sex
- Age at presentation.

Several studies have confirmed that the treatment of hypertension, even mild hypertension, will reduce the risk not only of stroke but of coronary artery disease as well.

PERIPHERAL VASCULAR DISEASE**Peripheral arterial disease**

Peripheral vascular disease (PVD) is commonly caused by atherosclerosis and usually affects the aorto-iliac or infringuinal arteries. It is present in 7% of middle-aged men and 4.5% of middle-aged women, but these patients are more likely to die of myocardial infarction or stroke than lose their leg.

Limb ischaemia may be classified as chronic or acute.

Chronic lower limb ischaemia**Symptoms**

Peripheral arterial disease can be described using the Fontaine classification:

- Stage I – asymptomatic
- Stage II – intermittent claudication
- Stage III – rest pain/nocturnal pain
- Stage IV – necrosis/gangrene.

Patients with *intermittent claudication* complain of exertional discomfort most commonly in the calf which is relieved by rest. Patients with aorto-iliac disease may experience pain in the buttock, hip or thigh and may notice erectile dysfunction. The 'claudication-distance' may be reproducible.

Patients with *rest pain* experience severe unremitting pain in the foot, which stops a patient from sleeping. It is partially relieved by dangling the foot over the edge of the bed or standing on a cold floor.

Patients with severe PVD or critical lower limb ischaemia may have ulceration or *necrosis* of the tissue (*gangrene*).

Signs

The lower limbs are cold with dry skin and lack of hair. Pulses may be diminished or absent. Ulceration may occur in association with dark discoloration of the toes or gangrene. The abdomen should be examined for a possible aneurysm.

Risk factors

Common risk factors are:

- Smoking
- Diabetes
- Hypercholesterolaemia
- Hypertension.

Premature atherosclerosis in patients aged <45 years may be associated with thrombophilia and hyperhomocysteinaemia.

Differential diagnosis

Symptoms may be confused with those of:

- Spinal canal claudication (but all pulses are present)
- Osteoarthritis hip/knee (knee pain often at rest)
- Peripheral neuropathy (associated with numbness and tingling)
- Popliteal artery entrapment (young patients who may have normal pulses)
- Venous claudication (bursting pain on walking with a previous history of a DVT)
- Fibromuscular dysplasia
- Buerger's disease (young males, heavy smokers).

Investigations

An estimation of the anatomical level of disease may be possible with the examination of pulses. The severity of disease is indicated by *ankle/brachial pressure index* (ABPI). This is a measurement of the cuff pressure at which blood flow is detectable by Doppler in the posterior tibial or anterior tibial arteries compared to the brachial artery (ankle/brachial pressure). Intermittent claudication is associated with an ABPI of 0.5–0.9. Values of <0.5 are associated with critical limb ischaemia. The sensitivity of the test may be improved by a fall in ABPI after exercise. If the arteries are heavily calcified and incompressible, i.e. in renal or diabetic disease, the ABPI will be falsely elevated. In these patients toe pressure values are more sensitive. Diagnostic imaging includes:

- Digital subtraction angiography (DSA) – provides an arterial map (Fig. 14.122) but requires peripheral arterial cannulation and exposes the patient to iodinated contrast and should be reserved for patients immediately prior to intervention.
- Duplex ultrasound using B-mode ultrasound and colour Doppler can provide an accurate anatomical map of the lower limbs with sensitivity of 87% and specificity of

Figure 14.122 Angiogram showing occlusion of the right external iliac artery. CI, common iliac; II, internal iliac; EI, external iliac.

94% compared to angiography although it is operator dependent.

- 3D-contrast enhanced magnetic resonance angiography provides excellent imaging of both legs with a single contrast injection without exposure to ionizing radiation. Sensitivity of 97% and specificity of 96% are reported.
- Computed tomography angiography is an effective alternative to MRA although extensive calcification may obscure stenoses. CTA requires ionizing radiation and iodinated contrast media.

Management

Medical

All patients with peripheral vascular disease need aggressive risk factor management. Patients are encouraged to stop smoking and need smoking cessation advice. Patients with diabetes mellitus need regular chiropody care and diabetic management. Hypercholesterolaemia should be treated as this reduces disease progression. It has been shown by the Heart Protection Study that even the reduction of a normal cholesterol level reduces mortality from cardiovascular disease. Patients with peripheral arterial disease and a total cholesterol above 3.5 mmol/L should be treated with statin therapy. Low-dose aspirin reduces the risk of myocardial infarction and stroke in patients with peripheral vascular disease. Patients should be encouraged to exercise and to avoid obesity.

Pharmacological

- **Cilostazol** is a phosphodiesterase III inhibitor that increases levels of cyclic AMP and produces vasodilation and reversibly inhibits platelet aggregation. At a dose of 100 mg twice daily it can increase walking distance in patients with short-distance claudication.
- **Naftidrofuryl** is a vasodilator agent than inhibits vascular and platelet 5-HT₂ receptors can reduce lactic acid levels. At a dose of 1–200 mg three times a day it may increase walking distance and improve quality of life.

- **Oxpentifylline, inositol nicotinate, and cinnarizine** are not currently recommended for patients with claudication.

Surgical/radiological

Vascular intervention for stable claudication is not generally recommended except in patients with severe or disabling symptoms. *Percutaneous transluminal angioplasty* is the first option and is carried out via a catheter inserted into the femoral artery. The long-term patency rates decrease as the angioplasty becomes more distal. The long-term results of angioplasty appear to be similar to those of a continued exercise programme. Arterial stents may be deployed in recurrent iliac disease, and drug-eluting stents allowing long-term patency are being used, e.g. paclitaxel. *Bypass procedures* may be performed using Dacron, polytetrafluoroethylene (PTFE) or autologous veins. Bypasses to distal vessels have poorer long-term patencies. Prosthetic grafts have equal patencies in above-knee bypasses but are inferior to veins below the knee. In severe ischaemia with unreconstructable arterial disease an *amputation* may be necessary. An amputation may lead to loss of independence, with only 70% of below-knee and 30% of above-knee amputees achieving full mobility.

Acute lower limb ischaemia

Symptoms

Patients complain of the five Ps. They complain of: *pain*, that the leg looks white (*pallor*), *paraesthesia*, *paralysis* and that it feels *perishingly* cold. The pain is unbearable and normally requires opioids for relief.

Signs

The limb is cold with mottling or marbling of the skin. Pulses are diminished or absent. The sensation and movement of the leg are reduced in severe ischaemia. Patients may develop a compartment syndrome with pain in the calf on compression.

Causes

Acute limb ischaemia (ALI) may occur because of embolic or thrombotic disease. **Embolic disease** is commonly due to cardiac thrombus and cardiac arrhythmias. Rheumatic fever is now an uncommon cause and the frequency of cardiac embolic ALI is also on the decline. Emboli may also occur secondary to aneurysm thrombus or thrombus on atherosclerotic plaques. Emboli from atrial myxomas are rare.

Acute limb ischaemia is now often due to **thrombotic disease**. Acute thrombus usually forms on a chronic atherosclerotic stenosis in a patient who has previously reported symptoms of claudication. Thrombus may also form in normal vessels in patients who are hypercoagulable because of malignancy or thrombophilia defects. Prosthetic or venous grafts may also thrombose either de novo or secondary to a developing stenosis either in the graft or in the native vessels. Popliteal aneurysms may thrombose or embolize distally. **Acute upper limb ischaemia** may be caused by similar processes or occur secondary to external compression with a cervical rib/band.

Investigation and management

Investigations are similar to those described for chronic lower limb disease.

Medical

Management is dependent on the degree of ischaemia. Patients showing improvement may be treatable with heparin

and appropriate treatment of the underlying cause. Patients with emboli following myocardial infarction or atrial fibrillation need long-term warfarin.

Surgical/radiological

Patients with mild to moderate ischaemic symptoms who have occluded a graft may need graft thrombolysis. Intra-arterial thrombolysis may reveal an underlying stenosis within a graft or native vessel that could be treated with angioplasty. Patients with an embolus may benefit from its surgical removal (embolectomy). A bypass graft may be required after occlusion of a popliteal aneurysm or acute-on-chronic lower limb arterial disease. When an ischaemic limb is revascularized, the sudden improvement in blood flow can cause reperfusion injury with release of toxic metabolites into the circulation. In muscle compartments the consequent oedema may lead to a 'compartment syndrome', which requires fasciotomies (release of the fascia to prevent muscle damage). An amputation may be warranted in unreconstructable or severe ischaemia. In patients dying from other causes, acute limb ischaemia may occur and intervention may then be inappropriate.

Aneurysmal disease

Aneurysms are classified as true and false. An aneurysm is defined if there is a permanent dilatation of the artery to twice the normal diameter. In true aneurysms the arterial wall forms the wall of the aneurysm. The arteries most frequently involved are the abdominal aorta, iliac, popliteal, femoral artery and thoracic aorta (in decreasing frequency). In false aneurysms (pseudoaneurysms) the surrounding tissues form the wall of the aneurysm. False aneurysms can occur following femoral artery puncture. A haematoma is formed because of inadequate compression of the entry site and continued bleeding into the surrounding compressed soft tissue forms the wall of this aneurysm.

Abdominal aortic aneurysm

Abdominal aortic aneurysms (AAA) occur most commonly below the renal arteries (infrarenal). The incidence increases with age, being present in 5% of the population >60 years. They occur five times more frequently in men and in one in four male children of an affected individual. Aneurysms may occur secondary to atherosclerosis, infection (syphilis, *Escherichia coli*, *Salmonella*) and trauma, or may be genetic (Marfan's syndrome, Ehlers-Danlos syndrome).

Symptoms

Most aneurysms are asymptomatic and are found on routine abdominal examination, plain X-ray or during urological investigations. Rapid expansion or rupture of an AAA may cause *severe pain* (epigastric pain radiating to the back). A ruptured AAA causes *hypotension*, *tachycardia*, *profound anaemia* and *sudden death*. The symptoms of rupture may mimic renal colic, diverticulitis and severe lower abdominal or testicular pain. Gradual erosion of the vertebral bodies may cause nonspecific back pain. The aneurysm may embolize distally. Inflammatory aneurysms can obstruct adjacent structures, e.g. ureter, duodenum and vena cava. Rarely patients with aneurysms can present with severe haematemesis secondary to an aortoduodenal fistula.

Signs

The aorta is retroperitoneal and in overweight patients there may be no overt signs. An aneurysm is suspected if a

pulsatile, expansile abdominal mass is felt. The presence of an AAA should alert a clinician to the possibility of popliteal aneurysms. Patients may present with 'trash feet', dusky discoloration of the digits secondary to emboli from the aortic thrombus.

Investigations

The UK NHS has introduced a screening programme for AAA using ultrasound for all men in their 65th year (<http://aaa.screening.nhs.uk/public>), although scanning at men and women at an earlier age may be appropriate in first-degree relatives of an affected individual. Patients diagnosed with an AAA may require further assessment with MRI or CT to assess the anatomical relationship to the renal and visceral vessels and for patients referred for intervention.

Management

Like any operation, the management of an asymptomatic aneurysm depends on the balance of operative risk and conservative management. The UK Small Aneurysm Trial showed that patients with infrarenal AAA did best with an operation if the aneurysm was:

- ≥ 5.5 cm diameter
- expanding >1 cm/year
- symptomatic.

Medical

Patients with aneurysmal disease need careful control of hypertension, to stop smoking and to have lipid-lowering medication. Patients with AAA <5.5 cm are followed up by regular ultrasound surveillance.

Repair of abdominal aortic aneurysm

Standard therapy is open surgical repair with insertion of a Dacron or Gore-Tex graft.

Endovascular stent

Endovascular stent insertion (via the femoral or iliac arteries) is a non-surgical approach to AAA repair. The endovascular Aneurysm Repair studies EVAR (stent vs open surgical repair) and EVAR 2 (stent vs medical therapy in patients unsuitable for open repair) investigated the role of endovascular stents in patients with AAA ≥ 5.5 cm on CT. In EVAR the 30-day mortality rate was 1.7% with stenting versus 4.7% with surgery ($p=0.009$) but the long-term mortality rate was similar in both groups at 4 years. In EVAR 2 the 30-day mortality rate with stenting was 9%. Long-term mortality rate was similar in both stent and medical therapy groups. A meta-analysis of three randomized control trials demonstrated a 30-day mortality rate of 2% for stent-graft repair versus 5% for open surgical repair; with reductions in ITU and in-hospital stay with stent-graft repair.

Laparoscopic surgery

An alternative to open-surgical repair or endovascular stenting is laparoscopic repair that is performed with hand-assisted laparoscopic surgery (HALS, requiring a midline mini-laparotomy) or by total laparoscopic surgery (TLS). In non-randomized controlled trials both methods were associated with reduced length of stay, although the operating times were longer.

Prognosis

After repair, patients with an AAA should return to normal activity within a few months.

Thoraco-abdominal aneurysm (TAA)

The ascending, arch or descending thoracic aorta may become aneurysmal. Ascending TAAs occur most commonly in patients with Marfan's syndrome or hypertension. Descending or arch TAAs occur secondary to atherosclerosis and are now rarely due to syphilis.

Symptoms

Most aneurysms are asymptomatic and are found on routine chest X-ray or cardiological investigation. Rapid expansion may cause severe pain (chest pain radiating to the upper back) and rupture is associated with hypotension, tachycardia and death. Chest symptoms from expansion may include stridor (compressed bronchial tree), haemoptysis (aortobronchial fistula) and hoarseness (compression of the recurrent laryngeal nerve). Aorto-oesophageal fistula uncommonly causes haematemesis.

Investigations

- **CT or MRI scans** are used for assessment of a TAA.
- **Aortography** may be used to assess the position of the key branches in relation to the aneurysm.
- **Transoesophageal echocardiography** can be helpful by identifying an aortic dissection.

Management

If the aneurysm is >6 cm then operative repair or stenting may be appropriate, but these can be technically difficult and carry a high risk of mortality and paraplegia. EVAR is at present the procedure of choice for isolated descending thoracic aneurysms.

Acute aortic syndromes

Acute aortic syndromes include aortic dissection, intramural haematoma (IMH) and penetrating aortic ulcers. Aortic dissection usually begins with a tear in the intima. Blood penetrates the diseased medial layer and then cleaves the intimal lamina leading to dissection. IMH is considered a precursor of dissection in which there is rupture of the vasa vasorum in the aortic media with aortic wall infarction. IMH is typically in the descending thoracic aorta. Deep penetrating aortic plaques may lead to IMH, dissection or ulceration/perforation. Aortic dissection is predisposed in patients with autoimmune rheumatic disorders and Marfan's and Ehlers-Danlos syndromes.

Aortic dissection can be classified according to the timing of diagnosis from the origin of symptoms: acute <2 weeks, subacute 2–8 weeks, chronic >8 weeks with mortality and extension decreasing with time. They can also be classified anatomically:

- **Type A:** involving the aortic arch and aortic valve proximal to the left subclavian artery origin. Includes De Bakey type I (extends to the abdominal aorta) and De Bakey type II (localized to ascending aorta)
- **Type B:** involving the descending thoracic aorta distal to the left subclavian artery origin. De Bakey type III (Fig. 14.123).

Symptoms

Most patients present with a sudden onset of severe and central *chest pain* often that radiates to the back and down the arms, mimicking myocardial infarction. The pain is often described as tearing in nature and may be migratory.

Figure 14.123 Classification of aortic aneurysms (a–e).

Signs

Patients may be shocked and may have neurological symptoms secondary to loss of blood supply to the spinal cord. They may develop aortic regurgitation, coronary ischaemia, and cardiac tamponade. Distal extension may produce acute kidney failure, acute lower limb ischaemia or visceral ischaemia. Peripheral pulses may be absent.

Investigations

The mediastinum may be widened on *chest X-ray*, but urgent *CT scan* or *transoesophageal echocardiography* or *MRI* will confirm the diagnosis (Fig. 14.95).

Management

At least 50% of patients are hypertensive and they may require urgent antihypertensive medication to reduce blood pressure to under 120 mmHg with intravenous beta-blockers (labetalol, metoprolol) and vasodilators (GTN). Type A dissections should undergo surgery (arch replacement) if fit enough, as medical management carries a high mortality (50% within 2 weeks). Type B dissections carry a better prognosis with survival of 89% at 1 month and should be initially be managed medically unless they develop complications. Endovascular intervention with stents may be indicated in patients with rapidly expanding dissections (>1 cm/year), critical diameter (>5.5 cm), refractory pain or malperfusion syndrome, blunt chest trauma, penetrating aortic ulcers or IMH. Patients will require long-term follow-up with CT or MRI.

Raynaud's phenomenon or Raynaud's disease

Raynaud's phenomenon consists of spasm of the digital arteries, usually precipitated by cold and relieved by heat. If there is no underlying cause, it is known as Raynaud's disease. This affects 5% of the population, mostly women. The disorder is usually bilateral with fingers affected more commonly than toes.

Symptoms

Vasoconstriction causes *skin pallor* followed by *cyanosis* due to sluggish blood flow, then redness secondary to hyperaemia. The duration of the attacks is variable but they can sometimes last for hours. Numbness, a burning sensation and severe pain occur as the fingers warm up. In chronic, severe disease tissue *infarction* and *digital loss* can occur.

Diagnosis

Primary Raynaud's disease needs to be differentiated from secondary treatable causes leading to Raynaud's phenomenon. These are the rheumatic autoimmune disorders such as systemic sclerosis. It can be associated with atherosclerosis or occupations that involve the use of vibrating tools. Ergot-containing drugs and beta-blockers, and smoking can aggravate symptoms.

Management

Patients should avoid cold provocation by wearing gloves and warm clothes, and stop smoking. Vasodilators can be prescribed but are often unacceptable as cerebral

vasodilatation causes severe headaches. Sympathectomy or prostacyclin infusion can be helpful in severe disease.

Takayasu's disease

This is rare, except in Japan. It is known as the pulseless disease or aortic arch syndrome. It is of unknown aetiology and occurs in females. There is a vasculitis involving the aortic arch as well as other major arteries. There is also a systemic illness, with pain and tenderness over the affected arteries. Absent peripheral pulses and hypertension are common. Corticosteroids help the constitutional symptoms. Eventually heart failure and strokes may occur but most patients survive for at least 5 years. Treatment may require a surgical bypass to improve perfusion of the affected areas.

Thromboangiitis obliterans (Buerger's disease)

This disease, involving the small vessels of the lower limbs, occurs in young men who smoke. It is thought by some workers to be indistinguishable from atheromatous disease. However, pathologically there is inflammation of the arteries and sometimes veins that may indicate a separate disease entity. Clinically, it presents with severe claudication and rest pain leading to gangrene. A thrombophlebitis is sometimes present. Treatment is as for all peripheral vascular disease, but patients must stop smoking.

Cardiovascular syphilis

This gives rise to:

- Uncomplicated aortitis
- Aortic aneurysms, usually in the ascending part
- Aortic valvulitis with regurgitation
- Stenosis of the coronary ostia.

The diagnosis is confirmed by serology. Treatment is with penicillin. Aneurysms and valvular disease are treated as necessary by the usual methods.

Peripheral venous disease

Varicose veins

Varicose veins are a common problem, sometimes giving rise to pain. They are treated by injection or surgery.

Venous thrombosis

Thrombosis can occur in any vein, but the veins of the leg and the pelvis are the most common sites.

Superficial thrombophlebitis

This commonly involves the saphenous veins and is often associated with varicosities. Occasionally the axillary vein is involved, usually as a result of trauma. There is local superficial inflammation of the vein wall, with secondary thrombosis.

The clinical picture is of a painful, tender, cord-like structure with associated redness and swelling.

The condition usually responds to symptomatic treatment with rest, elevation of the limb and analgesics (e.g. non-steroidal anti-inflammatory drugs). The Comparison of Arixtra in Lower Limb Superficial Vein Thrombosis with Placebo (CALISTO) trial demonstrated that a 45-day course of subcutaneous fondaparinux 2.5 mg o.d. compared with placebo significantly reduced the rate of thromboembolic events (pulmonary embolism and deep vein thrombosis) from 1.3% to

0.2% and limited the extension of superficial vein thrombosis to the saphenofemoral junction from 3.4% to 0.3% with no increased risk of bleeding.

Deep vein thrombosis

A thrombus forms in the vein, and any inflammation of the vein wall is secondary to this.

Thrombosis commonly occurs after periods of immobilization, but it can occur in normal individuals for no obvious reasons. The precipitating factors are discussed on page 728.

A deep vein thrombosis in the legs occurs in 50% of patients after prostatectomy (without prophylactic heparin) or following a cerebral vascular event. In addition, 10% of patients with a myocardial infarct have a clinically detected deep vein thrombosis.

Thrombosis can occur in any vein of the leg or pelvis, but is particularly found in veins of the calf. It is often undetected; autopsy figures give an incidence of over 60% in hospitalized patients. Axillary vein thrombosis occasionally occurs, sometimes related to trauma, but usually for no obvious reason.

Clinical features

The individual may be asymptomatic, presenting with clinical features of pulmonary embolism (see p. 764).

A major presenting feature is *pain* in the calf, often with swelling, redness and *engorged superficial veins*. The affected calf is often warmer and there may be ankle oedema. *Homan's sign* (pain in the calf on dorsiflexion of the foot) is often present, but is not diagnostic and occurs with all lesions of the calf.

Thrombosis in the iliofemoral region can present with severe pain, but there are often few physical signs apart from occasional swelling of the thigh and/or ankle oedema.

Complete occlusion, particularly of a large vein, can lead to a *cyanotic discoloration* of the limb and severe oedema, which can very rarely lead to venous gangrene.

Pulmonary embolism can occur with any deep vein thrombosis but is more frequent from an iliofemoral thrombosis and is rare with thrombosis confined to veins below the knee. In 20–30% of patients, spread of thrombosis can occur proximally without clinical evidence, so careful monitoring of the leg, usually by ultrasound, is required.

Investigations

Clinical diagnosis is unreliable but combined with D-dimer level it has a sensitivity of 80%. Confirmation of an iliofemoral thrombosis can usually be made with *B mode venous compression, ultrasonography or Doppler ultrasound* with a sensitivity and specificity over 90%.

Below-knee thromboses can be detected reliably only by *venography* with non-invasive techniques, ultrasound, fibrinogen scanning and impedance plethysmography, having a sensitivity of only 70%. A venogram is performed by injecting a vein in the foot with contrast, which will detect virtually all thrombi that are present.

Treatment

The main aim of therapy is to prevent pulmonary embolism, and all patients with thrombi above the knee must be anticoagulated. Anticoagulation of below-knee thrombi is now recommended for 6 weeks, as 30% of patients will have an extension of the clot proximally. Bed rest is advised until the patient is fully anticoagulated. The patient should then be mobilized, with an elastic stocking giving graduated pressure over the leg.

Low-molecular-weight heparins (LMWH) (see p. 427) have replaced unfractionated heparin as they are more

effective, they do not require monitoring and there is less risk of bleeding. DVTs are being treated at home with low-molecular-weight heparin. Warfarin is started immediately and the heparin stopped when the INR is in the target range. The duration of warfarin treatment is debatable – 3 months is the period usually recommended, but 4 weeks is long enough if a definite risk factor (e.g. bed rest) has been present. Recurrent DVTs need permanent anticoagulants. The target INR should be 2.5. Anticoagulants do not lyse the thrombus that is already present. Unfractionated heparin should only be used if LMWH is unavailable.

Thrombolytic therapy (see p. 426) is occasionally used for patients with a large iliofemoral thrombosis.

Prognosis

Destruction of the deep vein valves produces a clinically painful, swollen limb that is made worse by standing and is accompanied by oedema and sometimes venous eczema. It occurs in approximately half of the patients with clinically symptomatic deep vein thrombosis, and it means that elastic support stockings are then required for life.

Prevention

An estimated 25 000 people in the UK die every year from a preventable hospital-acquired venous thromboembolism (VTE). In January 2010 the National Institute for Health and Clinical Excellence provided guidelines on the assessment and prevention of VTE in patients admitted to hospital:

- All patients should be assessed on admission to hospital (and again within 24 hours or when a change occurs in the patient's clinical condition).
- Medical patients are at risk if they have reduced mobility for ≥ 3 days or if their mobility is reduced and they have ≥ 1 risk factor for VTE (Table 14.54).
- Surgical and trauma patients are at risk:
 - if they undergo a surgical procedure with a combined anaesthetic and surgery of >90 min (60 min if surgery on pelvis or lower limb)
 - if they are admitted with an acute inflammatory or intra-abdominal condition
 - if they have significantly reduced mobility
 - if they have ≥ 1 risk factor for VTE.

Patients at risk should be considered for pharmacological prophylaxis (fondaparinux or low-molecular-weight heparin or unfractionated heparin if renal impairment) unless they have a risk factor for bleeding (Table 14.55) that outweighs the benefits of VTE prophylaxis. Patients should also be encouraged to mobilize where possible and mechanical VTE (anti-embolism stockings (thigh or knee length), foot impulse devices, intermittent pneumatic compression devices (thigh or knee length) may be appropriate in certain patients. On discharge patients should be provided with advice on the signs and symptoms of VTE and if prescribed pharmacological or mechanical prophylaxis advice on their usage. (Anti-thrombin is now being used in orthopaedic surgery, see Chapter 8.)

Table 14.54 Risk factors for venous thromboembolism

Active cancer or cancer treatment
 Age >60 years
 Critical care admission
 Dehydration
 Known thrombophilias
 Obesity (BMI >30)
 Significant medical comorbidities (e.g. heart disease, metabolic, endocrine or respiratory pathologies, acute infectious diseases, inflammatory conditions)
 Personal history or first-degree relative with a history of VTE
 Use of hormone replacement therapy or oestrogen-containing contraceptive therapy
 Varicose veins with phlebitis
 Pregnancy/childbirth

INTRODUCTION

The main role of the respiratory system is to extract oxygen from the external environment and dispose of waste gases, principally carbon dioxide. This requires the lungs to function as efficient bellows, bringing in fresh air and delivering it to the alveoli, and expelling used air at an appropriate rate. Gas exchange is achieved by exposing thin-walled capillaries to the alveolar gas and matching ventilation to blood flow through the pulmonary capillary bed. In doing this, the lungs expose a large area of tissue, which can be damaged by dusts, gases and infective agents. Host defence is therefore a key priority for the lung and is achieved by a combination of structural and immunological defences.

STRUCTURE OF THE RESPIRATORY SYSTEM

The nose, pharynx and larynx

See [Chapter 21](#) (p. 1052).

The trachea, bronchi and bronchioles

The trachea is 10–12 cm in length. It lies slightly to the right of the midline and divides at the carina into right and left main bronchi. The carina lies under the junction of the manubrium sterni and the second right costal cartilage. The right main bronchus is more vertical than the left and, hence, inhaled material is more likely to end up in the right lung.

The right main bronchus divides into the upper lobe bronchus and the intermediate bronchus, which further subdivides into the middle and lower lobe bronchi. On the left the main bronchus divides into upper and lower lobe bronchi only. Each lobar bronchus further divides into segmental and subsegmental bronchi. There are about 25 divisions in all between the trachea and the alveoli.

The first seven divisions are bronchi that have:

- walls consisting of cartilage and smooth muscle
- epithelial lining with cilia and goblet cells
- submucosal mucus-secreting glands
- endocrine cells – Kulchitsky or APUD (amine precursor and uptake decarboxylation) containing 5-hydroxytryptamine.

The next 16–18 divisions are bronchioles that have:

- no cartilage and a muscular layer that progressively becomes thinner
- a single layer of ciliated cells but very few goblet cells
- granulated Clara cells that produce a surfactant-like substance.

The ciliated epithelium is a key defence mechanism. Each cell bears approximately 200 cilia beating at 1000 beats per minute in organized waves of contraction. Each cilium consists of nine peripheral parts and two inner longitudinal fibrils in a cytoplasmic matrix ([Fig. 15.1](#)). Nexin links join the peripheral pairs. Dynein arms consisting of ATPase protein project towards the adjacent pairs. Bending of the cilia results from a sliding movement between adjacent fibrils powered by an ATP-dependent shearing force developed by the dynein arms (see also p. 22). Absence of dynein arms leads to immotile

Figure 15.1 Cross-section of a cilium. Nine outer microtubular doublets and two central single microtubules are linked by spokes, nexin links and dynein arms.

Figure 15.2 Branches of a terminal bronchiole ending in the alveolar sacs.

cilia. Mucus, which contains macrophages, cell debris, inhaled particles and bacteria, is moved by the cilia towards the larynx at about 1.5 cm/min (the 'mucociliary escalator', see below).

The bronchioles finally divide within the acinus into smaller respiratory bronchioles that have alveoli arising from the surface (Fig. 15.2). Each respiratory bronchiole supplies approximately 200 alveoli via alveolar ducts. The term 'small airways' refers to bronchioles of <2 mm; the average lung contains about 30 000 of these.

The alveoli

There are approximately 300 million alveoli in each lung. Their total surface area is 40–80 m². The epithelial lining consists mainly of **type I pneumocytes** (Fig. 15.3). These cells have an extremely thin layer of cytoplasm, which only offers a thin barrier to gas exchange. *Type I cells* are connected to each other by tight junctions that limit the movements of fluid in and out of the alveoli. Alveoli are not completely airtight – many have holes in the alveolar wall allowing communication between alveoli of adjoining lobules (pores of Kohn).

Type II pneumocytes are slightly more numerous than type I cells but cover less of the epithelial lining. They are found generally in the borders of the alveolus and contain distinctive lamellar vacuoles, which are the source of surfactant. Type I pneumocytes are derived from type II cells. Large alveolar macrophages are present within the alveoli and assist in defending the lung.

Figure 15.3 The structure of alveoli, showing the pneumocytes and capillaries.

The lungs

The lungs are separated into lobes by invaginations of the pleura, which are often incomplete. The right lung has three lobes, whereas the left lung has two. The positions of the oblique fissures and the right horizontal fissure are shown in Figure 15.4. The upper lobe lies mainly in front of the lower lobe and therefore physical signs on the right side in the front of the chest are due to lesions of the upper lobe or the middle lobe.

Each lobe is further subdivided into bronchopulmonary segments by fibrous septa that extend inwards from the pleural surface. Each segment receives its own segmental bronchus.

The bronchopulmonary segment is further divided into individual lobules approximately 1 cm in diameter and generally pyramidal in shape, the apex lying towards the bronchiole that supplies it. Within each lobule a terminal bronchus supplies an acinus, and within this structure further divisions of the bronchioles eventually give rise to the alveoli.

The pleura

The pleura is a layer of connective tissue covered by a simple squamous epithelium. The visceral pleura covers the surface of the lung, lines the interlobar fissures, and is continuous at the hilum with the parietal pleura, which lines the inside of the hemithorax. At the hilum the visceral pleura continues alongside the branching bronchial tree for some distance before reflecting back to join the parietal pleura. In health, the pleurae are in apposition apart from a small quantity of lubricating fluid.

The diaphragm

The diaphragm is covered by parietal pleura above and peritoneum below. Its muscle fibres arise from the lower ribs and insert into the central tendon. Motor and sensory nerve fibres go separately to each half of the diaphragm via the phrenic nerves. Fifty per cent of the muscle fibres are of the slow-twitch type with a low glycolytic capacity; they are relatively resistant to fatigue.

Pulmonary vasculature and lymphatics

The lung has a dual blood supply, receiving deoxygenated blood from the right ventricle via the pulmonary artery and oxygenated blood via the bronchial circulation.

Figure 15.4 Surface anatomy of the chest.

The pulmonary artery divides to accompany the bronchi. The arterioles accompanying the respiratory bronchioles are thin-walled and contain little smooth muscle. The pulmonary venules drain laterally to the periphery of the lobules, pass centrally in the interlobular and intersegmental septa, and eventually join to form the four main pulmonary veins.

The bronchial circulation arises from the descending aorta. These bronchial arteries supply tissues down to the level of the respiratory bronchiole. The bronchial veins drain into the pulmonary vein, forming part of the normal physiological shunt.

Lymphatic channels lie in the interstitial space between the alveolar cells and the capillary endothelium of the pulmonary arterioles.

The tracheobronchial lymph nodes are arranged in five main groups: pulmonary, bronchopulmonary, subcarinal, superior tracheobronchial and paratracheal. For all practical purposes these form a continuous network of nodes from the lung substance up to the trachea.

Nerve supply to the lung

The innervation of the lung remains incompletely understood. Parasympathetic and sympathetic fibres (from the vagus and sympathetic chain respectively) accompany the pulmonary arteries and the airways. Airway smooth muscle is innervated by vagal afferents, postganglionic muscarinic vagal efferents and vagally derived non-adrenergic non-cholinergic (NANC) fibres which use a range of neurotransmitters including substance P, neurokinins A and B, calcitonin gene-related peptide, vasoactive intestinal polypeptide and various adenine and guanine phosphates. Three muscarinic receptor subtypes have been identified: M_1 receptors on parasympathetic ganglia, a smaller number of M_2 receptors on muscarinic nerve terminals, and M_3 receptors on airway smooth muscle. The parietal pleura is innervated from intercostal and phrenic nerves but the visceral pleura has no innervation.

PHYSIOLOGY OF THE RESPIRATORY SYSTEM

The nose

The major functions of nasal breathing are:

- To heat and moisten the air
- To remove particulate matter.

About 10000 L of air are inhaled daily. The relatively low flow rates and turbulence of inspired air in the nose mean that few particles greater than 10 microns (μm) diameter pass through the nose. Particles deposited on the nasal mucosa are removed within 15 minutes, compared with 60–120 days for particles that reach the alveoli. Nasal secretion contains IgA antibodies, lysozyme and interferons. In addition, the cilia of the nasal epithelium move the mucous gel layer rapidly back to the oropharynx where it is swallowed. Bacteria have little chance of settling in the nose. Mucociliary protection is less effective against viral infections because viruses bind to receptors on epithelial cells. The majority of rhinoviruses bind to an adhesion molecule, intercellular adhesion molecule 1 (ICAM-1), which is shared by neutrophils and eosinophils. Many noxious gases, such as SO_2 , are almost completely removed by nasal breathing.

Breathing

Lung ventilation can be considered in two parts:

- The mechanical process of inspiration and expiration
- The control of respiration to a level appropriate for metabolic needs.

Mechanical process

The lungs have an inherent elastic property that causes them to tend to collapse away from the thoracic wall, generating a negative pressure within the pleural space. The strength of this retractive force relates to the volume of the lung: at higher lung volumes the lung is stretched more, and a greater negative intrapleural pressure is generated. *Lung compliance* is a measure of the relationship between this retractive force and lung volume. At the end of a quiet expiration, the retractive force exerted by the lungs is balanced by the tendency of the thoracic wall to spring outwards. At this point, respiratory muscles are resting. The volume of air remaining in the lung after a quiet expiration is called the *functional residual capacity (FRC)*.

Inspiration from FRC is an active process: a negative intrapleural pressure is created by descent of the diaphragm and movement of the ribs upwards and outwards through contraction of the intercostal muscles. During tidal breathing in healthy individuals, inspiration is almost entirely due to contraction of the diaphragm. More vigorous inspiration requires the use of accessory muscles of ventilation (sternomastoid and scalene muscles). Respiratory muscles are similar to other skeletal muscles but are less prone to

Figure 15.5 Chemical and neurogenic factors in the control of ventilation. The strongest stimulant to ventilation is a rise in $P_a\text{CO}_2$ which increases $[\text{H}^+]$ in CSF. Sensitivity to this may be lost in COPD. In these patients hypoxaemia is the chief stimulus to respiratory drive; oxygen treatment may therefore reduce respiratory drive and lead to a further rise in $P_a\text{CO}_2$. An increase in $[\text{H}^+]$ due to metabolic acidosis as in diabetic ketoacidosis will increase ventilation with a fall in $P_a\text{CO}_2$ causing deep sighing (Kussmaul) respiration. The respiratory centre is depressed by severe hypoxaemia and sedatives (e.g. opiates) and stimulated by doxapram, large doses of aspirin and pyrexia. COPD, chronic obstructive pulmonary disease.

fatigue. However, inspiratory muscle fatigue contributes to respiratory failure in patients with severe chronic airflow limitation and in those with primary neurological and muscle disorders.

At rest or during low-level exercise, expiration is passive and results from the natural tendency of the lung to collapse.

Forced expiration involves activation of accessory muscles, chiefly those of the abdominal wall, which help to push up the diaphragm.

The control of respiration

Coordinated respiratory movements result from rhythmical discharges arising in an anatomically ill-defined group of interconnected neurones in the reticular substance of the brainstem, known as the respiratory centre. Motor discharges from the respiratory centre travel via the phrenic and intercostal nerves to the respiratory musculature.

In healthy individuals, the main driver for respiration is the arterial pH, which is closely related to the partial pressure of carbon dioxide in arterial blood. Oxygen levels in arterial blood are usually above the level which triggers respiratory drive. In a typical normal adult at rest:

- The pulmonary blood flow of 5 L/min carries 11 mmol/min (250 mL/min) of oxygen from the lungs to the tissues.
- Ventilation at about 6 L/min carries 9 mmol/min (200 mL/min) of carbon dioxide out of the body.
- The normal pressure of oxygen in arterial blood ($P_a\text{O}_2$) is between 11 and 13 kPa.
- The normal pressure of carbon dioxide in arterial blood ($P_a\text{CO}_2$) is 4.8–6.0 kPa.

Ventilation is controlled by a combination of neurogenic and chemical factors (Fig. 15.5).

Breathlessness on physical exertion is normal and not considered a symptom unless the level of exertion is very light, such as when walking slowly. Surveys of healthy western populations reveal that over 20% of the general population report themselves as breathless on relatively minor exertion. Although breathlessness is a very common symptom, the sensory and neural mechanisms underlying it remain obscure. The sensation of breathlessness is derived from at least three sources:

- **Changes in lung volume.** These are sensed by receptors in thoracic wall muscles signalling changes in their length.
- **Tension developed by contracting muscles.** This is sensed by Golgi tendon organs.
- **Central perception of the sense of effort.**

The airways of the lungs

From the trachea to the periphery, the airways decrease in size but increase in number. Overall, the cross-sectional area available for airflow increases as the total number of airways increases. The airflow rate is greatest in the trachea and slows progressively towards the periphery (since the velocity of airflow depends on the cross-sectional area). In the terminal airways, gas flow occurs solely by diffusion. The resistance to airflow is very low (0.1–0.2 kPa/L in a normal tracheobronchial tree), steadily increasing from the small to the large airways.

Airways expand as the lung volume increases. At full inspiration (*total lung capacity*, TLC) they are 30–40% larger in

calibre than at full expiration (*residual volume*, RV). In chronic obstructive pulmonary disease (COPD), the small airways are narrowed but this can be partially compensated by breathing closer to TLC.

Control of airway tone

Bronchomotor tone is maintained by vagal efferent nerves and can be reduced by atropine or β -adrenoceptor agonists. Adrenoceptors on the surface of bronchial muscles respond to circulating catecholamines – there is no direct sympathetic innervation. Airway tone shows a *circadian rhythm*, which is greatest at 04.00 and lowest in the mid-afternoon. Tone can be increased transiently by inhaled stimuli acting on epithelial nerve endings, which trigger reflex bronchoconstriction via the vagus. These stimuli include cigarette smoke, solvents, inert dust and cold air. Airway responsiveness to these stimuli increases following respiratory tract infections even in healthy subjects. In asthma, the airways are very irritable and as the circadian rhythm remains the same, asthmatic symptoms are usually worse in the early morning.

Airflow

Movement of air through the airways results from a difference between atmospheric pressure and the pressure in the alveoli; alveolar pressure is negative in inspiration and positive in expiration. During quiet breathing, the pleural pressure is negative throughout the breathing cycle. With vigorous expiratory efforts (e.g. cough), the pleural pressure becomes positive (up to 10 kPa). This compresses the central airways, but the smaller airways do not close off because the driving pressure for expiratory flow (alveolar pressure) is also increased.

Alveolar pressure (P_{ALV}) is equal to the pleural pressure (P_{PL}) plus the elastic recoil pressure (P_{EL}) of the lung.

When there is no airflow (i.e. during a pause in breathing), the tendency of the lungs to collapse (the positive recoil pressure) is exactly balanced by an equivalent negative pleural pressure.

As air flows from the alveoli towards the mouth there is a gradual drop of pressure owing to flow resistance (Fig. 15.6a).

In forced expiration, as mentioned above, the driving pressure raises both the alveolar pressure and the intrapleural pressure. Between the alveolus and the mouth, there is a point (C in Fig. 15.6b) where the airway pressure equals the intrapleural pressure, and the airway collapses. However, this collapse is temporary, as the transient occlusion of the airway results in an increase in pressure behind it (i.e. upstream) and this raises the intra-airway pressure so that the airways open and flow is restored. The airways thus tend to vibrate at this point of 'dynamic collapse'.

As lung volume decreases during expiration, the elastic recoil pressure of the lungs decreases and the 'collapse point' moves upstream (i.e. towards the smaller airways – see Fig. 15.6c). Where there is pathological loss of recoil pressure (as in chronic obstructive pulmonary disease, COPD), the 'collapse point' is located even further upstream and causes expiratory flow limitation. The measurement of the forced expiratory volume in 1 second (FEV_1) is a useful clinical index of this phenomenon. To compensate, patients with COPD often 'purse their lips' in order to increase airway pressure so that their peripheral airways do not collapse. During inspiration, the intrapleural pressure is always less than the intraluminal pressure within the intrathoracic airways, so increasing effort does not limit airflow. Inspiratory flow is limited only by the power of the inspiratory muscles.

Figure 15.6 Diagrams showing ventilatory forces.

(a) During resting at functional residual capacity.

(b) During forced expiration in normal subjects.

(c) During forced expiration in a patient with COPD. The respiratory system is represented as a piston with a single alveolus and the collapsible part of the airways within the piston (see text). C, collapse point; P_{ALV} , alveolar pressure; P_{EL} , elastic recoil pressure; P_{PL} , pleural pressure.

Flow-volume loops

The relationship between maximal flow rates and lung volume is demonstrated by the maximal flow-volume (MFV) loop (Fig. 15.7a).

In subjects with healthy lungs, maximal flow rates are rarely achieved even during vigorous exercise. However, in patients with severe COPD, limitation of expiratory flow occurs even during tidal breathing at rest (Fig. 15.7b). To increase ventilation these patients have to breathe at higher lung volumes and allow more time for expiration, both of which reduce the tendency for airway collapse. To compensate they increase flow rates during inspiration, where there is relatively less flow limitation.

The volume that can be forced in from the residual volume in 1 second (FIV_1) will always be greater than that which can be forced out from TLC in 1 second (FEV_1). Thus, the ratio of FEV_1 to FIV_1 is below 1. The only exception to this occurs when there is significant obstruction to the airways outside the thorax, such as tracheal tumour or retrosternal goitre. Expiratory airway narrowing is prevented by tracheal resistance and expiratory airflow becomes more effort-dependent. During forced inspiration this same resistance causes such negative intraluminal pressure that the trachea is compressed by the surrounding atmospheric pressure. Inspiratory flow thus becomes less effort-dependent, and the ratio of FEV_1 to FIV_1 exceeds 1. This phenomenon, and the characteristic

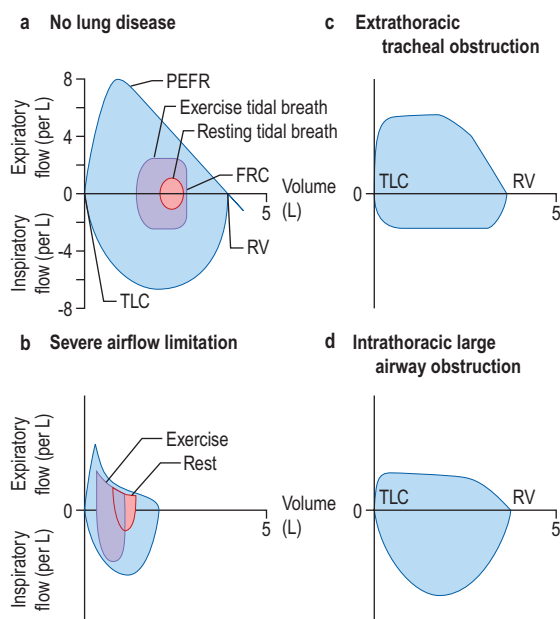

Figure 15.7 (a, b) Maximal flow-volume loops, showing the relationship between maximal flow rates on expiration and inspiration.

(a) In a normal subject.

(b) In a patient with severe airflow limitation. Flow-volume loops during tidal breathing at rest (starting from the functional residual capacity (FRC)) and during exercise are also shown. The highest flow rates are achieved when forced expiration begins at total lung capacity (TLC) and represent the peak expiratory flow rate (PEFR). As air is blown out of the lung, so the flow rate decreases until no more air can be forced out, a point known as the residual volume (RV). Because inspiratory airflow is only dependent on effort, the shape of the maximal inspiratory flow-volume loop is quite different, and inspiratory flow remains at a high rate throughout the manoeuvre. (c, d) Flow-volume loops of patients with large airway (tracheal) obstruction, showing plateauing of maximal expiratory flow.

(c) Extrathoracic tracheal obstruction with a proportionally greater reduction of maximal inspiratory (as opposed to expiratory) flow rate.

(d) Intrathoracic large airway obstruction; the expiratory plateau is more pronounced and inspiratory flow rate is less reduced than in (c). In severe airflow limitation the ventilatory demands of exercise cannot be met (cf. a, b), greatly reducing effort tolerance.

flow-volume loop, is diagnostic of extrathoracic airways obstruction (Fig. 15.7c).

Ventilation and perfusion relationships

For optimum gas exchange there must be a match between ventilation of the alveoli (\dot{V}_A) and their perfusion (\dot{Q}). However, in reality there is variation in the (\dot{V}_A/\dot{Q}) ratio in both normal and diseased lungs (Fig. 15.8). In the normal lung both ventilation and perfusion are greater at the bases than at the apices, but the gradient for perfusion is steeper, so the net effect is that ventilation exceeds perfusion towards the apices, while perfusion exceeds ventilation at the bases. Other causes of (\dot{V}_A/\dot{Q}) mismatch include direct shunting of deoxygenated blood through the lung without passing through alveoli (e.g. the bronchial circulation) and areas of lung that receive no blood (e.g. anatomical deadspace, bullae and areas of underperfusion during acceleration and deceleration, e.g. in aircraft and high performance cars).

An increased physiological shunt results in arterial hypoxaemia since it is not possible to compensate for some of the

Figure 15.8 Relationships between ventilation and perfusion: a schematic diagram showing the alveolar-capillary interface. The centre (b) shows normal ventilation and perfusion. On the left (a) there is a block in perfusion (physiological deadspace), while on the right (c) there is reduced ventilation (physiological shunting).

blood being underoxygenated by increasing ventilation of the well-perfused areas. An increased physiological deadspace just increases the work of breathing and has less impact on blood gases since the normally perfused alveoli are well ventilated. In more advanced disease this compensation cannot occur, leading to increased alveolar and arterial PCO_2 (P_ACO_2), together with hypoxaemia which cannot be compensated by increasing ventilation.

Hypoxaemia occurs more readily than hypercapnia because of the different ways in which oxygen and carbon dioxide are carried in the blood. Carbon dioxide can be considered to be in simple solution in the plasma, the volume carried being proportional to the partial pressure. Oxygen is carried in chemical combination with haemoglobin in the red blood cells, with a non-linear relationship between the volume carried and the partial pressure (Fig. 15.5, p. 341). Alveolar hyperventilation reduces the alveolar PCO_2 (P_ACO_2) and diffusion leads to a proportional fall in the carbon dioxide content of the blood (P_aCO_2). However, as the haemoglobin is already saturated with oxygen, there is no significant increase in the blood oxygen content as a result of increasing the alveolar PO_2 through hyperventilation. The hypoxaemia of even a small amount of physiological shunting cannot therefore be compensated for by hyperventilation.

In individuals who have mild degrees of \dot{V}_A/\dot{Q} mismatch, the P_aO_2 and P_aCO_2 will still be normal at rest. Increasing the requirements for gas exchange by exercise will widen the \dot{V}_A/\dot{Q} mismatch and the P_aO_2 will fall. \dot{V}_A/\dot{Q} mismatch is by far the most common cause of arterial hypoxaemia.

Alveolar stability

Pulmonary alveoli are essentially hollow spheres. Surface tension acting at the curved internal surface tends to cause the sphere to decrease in size. The surface tension within the alveoli would make the lungs extremely difficult to distend were it not for the presence of surfactant, an insoluble lipoprotein largely consisting of dipalmitoyl lecithin, which forms

a thin monomolecular layer at the air-fluid interface. Surfactant is secreted by type II pneumocytes within the alveolus and reduces surface tension so that alveoli remain stable.

Fluid surfaces covered with surfactant exhibit a phenomenon known as hysteresis; that is, the surface-tension-lowering effect of the surfactant can be improved by a transient increase in the size of the surface area of the alveoli. During quiet breathing, small areas of the lung undergo collapse, but it is possible to re-expand these rapidly by a deep breath; hence the importance of sighs or deep breaths as a feature of normal breathing. Failure of this mechanism, e.g. in patients with fractured ribs – gives rise to patchy basal lung collapse. Surfactant levels may be reduced in a number of diseases that cause damage to the lung (e.g. pneumonia). Lack of surfactant plays a central role in the respiratory distress syndrome of the newborn. Severe reduction in perfusion of the lung impairs surfactant activity and this may explain the characteristic areas of collapse associated with pulmonary embolism.

DEFENCE MECHANISMS OF THE RESPIRATORY TRACT

Pulmonary disease often results from a failure of the normal host defence mechanisms of the healthy lung (Fig. 15.9). These can be divided into physical, physiological, humoral and cellular mechanisms.

Physical and physiological mechanisms

Humidification

This prevents dehydration of the epithelium.

Particle removal

Over 90% of particles greater than 10 μm diameter are removed in the nostril or nasopharynx. This includes most pollen grains, which are typically >20 μm in diameter. Particles between 5 and 10 μm become impacted at the carina. Particles smaller than 1 μm tend to remain airborne, thus the

particles capable of reaching the deep lung are those in the 1–5 μm range.

Particle expulsion

This is effected by coughing, sneezing or gagging.

Respiratory tract secretions (Fig. 15.9)

The mucus of the respiratory tract is a gelatinous substance consisting of water and highly glycosylated proteins (mucins). The mucus forms a thick gel that is relatively impermeable to water and floats on a liquid or sol layer found around the cilia of the epithelial cells. The gel layer is secreted from goblet cells and mucous glands as distinct globules that coalesce increasingly in the central airways to form a more or less continuous mucus blanket. In addition to the mucins, the gel contains various antimicrobial molecules (lysozyme, defensins), specific antibodies (IgA) and cytokines, which are secreted by cells in airways and get incorporated into the mucus gel. Bacteria, viruses and other particles get trapped in the mucus and are either inactivated or simply expelled before they can do any damage. Under normal conditions the tips of the cilia engage with the undersurface of the gel phase and by coordinated movement they push the mucus blanket upwards and outwards to the pharynx where it is either swallowed or coughed up. While it only takes 30–60 minutes for mucus to be cleared from the large bronchi, it can be several days before mucus is cleared from respiratory bronchioles. One of the major long-term effects of cigarette smoking is a reduction in mucociliary transport. This contributes to recurrent infection and prolongs contact with carcinogenic material. Air pollutants, local and general anaesthetics and products of bacterial and viral infection also reduce mucociliary clearance.

Congenital defects in mucociliary transport lead to recurrent infections and eventually to bronchiectasis. For example, in the 'immotile cilia' syndrome there is an absence of the dynein arms in the cilia themselves, while in cystic fibrosis there is ciliary dyskinesia and abnormally thick mucus.

Humoral and cellular mechanisms

Nonspecific soluble factors

- **α -Antitrypsin** (α_1 -antiprotease, see p. 341) in lung secretions is derived from plasma. It inhibits chymotrypsin and trypsin and neutralizes proteases including neutrophil elastase.
- **Antioxidant defences** include enzymes such as superoxide dismutase and low-molecular-weight antioxidant molecules (ascorbate, urate) in the epithelial lining fluid. In addition, lung cells are protected by an extensive range of intracellular defences, especially members of the glutathione S-transferase (GST) superfamily.
- **Lysozyme** is an enzyme found in granulocytes that has bactericidal properties.
- **Lactoferrin** is synthesized from epithelial cells and neutrophil granulocytes and has bactericidal properties.
- **Interferons** are produced by most cells in response to viral infection and are potent modulators of lymphocyte function.
- **Complement** in secretions is also derived from plasma. In association with antibodies, it plays a major role in cytotoxicity.
- **Surfactant protein A** (SPA) is one of four species of surfactant proteins which opsonizes bacteria/particles, enhancing phagocytosis by macrophages.

Figure 15.9 Defence mechanisms present at the epithelial surface.

- **Defensins** are bactericidal peptides present in the azurophil granules of neutrophils.
- **Dimeric secretory IgA** targets specific antigens (p. 262).

Innate and adaptive immunity

These mechanisms act as a defence against microbes, inorganic substances, e.g. asbestos, particulate matter, such as dust, and other antigens. They act by aiding opsonization so that macrophages can better ingest foreign material.

With infection, neutrophils migrate out of pulmonary capillaries into the air spaces and phagocytose and kill microbes with, for example, antimicrobial proteins (lactoferrin), degradative enzymes (elastase) and oxidant radicals. In addition, neutrophil extracellular traps (NET) ensnare and kill extracellular bacteria. Neutrophils also generate a variety of mediators, e.g. TNF- α , IL-1 and chemokines which activate dendritic cells and B cells and produce the T-cell-activating cytokine IL-12. The latter enhances neutrophil-mediated defence during pneumonia. Dendritic cells are antigen presenting cells and are key to the adaptive immune response (p. 58).

Microbes are detected by host cells by pattern recognition receptors, e.g. toll-like receptors. These act via NF- κ B transcription factors in the epithelial cells to produce adhesion molecules, chemokines and colony stimulating factors to initiate inflammation. Inflammation is necessary for innate immunity and host defence but can lead to lung damage: there is a fine line between defence and injury.

SYMPTOMS**Runny, blocked nose and sneezing**

Nasal symptoms (see also p. 691) are extremely common and both common colds and allergic rhinitis cause 'runny nose' (rhinorrhoea), nasal blockage and attacks of sneezing. In allergic rhinitis, symptoms may be intermittent, following contact with pollens or animal danders, or persistent, especially when house-dust mite is the allergen. Colds are frequent during the winter but if the symptoms persist for weeks the patient probably has perennial rhinitis rather than persistent viral infection.

Nasal secretions are usually thin and runny in allergic rhinitis but thicker and discoloured with viral infections. Nose bleeds and blood-stained nasal discharge are common and rarely indicate serious pathology. However, a blood-stained nasal discharge associated with nasal obstruction and pain may be the presenting feature of a nasal tumour (p. 1051). Nasal polyps typically present with nasal blockage and loss of smell.

Cough

Cough (see also p. 822) is the commonest symptom of lower respiratory tract disease. It is caused by mechanical or chemical stimulation of cough receptors in the epithelium of the pharynx, larynx, trachea, bronchi and diaphragm. Afferent receptors go to the cough centre in the medulla where efferent signals are generated to the expiratory musculature. Smokers often have a morning cough with a little sputum. A productive cough is the cardinal feature of chronic bronchitis, while dry coughing, particularly at night, can be a symptom of asthma. Cough also occurs in asthmatics after mild exertion or following forced expiration. Cough can also occur for psychological reasons without any definable pathology.

A worsening cough is the most common presenting symptom of lung cancer. The normal explosive character of the cough is lost when a vocal cord is paralysed, usually as

a result of lung cancer infiltrating the left recurrent laryngeal nerve – sometimes termed a bovine cough. Cough can be accompanied by stridor in whooping cough or if there is laryngeal or tracheal obstruction.

Sputum

Approximately 100 mL of mucus is produced daily in a healthy, non-smoking individual. This flows gradually up the airways, through the larynx, and is then swallowed. Excess mucus is expectorated as sputum. Cigarette smoking is the commonest cause of excess mucus production.

Mucoid sputum is clear and white but can contain black specks resulting from the inhalation of carbon. Yellow or green sputum is due to the presence of cellular material, including bronchial epithelial cells, or neutrophil or eosinophil granulocytes. Yellow sputum is not necessarily due to infection, as eosinophils in the sputum, as seen in asthma, can give the same appearance. The production of large quantities of yellow or green sputum is characteristic of bronchiectasis.

Haemoptysis (blood-stained sputum) varies from small streaks of blood to massive bleeding.

- The commonest cause of mild haemoptysis is acute infection, particularly in exacerbations of chronic obstructive pulmonary disease (COPD) but it should not be attributed to this without investigation.
- Other common causes are pulmonary infarction, bronchial carcinoma and tuberculosis.
- In lobar pneumonia, the sputum is usually rusty in appearance rather than frankly blood-stained.
- Pink, frothy sputum is seen in pulmonary oedema.
- In bronchiectasis, the blood is often mixed with purulent sputum.
- Massive haemoptyses (>200 mL of blood in 24 hours) are usually due to bronchiectasis or tuberculosis.
- Uncommon causes of haemoptyses are idiopathic pulmonary haemosiderosis, Goodpasture's syndrome, microscopic polyangiitis, trauma, blood disorders and benign tumours.

Haemoptysis should always be investigated. Although a diagnosis can often be made from a chest X-ray, a normal chest X-ray does not exclude disease. However, if the chest X-ray is normal, CT scanning and bronchoscopy are only diagnostic in about 5% of patients with haemoptysis.

Firm plugs of sputum may be coughed up by patients suffering from an exacerbation of allergic bronchopulmonary aspergillosis. Sometimes such sputum looks like casts of inflamed bronchi.

Breathlessness

Dyspnoea is a sense of awareness of increased respiratory effort that is unpleasant and that is recognized by the patient as being inappropriate. Patients often complain of tightness in the chest; this must be differentiated from angina.

Breathlessness should be assessed in relation to the patient's lifestyle. For example, a moderate degree of breathlessness will be totally disabling if the patient has to climb many flights of stairs to reach home.

Orthopnoea (see p. 675) is breathlessness on lying down. While it is classically linked to heart failure, it is partly due to the weight of the abdominal contents pushing the diaphragm up into the thorax. Such patients may also become breathless on bending over.

Tachypnoea and hyperpnoea are, respectively, an increased rate of breathing and an increased level of

ventilation. These may be appropriate responses (e.g. during exercise).

Hyperventilation is inappropriate overbreathing. This may occur at rest or on exertion and results in a lowering of the alveolar and arterial PCO_2 (see p. 1178).

Paroxysmal nocturnal dyspnoea (see p. 798) is acute episodes of breathlessness at night, typically due to heart failure.

Wheezing

Wheezing is a common complaint and results from airflow limitation due to any cause. The symptom of wheezing is not diagnostic of asthma; other causes include vocal cord dysfunction, bronchiolitis and chronic obstructive pulmonary disease (COPD). Conversely, wheeze may be absent in the early stages of asthma.

Chest pain

The most common type of chest pain reported in respiratory disease is a localized sharp pain, often termed pleuritic. It is made worse by deep breathing or coughing and the patient can usually localize it. Localized anterior chest pain with tenderness of a costochondral junction is caused by costochondritis. Shoulder tip pain suggests irritation of the diaphragmatic pleura, while central chest pain radiating to the neck and arms is likely to be cardiac. Retrosternal soreness is associated with tracheitis, while malignant invasion of the chest wall causes a constant, severe, dull pain.

EXAMINATION OF THE RESPIRATORY SYSTEM

The nose (see p. 1051)

The chest

Examination of the chest

Inspection

Assess mental alertness, cyanosis, breathlessness at rest, use of accessory muscles, any deformity or scars on the chest and movement on both sides. CO_2 intoxication causes coarse tremor or flap of the outstretched hands. Prominent veins on the chest may imply obstruction of the superior vena cava.

Cyanosis (see p. 676) is a dusky colour of the skin and mucous membranes, due to the presence of more than 50 g/L of desaturated haemoglobin. When due to central causes, cyanosis is visible on the tongue (especially the underside) and lips. Patients with central cyanosis will also be cyanosed peripherally. Peripheral cyanosis without central cyanosis is caused by a reduced peripheral circulation and is noted on the fingernails and skin of the extremities with associated coolness of the skin.

Finger clubbing is present when the normal angle between the base of the nail and the nail fold is lost. The base of the nail is fluctuant owing to increased vascularity, and there is an increased curvature of the nail in all directions, with expansion of the end of the digit. Some causes of clubbing are given in Table 15.1. Clubbing is not a feature of uncomplicated COPD.

Palpation and percussion

Check the position of the trachea and apex beat. Examine the supraclavicular fossa for enlarged lymph nodes. The distance between the sternal notch and the cricoid cartilage

Table 15.1 Some causes of finger clubbing

Respiratory

Bronchial carcinoma, especially epidermoid (squamous cell) type (major cause)
Chronic suppurative lung disease:
Bronchiectasis
Lung abscess
Empyema
Pulmonary fibrosis (e.g. idiopathic lung fibrosis)
Pleural and mediastinal tumours (e.g. mesothelioma)
Cryptogenic organizing pneumonia

Cardiovascular

Cyanotic heart disease
Subacute infective endocarditis
Atrial myxoma

Miscellaneous

Congenital – no disease
Cirrhosis
Inflammatory bowel disease

(three to four finger breadths in full expiration) is reduced in patients with severe airflow limitation. Check chest expansion. A tape measure is used if precise or serial measurements are needed, e.g. in ankylosing spondylitis. Local discomfort over the sternochondral joints suggests costochondritis. In rib fractures, compression of the chest laterally and anteroposteriorly produces localized pain. On percussion, liver dullness is usually detected anteriorly at the level of the sixth rib. Liver and cardiac dullness disappear when lungs are over-inflated (Table 15.2).

Auscultation

Ask the patient to take deep breaths through the mouth. Inspiration should be more prolonged than expiration. Normal breath sounds are caused by turbulent flow in the larynx and sound harsher anteriorly over the upper lobes (particularly on the right). Healthy lungs filter out most of the high-frequency component, and the resulting sounds are called vesicular.

If the lung is consolidated or collapsed, the high-frequency hissing components of breath are not attenuated, and can be heard as 'bronchial breathing'. Similar sounds may be heard over areas of localized fibrosis or bronchiectasis. Bronchial breathing is accompanied by whispering pectoriloquy (whispered, high-pitched sounds can be heard distinctly through a stethoscope).

Added sounds

Wheeze. Wheeze results from vibrations in the collapsible part of the airways when apposition occurs as a result of the flow-limiting mechanisms. Wheeze is usually heard during expiration and is commonly but not invariably present in asthma and in chronic obstructive pulmonary disease. In acute severe asthma wheeze may not be heard, as airflow may be insufficient to generate the sound. Wheezes may be monophonic (single large airway obstruction) or polyphonic (narrowing of many small airways). An end-inspiratory wheeze or 'squeak' may be heard in obliterative bronchiolitis.

Crackles. These brief crackling sounds are probably produced by opening of previously closed bronchioles – early inspiratory crackles are associated with diffuse airflow limitation, while late inspiratory crackles are characteristically heard in pulmonary oedema, lung fibrosis and bronchiectasis.

Pleural rub. A creaking or groaning sound that is usually well localized. It indicates inflammation and roughening of

Symptoms

Examination of the respiratory system

Table 15.2 Physical signs of respiratory disease

Pathological process	Chest wall movement (reduced)	Mediastinal displacement	Percussion note	Breath sounds	Vocal resonance	Added sounds
Consolidation (i.e. lobar pneumonia)	Affected side	None	Dull	Bronchial	Increased	Fine crackles
Collapse						
Major bronchus	Affected side	Towards lesion	Dull	Diminished or absent	Reduced or absent	None
Peripheral bronchus	Affected side	Towards lesion	Dull	Bronchial	Increased	Fine crackles
Fibrosis						
Localized	Affected side	Towards lesion	Dull	Bronchial	Increased	Coarse crackles
Generalized (e.g. idiopathic lung fibrosis)	Both sides	None	Normal	Vesicular	Increased	Fine crackles
Pleural effusion (>500 mL)	Affected side	Away from lesion (in massive effusion)	Stony dull	Vesicular reduced or absent	Reduced or absent	None
Large pneumothorax	Affected side	Away from lesion	Normal or hyperresonant	Reduced or absent	Reduced or absent	None
Asthma	Both sides	None	Normal	Vesicular Prolonged expiration	Normal	Expiratory polyphonic wheeze
Chronic obstructive pulmonary disease	Both sides	None	Normal	Vesicular Prolonged expiration	Normal	Expiratory polyphonic wheeze and coarse crackles

the pleural surfaces, which normally glide silently over one another.

Vocal resonance. Healthy lung attenuates high-frequency notes, as compared to the lower-pitched components of speech. Consolidated lung has the reverse effect, transmitting high frequencies well; the spoken word then takes on a bleating quality. Whispered (and therefore high-pitched) speech can be clearly heard over consolidated areas, as compared to healthy lung. Low-frequency sounds such as 'ninety-nine' are well transmitted across healthy lung to produce vibration that can be felt over the chest wall. Consolidated lung transmits these low-frequency noises less well, and pleural fluid severely dampens or obliterates the vibrations altogether. Tactile vocal fremitus is the palpation of this vibration, usually by placing the edge of the hand on the chest wall. For all practical purposes this duplicates the assessment of vocal resonance and is not routinely performed as part of the chest examination.

Cardiovascular system examination (p. 676) gives additional information about the lungs.

Additional bedside tests

Since so many patients with respiratory disease have airflow limitation, airflow should be routinely measured using a peak flow meter or spirometer. This is a much more useful assessment of airflow limitation than any physical sign.

INVESTIGATION OF RESPIRATORY DISEASE

Imaging

Radiology is essential in investigating most chest symptoms. Some diseases such as tuberculosis or lung cancer may be undetectable on clinical examination but are obvious on the

chest X-ray. Conversely, asthma or chronic bronchitis may be associated with a normal chest X-ray. Always try to get previous films for comparison.

Chest X-ray

When viewing films consider:

- **Centring of the film.** The distance between each clavicular head and the spinal processes should be equal
- **Penetration** (check film is not too dark)
- **View.** Routine films are taken postero-anterior (PA), i.e. the film is placed in front of the patient with the X-ray source behind. Anteroposterior (AP) films are taken only in very ill patients who are unable to stand up or be taken to the radiology department; the cardiac outline appears bigger and the scapulae cannot be moved out of the way. Lateral chest X-rays were often performed in the past to localize pathology, but CT scans have replaced these.

Look at:

- The shape and bony structure of the chest wall
- Whether the trachea is central
- Whether the diaphragm is elevated or flat
- The shape, size and position of the heart
- The shape and size of the hilar shadows
- The size and shape of any lung abnormalities and vascular shadowing.

X-ray abnormalities

Collapse and consolidation

Simple pneumonia is easy to recognize (see Fig. 15.33) but look carefully for any evidence of collapse (Fig. 15.10, Table 15.3). Loss of volume or crowding of the ribs are the best indicators of lobar collapse. The lung lobes collapse in

Figure 15.10 Collapse of the left upper lobe. Chest X-ray showing triangular shadow in the left upper zone, next to the mediastinum.

Table 15.3 Causes of collapse of the lung

Enlarged tracheobronchial lymph nodes due to malignant disease, tuberculosis
 Inhaled foreign bodies (e.g. peanuts) in children, usually in the right main bronchus
 Bronchial casts or plugs (e.g. allergic bronchopulmonary aspergillosis)
 Retained secretions – postoperatively and in debilitated patients

characteristic directions. The lower lobes collapse downwards and towards the mediastinum, the left upper lobe collapses forwards against the anterior chest wall, while the right upper lobe collapses upwards and inwards, forming the appearance of an arch over the remaining lung. The right middle lobe collapses anteriorly and inward, obscuring the right heart border. If a whole lung collapses, the mediastinum will shift towards the side of the collapse. Uncomplicated consolidation does not cause mediastinal shift or loss of lung volume, so any of these features should raise the suspicion of an endobronchial obstruction.

Pleural effusion

Pleural effusions (see Fig. 15.45) need to be larger than 500 mL to cause much more than blunting of the costophrenic angle. On an erect film they produce a characteristic shadow with a curved upper edge rising into the axilla. If very large, the whole of one hemithorax may be opaque, with mediastinal shift away from the effusion.

Fibrosis

Localized fibrosis causes streaky shadowing, and the accompanying loss of lung volume causes mediastinal structures to move to the same side. More generalized fibrosis can lead to a honeycomb appearance (see p. 849), seen as diffuse shadows containing multiple circular translucencies a few millimetres in diameter.

Round shadows

Lung cancer is the commonest cause of large round shadows but many other causes are recognized (Table 15.4).

Miliary mottling

This term, derived from the Latin for millet, describes numerous minute opacities, 1–3 mm in size. The commonest causes are tuberculosis, pneumoconiosis, sarcoidosis, idiopathic pulmonary fibrosis and pulmonary oedema (see Fig. 14.15), although pulmonary oedema is usually perihilar and

Table 15.4 Causes of round shadows (>3 cm) in the lung

Carcinoma
 Metastatic tumours (usually multiple shadows)
 Lung abscess (usually with fluid level)
 Encysted interlobar effusion (usually in horizontal fissure)
 Hydatid cysts (often with a fluid level)
 Arteriovenous malformations (usually adjacent to a vascular shadow)
 Aspergilloma
 Rheumatoid nodules
 Tuberculoma (may be calcification within the lesion)
 Rare causes:
 Bronchial carcinoid
 Cylindroma
 Chondroma
 Lipoma
 Other shadows related to mediastinum:
 Pericardium
 Oesophagus
 Spinal cord

} Seen on lateral chest X-ray

accompanied by larger, fluffy shadows. Pulmonary microlithiasis is a rare but striking cause of miliary mottling.

Computed tomography

CT provides excellent images of the lungs and mediastinal structures (Fig. 15.11). Narrow slice, high-resolution CT scans show the lung parenchyma well, while thicker slice staging CT scans are used for diagnosis of malignant disease. Mediastinal structures are shown more clearly after injecting intravenous contrast medium.

CT is essential in staging bronchial carcinoma by demonstrating tumour size, nodal involvement, metastases and invasion of mediastinum, pleura or chest wall. CT-guided needle biopsy allows samples to be obtained from peripheral masses. Staging scans should assess liver and adrenals, which are common sites for metastatic disease.

High-resolution CT (HRCT) scanning samples lung parenchyma with 1–2 mm thickness scans at 10–20 mm intervals and are used to assess diffuse inflammatory and infective parenchymal processes. It is valuable in:

- Evaluating diffuse disease of the lung parenchyma, including sarcoidosis, hypersensitivity pneumonitis, occupational lung disease, and any other form of interstitial pulmonary fibrosis.
- Diagnosis of bronchiectasis. HRCT has a sensitivity and specificity >90%.
- Distinguishing emphysema from diffuse parenchymal lung disease or pulmonary vascular disease as a cause of a low gas transfer factor with otherwise normal lung function.
- Suspected opportunistic lung infection in immunocompromised patients
- Diagnosis of lymphangitis carcinomatosa.

Multi-slice CT scanners can produce detailed images in two or three dimensions in any plane. This detail is particularly useful for the detection of pulmonary emboli. Pulmonary nodules and airway disease are more easily defined and the technique makes HRCT less necessary.

Magnetic resonance imaging

MRI is less valuable than CT in assessing the lung parenchyma. In the mediastinum, MRI with ECG-gating allows

Figure 15.11 CT scans of the lung. (a) Lung setting – showing normal lung markings. 1, right hilum; 2, mediastinum; 3, left hilum; 4, lung vessels; 5, left main bronchus; 6, right main bronchus; 7, peripheral lung vessels. (b) Mediastinal (soft tissue) setting – showing normal mediastinal structures following intravenous contrast enhancement. 1, rib; 2, descending left pulmonary artery; 3, scapula; 4, subcutaneous fat; 5, left main bronchus; 6, descending aorta; 7, spinal canal; 8, vertebral body; 9, oesophagus; 10, right main bronchus; 11, right pulmonary artery; 12, muscle; 13, right superior pulmonary vein; 14, superior vena cava; 15, costal cartilage; 16, ascending aorta; 17, sternum; 18, thymic remnant; 19, pulmonary trunk; 20, left superior pulmonary vein. (c) Post-contrast scan showing large right upper zone carcinoma with enlarged lymph nodes in the mediastinum surrounding the trachea.

accurate imaging of the heart and aortic aneurysms, and MRI has been used in staging lung cancer, for assessing tumour invasion in the mediastinum, chest wall and at the lung apex, because it produces good images in the sagittal and coronal planes. Vascular structures can be clearly differentiated as flowing blood produces a signal void on MRI.

Positron emission tomography (PET)

Tumours take up labelled fluorodeoxyglucose (FDG), which emits positrons that can be imaged and helps to differentiate benign from malignant tumours. In bronchial carcinoma, PET scanning combined with CT is now the investigation of choice for assessing lymph nodes and metastatic disease.

Scintigraphic imaging

Isotopic lung scans were used widely for the detection of pulmonary emboli but are now performed less often owing to widespread use of D-dimer measurements and CT pulmonary angiography.

Perfusion scan

Macro-aggregated human albumin labelled with technetium-99m (^{99m}Tc) is injected intravenously. The particles impact in pulmonary capillaries, where they remain for a few hours. A gamma camera is then used to detect the deposition of the particles. The resultant pattern indicates the distribution of pulmonary blood flow; cold areas occur where there is defective blood flow (e.g. in pulmonary emboli).

Ventilation-perfusion scan

Xenon-133 gas is inhaled and its distribution is detected at the same time as the perfusion scan. Areas affected by

pulmonary embolism will have reduced perfusion relative to ventilation (see [Chapter 14](#)). Other lung diseases (e.g. asthma or pneumonia) impair both ventilation and perfusion. Unfortunately, a pulmonary embolus can affect the lung substance (e.g. atelectasis) leading to reduced ventilation. Nevertheless, this is a better technique than perfusion scan alone.

Ultrasound (USS)

Ultrasound is useful for diagnosing and aspirating small pleural effusions, and for the safe placement of intercostal drains. Ultrasound guided biopsy is used for lung masses that abut the pleura, but ultrasound is not useful for lung parenchymal disease as ultrasound energy is scattered by air. Endobronchial ultrasound is helpful.

Respiratory function tests (Table 15.5)

In clinical practice, airflow limitation can be assessed by relatively simple tests that have good intra-subject repeatability. Results must be compared with predicted values for healthy subjects as normal ranges vary with sex, age and height. Moreover, there is considerable variation between healthy individuals of the same size and age; the standard deviation for the peak expiratory flow rate is approximately 50 L/min, and for the FEV_1 it is approximately 0.4 L. Repeated measurements of lung function are useful for assessing the progression of disease in individual patients.

Tests of ventilatory function

These tests are used mainly to assess the degree of airflow limitation during expiration.

Table 15.5 Respiratory function tests and exercise tests

Test	Use	Advantages	Disadvantages
PEFR	Monitoring changes in airflow limitation in asthma	Portable Can be used at the bedside	Effort-dependent Poor measure of chronic airflow limitation
FEV₁, FVC, FEV₁/FVC	Assessment of airflow limitation The best single test	Reproducible Relatively effort-independent	Bulky equipment but smaller portable machines available
Flow-volume curves	Assessment of flow at lower lung volumes Detection of large airway obstruction both intra- and extrathoracic (e.g. tracheal stenosis, tumour)	Recognition of patterns of flow-volume curves for different diseases	Sophisticated equipment needed for full test but expiratory loop now possible with compact spirometry
Airways resistance	Assessment of airflow limitation	Sensitive	Technique difficult to perform
Lung volumes	Differentiation between restrictive and obstructive lung disease	Effort-independent, complements FEV ₁	Sophisticated equipment needed
Gas transfer	Assessment and monitoring of extent of interstitial lung disease and emphysema	Non-invasive (compared with lung biopsy or radiation from repeated chest X-rays and CT)	Sophisticated equipment needed
Blood gases	Assessment of respiratory failure	Can detect early lung disease when measured during exercise	Invasive
Pulse oximetry	Postoperative, sleep studies and respiratory failure	Continuous monitoring Non-invasive	Measures saturation only
Exercise tests (6-min walk)	Practical assessment for disability and effects of therapy	No equipment required	Time-consuming Learning effect At least two walks required
Cardiorespiratory assessment	Early detection of lung/heart disease Fitness assessment	Differentiates breathlessness due to lung or heart disease	Expensive and complicated equipment required

Spirometry

The patient takes a maximum inspiration followed by a forced expiration (for as long as possible) into the spirometer. The spirometer measures the one second forced expiratory volume (FEV₁) and the total volume of exhaled gas (forced vital capacity, FVC). Both FEV₁ and FVC are related to height, age and sex (Fig. 15.12).

In airflow limitation, the FEV₁ is reduced as a percentage of FVC. In normal health the FEV₁/FVC ratio is around 75%. With increasing airflow limitation FEV₁ falls proportionately more than FVC, so the FEV₁/FVC ratio is reduced. With restrictive lung disease FEV₁ and FVC are reduced proportionately and the FEV₁/FVC ratio remains normal or may even increase because of enhanced elastic recoil.

In chronic airflow limitation (particularly in COPD and asthma) the total lung capacity (TLC) is usually increased, yet there is nearly always some reduction in the FVC. This is due to collapse of small airways causing obstruction to airflow before the normal residual volume (RV) is reached. This trapping of air within the lung is a characteristic feature of these diseases.

Peak expiratory flow rate (PEFR)

This is an extremely simple and cheap test. Subjects take a full inspiration to total lung capacity and then blow out forcefully into the peak flow meter (Fig. 15.13). The best of three attempts is recorded.

Although reproducible, PEFR is mainly dependent on the flow rate in larger airways and it may be falsely reassuring in patients with moderate airflow limitation. PEFR is mainly used to diagnose asthma, and to monitor exacerbations of asthma and response to treatment. Regular measurements of peak flow rates on waking, during the afternoon, and before going to bed demonstrate the wide diurnal variations

a Normal**b Restrictive pattern****c Airflow limitation**

Figure 15.12 Spirometry. Volume-time curves showing (a) normal patterns for age and sex, (b) restrictive pattern (FEV₁ and FVC reduced), (c) airflow limitation (FEV₁ only reduced).

in airflow limitation that characterize asthma and allow objective assessment of response to treatment (Fig. 15.14).

Other ventilatory function tests

Measurement of airways resistance in a body box (plethysmograph) is more sensitive but the equipment is expensive

a Peak flow meter

b Graph of normal readings

and the necessary manoeuvres are too exhausting for many patients with chronic airflow limitation.

Flow-volume loops

Plotting flow rates against expired volume (flow-volume loops, see Fig. 15.7) shows the site of airflow limitation within the lung. At the start of expiration from TLC, maximum resistance is from the large airways, and this affects the flow rate for the first 25% of the curve. As air is exhaled, lung volume reduces and the flow rate becomes dependent on the resistance of smaller airways. In chronic obstructive pulmonary disease (COPD), where the disease mainly affects the smaller airways, expiratory flow rates at 50% or 25% of the vital capacity are disproportionately reduced when compared with flow rates at larger lung volumes. Flow-volume loops will also show obstruction of large airways, e.g. tracheal narrowing due to tumour or retrosternal goitre.

Lung volumes

The subdivisions of lung volume are shown in Figure 15.15. Tidal volume and vital capacity can be measured using a simple spirometer, but alternative techniques are needed to measure TLC and RV. TLC is measured by inhaling air containing a known concentration of helium and measuring its dilution in the exhaled air. RV can be calculated by subtracting the vital capacity from the TLC.

Figure 15.15 The subdivisions of the lung volume.

TLC measurements using this technique are inaccurate if there are large cystic spaces in the lung, because helium cannot diffuse into them. Under these circumstances the thoracic gas volume can be measured more accurately using a body plethysmograph. The difference between measurements made by these two methods shows the extent of non-communicating air space within the lungs.

Transfer factor

To measure the efficiency of gas transfer across the alveolar-capillary membrane carbon monoxide is used as a surrogate, since its diffusion rate is similar to oxygen. A low concentration of carbon monoxide is inhaled and the rate of absorption calculated. In normal lungs the transfer factor accurately reflects the diffusing capacity of the lungs for oxygen and depends on the thickness of the alveolar-capillary membrane. In lung disease the diffusing capacity (D_{CO}) is also affected by the ventilation-perfusion relationship. To control for differences in lung volume, the uptake of carbon monoxide is expressed relative to lung volume as a transfer coefficient (K_{CO}).

Gas transfer is reduced in patients with severe degrees of emphysema and fibrosis, but also in heart failure and

anaemia. Although relatively nonspecific, gas transfer is particularly useful in the detection and monitoring of diseases affecting the lung parenchyma (e.g. idiopathic pulmonary fibrosis, sarcoidosis, asbestosis).

Measurement of blood gases

This technique is described on [page 891](#).

Measurement of the partial pressures of oxygen and carbon dioxide in arterial blood is essential in managing respiratory failure and severe asthma, when repeated measurements are often the best guide to therapy.

Peripheral oxygen saturation (S_{pO_2}) can be continuously measured using an oximeter with either ear or finger probes. Pulse oximetry has become an essential part of routine monitoring of patients in hospital and clinics. It is also useful in exercise testing and reduces the need to measure arterial blood gases.

Exhaled nitric oxide

Nitric oxide is produced by the bronchial epithelium and increases in asthma and other forms of airway inflammation. Measuring exhaled NO can guide therapy in asthma that is difficult to control.

Haematological and biochemical tests

It is useful to measure:

- Haemoglobin, to detect anaemia or polycythaemia
- Packed cell volume (secondary polycythaemia occurs with chronic hypoxia)
- Routine biochemistry (often disturbed in carcinoma and infection)
- D-dimer to detect intravascular coagulation. A negative test makes pulmonary embolism very unlikely.

Other blood investigations sometimes required include α_1 -antitrypsin levels, *Aspergillus* antibodies, viral and mycoplasma serology, autoantibody profiles and specific IgE measurements.

Sputum

Sputum should be inspected for colour:

- Yellowish-green indicates inflammation (infection or allergy)
- Blood suggests neoplasm or pulmonary infarct (see haemoptysis, [p. 798](#)).

Microbiological studies (e.g. Gram-stain and culture) are rarely helpful in upper respiratory tract infections or in acute or chronic bronchitis. They are of value in:

- Pneumonia
- Tuberculosis
- Unusual clinical problems
- *Aspergillus* lung disease.

Sputum cytology

This is useful in the diagnosis of bronchial carcinoma and asthma. Its advantages are speed, cheapness and its non-invasive nature.

However, not everyone can produce sputum and a reliable cytologist is needed. Sputum can be induced by inhalation of nebulized hypertonic saline (5%). Better samples can be obtained by bronchoscopy and bronchial washings (see [p. 797](#)).

Exercise tests

The predominant symptom in respiratory medicine is breathlessness. The degree of disability produced by

breathlessness can be assessed by asking the patient to walk for 6 minutes along a measured track. This has been shown to be a reproducible and useful test once the patient has undergone an initial training walk to overcome the learning effect. Additional information can be obtained by using pulse oximetry during exercise to assess desaturation.

More sophisticated cardiopulmonary exercise tests are useful in investigating unexplained breathlessness. Measurement of uptake of oxygen ($\dot{V}O_2$), work performed, heart rate and blood pressure together with serial ECGs allows the following:

- The early detection of lung disease
- The detection of myocardial ischaemia
- The distinction between lung and heart disease
- Assessment of fitness
- Assessment of inappropriate hyperventilation on exertion fitness.

Pleural aspiration

Diagnostic aspiration is necessary for all but very small effusions. Nowadays this is usually done under ultrasound guidance, using full aseptic precautions. A needle attached to a 20 mL syringe is inserted under local anaesthesia through an intercostal space towards the top of an area of dullness. Fluid is withdrawn and the presence of any blood is noted. Samples are sent for protein estimation, lactate dehydrogenase (LDH), cytology and bacteriological examination, including culture and Ziehl-Neelsen/auramine stain for tuberculosis. Large amounts of fluid can be aspirated through a large-bore needle to help relieve extreme breathlessness.

Pleural biopsy

Pleural biopsy used to be performed at the bedside, but is now generally done under direct vision using video-assisted thoracoscopy.

Intercostal drainage

This is carried out when large effusions are present, producing severe breathlessness, or for drainage of an empyema (see [Practical Box 15.1](#)). Drains should be inserted with ultrasound guidance. Pleurodesis is performed for recurrent/malignant effusion.

Mediastinoscopy and scalene node biopsy

Mediastinoscopy is used in the diagnosis of mediastinal masses and in staging nodal disease in carcinoma of the bronchus. An incision is made just above the sternum and a mediastinoscope inserted by blunt dissection.

Fibreoptic bronchoscopy

See [Practical Box 15.2](#) and [Fig. 15.16](#).

Under local anaesthesia and sedation, the central airways can be visualized down to subsegmental level and biopsies taken for histology. More distal lesions may be sampled by washing or blind brushing. Diffuse inflammatory and infective lung processes may be sampled by bronchoalveolar lavage and transbronchial biopsy. The yield is best in sarcoidosis, lymphangitis carcinomatosa and hypersensitivity pneumonitis. Other fibrotic lung diseases usually yield non-diagnostic samples so it may be more relevant to proceed directly to open or thoracoscopic lung biopsy. Endoscopic

**Practical Box 15.1****Intercostal drainage**

- Explain to the patient the nature of the procedure.
- Get written consent.
 1. Identify the site for aspiration (using ultrasound in most cases).
 2. Carefully sterilize the skin over the aspiration site.
 3. Anaesthetize the skin, muscle and pleura with 2% lidocaine.
 4. Make a small incision, and insert an 8–12 French gauge drain, using the Seldinger technique. A needle is used to enter the pleural space, and then withdrawn over a guide wire over which the catheter is then inserted. (A larger calibre catheter is needed for drainage of empyema, or a 28 French gauge Argyle catheter.)
 5. Attach to a three-way tap and 50 mL syringe and aspirate up to 1000 mL. Stop aspiration if the patient becomes uncomfortable – shock may ensue if too much fluid is withdrawn too quickly.
 6. If the drain is to stay in, secure to skin with suture and sterile dressing.
 7. Attach the drain to an underwater seal drainage bottle and allow fluid to drain. Clamp the drain and release periodically, especially if patient becomes uncomfortable (usually up to 1000 mL at a time before clamping for a few hours).
 8. Perform chest X-ray to check position of drain.

For pleurodesis

Tetracycline 500 mg or bleomycin 15 units in 30–50 mL sodium chloride 0.9% solution is instilled into the pleural cavity to achieve pleurodesis in recurrent/malignant effusion.

**Practical Box 15.2****Fibreoptic bronchoscopy**

This enables the direct visualization of the bronchial tree as far as the subsegmental bronchi under a local anaesthetic. Informed written consent should be obtained after explaining the nature of the procedure.

Indications

- Lesions requiring biopsy seen on chest X-ray
- Haemoptysis
- Stridor
- Positive sputum cytology for malignant cells with no chest X-ray abnormality
- Collection of bronchial secretions for bacteriology, especially tuberculosis
- Recurrent laryngeal nerve paralysis of unknown aetiology
- Infiltrative lung disease (to obtain a transbronchial biopsy)
- Investigation of collapsed lobes or segments and aspiration of mucus plugs.

Disadvantages

- All patients require sedation to tolerate the procedure.
- Minor and transient cardiac dysrhythmias occur in up to 40% of patients on passage of the bronchoscope through the larynx. Monitoring is required.
- Oxygen supplementation is required in patients with P_{aO_2} below 8 kPa.
- Fibreoptic bronchoscopy should be performed with care in the very sick, and transbronchial biopsies avoided in ventilated patients owing to the increased risk of pneumothorax.
- Massive bleeding may occur after biopsy of vascular lesions or carcinoid tumours. Rigid bronchoscopy may be required to allow adequate access to the bleeding point for haemostasis.

Figure 15.16 Normal endobronchial appearances as seen at fibreoptic bronchoscopy.

bronchoscopic ultrasound enables direct sampling of lymph nodes for diagnostic staging of lung cancer.

Video-assisted thoracoscopic (VATS) lung biopsy

This technique has largely replaced open thoracotomy when a lung biopsy is required (p. 850).

Skin-prick tests

Allergen solutions are placed on the skin (usually the volar surface of the forearm) and the epidermis is broken using a 1 mm tipped lancet. A separate lancet should be used for each allergen. If the patient is sensitive to the allergen a wheal develops. The wheal diameter is measured after 10 minutes. A wheal of at least 3 mm diameter is regarded as positive provided that the control test is negative. The results should always be interpreted in the light of the history. Skin tests are not affected by bronchodilators or corticosteroids but antihistamines should be discontinued at least 48 hours before testing.

SMOKING AND AIR POLLUTION

Smoking

Prevalence

Cigarette smoking is declining in the western world. In 1974 in the UK, 51% of men and 41% of women smoked cigarettes – nearly half the adult population. Now 22% of men and 21% of women aged 16 years and over smoke. The highest rates are in women aged 20–24, 31% of whom smoke, and men aged 25–34, 30% of whom smoke. The highest rates of cigarette consumption per capita are in Greece, Russia and parts of Eastern Europe. In global terms the USA ranks 39th and the UK is now down to 65th, close to the rates in Sweden and Malaysia. Smoking continues to increase in many developing countries, particularly among women.

Toxic effects

Cigarette smoke contains polycyclic aromatic hydrocarbons and nitrosamines, which are potent carcinogens and mutagens in animals. It causes release of enzymes from neutrophil granulocytes and macrophages that are capable of destroying elastin and leading to lung damage. Pulmonary epithelial permeability increases even in symptomless cigarette smokers, and correlates with the concentration of carboxy-haemoglobin in blood. This altered permeability may allow easier access for carcinogens.

Table 15.6 The dangers of cigarette smoking**General**

Lung cancer
 COPD
 Carcinoma of the oesophagus
 Ischaemic heart disease
 Peripheral vascular disease
 Bladder cancer
 An increase in abnormal spermatozoa
 Memory problems

Maternal smoking

A decrease in birthweight of the infant
 An increase in fetal and neonatal mortality
 An increase in asthma

Passive smoking

Risk of asthma, pneumonia and bronchitis in infants of smoking parents
 An increase in cough and breathlessness in smokers and non-smokers with COPD and asthma
 Increased cancer risk

Table 15.7 Effects of smoking on the lung**Large airways**

Increase in submucosal gland volume
 Increase in number of goblet cells
 Chronic inflammation
 Metaplasia and dysplasia of the surface epithelium

Small airways

Increase in number and distribution of goblet cells
 Airway inflammation and fibrosis
 Epithelial metaplasia/dysplasia
 Carcinoma

Parenchyma

Proximal acinar scarring
 Increase in alveolar macrophage numbers
 Emphysema (centri-acinar, pan-acinar)

The dangers

Cigarette smoking is addictive and harmful to health (Table 15.6). People usually start smoking in adolescence for psychosocial reasons and, once they smoke regularly, the pharmacological properties of nicotine encourage persistence, by their effect on the smoker's mood. Very few cigarette smokers (<2%) can limit themselves to occasional or intermittent smoking.

Significant dose-response relationships exist between cigarette consumption, airway inflammation (Table 15.7) and lung cancer mortality. Sputum production and airflow limitation increase with daily cigarette consumption, and effort tolerance decreases. Smoking 20 cigarettes daily for 20 years increases the lifetime risk of lung cancer by about 10 times compared to a lifelong non-smoker. Smoking and asbestos exposure are synergistic risk factors for lung cancer, with a combined risk of about 90 times that of unexposed non-smokers.

Cigarette smokers who change to cigars or pipe-smoking can reduce their risk of lung cancer. However, pipe and cigar smokers remain at greater risk of lung cancer than lifelong non-smokers or former smokers.

Environmental tobacco smoke ('passive smoking') has been shown to increase the frequency and severity of asthma attacks in children and may also increase the incidence of asthma. It is also associated with a small but definite increase in lung cancer. Worldwide, second hand smoke was estimated to affect 40% of children, 33% of non-smoking males and 35% of non-smoking females in 2004. This caused a 1% worldwide mortality and 0.7% of the total worldwide burden of disease in DALYs (disability-adjusted life years).

Stopping smoking

If the entire population could be persuaded to stop smoking, the effect on healthcare use would be enormous. National campaigns, bans on advertising and a substantial increase in the cost of cigarettes are the best ways of achieving this at the population level. Smoking bans in the workplace, pubs and public spaces have also helped. Meanwhile, active encouragement to stop smoking remains a useful approach for individuals. Smokers who want to stop should have access to smoking cessation clinics to provide behavioural support. Nicotine replacement therapy (NRT) and bupropion are effective aids to smoking cessation in those smoking >10 cigarettes/day. Both should only be used in smokers who commit to a target stop date, and the initial prescription should be for 2 weeks beyond the target stop date. NRT is the preferred choice; there is no evidence that combined therapy offers any advantage. Therapy should be changed after 3 months if abstinence is not achieved.

Varenicline is an oral partial agonist on the $\alpha_4\beta_2$ subtype of the nicotinic acetylcholine receptor. It stimulates the nicotine receptor and reduces withdrawal symptoms and also the craving for cigarettes. A 12-week course increases the chance of stopping smoking four times; its main side-effects are nausea and sometimes severe depression. Cytisine, which has high affinity for the same receptor, also aids smoking cessation.

Air pollution and epidemiology

Atmospheric air pollution, due to the burning of coal for energy and heat, has been a feature of urban living in developed countries for at least two centuries. It consists of black smoke and sulphur dioxide (SO_2). Air pollution of this type peaked in the 1950s in the UK, until legislation led to restrictions on coal burning. Such pollution remains common in some parts of Eastern Europe and Russia and is increasing in newly industrialized countries (especially India and China). The combustion of hydrocarbon fuels in motor vehicles has led to new forms of air pollution, consisting of primary pollutants such as nitrogen oxides (NO and NO_2), diesel particulates, polyaromatic hydrocarbons and ozone, a secondary pollutant generated by photochemical reactions in the atmosphere (ozone levels are highest in sunny, rural areas). Levels of NO_2 can be high in poorly ventilated kitchens and living rooms where gas is used for cooking and in fires.

Particulate matter consists of coarse particles (10–2.5 μm in aerodynamic diameter), produced by construction work and farming, and fine particles (<2.5 μm) generated from burning fossil fuels. Fine particulates ($\text{PM}_{2.5}$) remain airborne for long periods and are carried into rural areas. Several respiratory and cardiac problems are exacerbated by these very small particles.

The WHO global air-quality guidelines suggest 24 hour values of <25 $\mu\text{g}/\text{m}^3$ for PM_{25} for the short term and 10 $\mu\text{g}/\text{m}^3$ in the long term. In Europe, 70% of the particulates present in urban air result from the combustion of diesel fuel, providing a background concentration of 3–5 $\mu\text{g}/\text{m}^3$. The WHO estimates that air pollution causes 800 000 premature deaths worldwide every year.

Deaths from respiratory and cardiovascular disease occur mainly in older populations; air pollution mainly causes bronchitis in children. Pollution from motor vehicles has been linked to increased hospital admissions, reduced lung function in children and younger adults and an increase in lung cancer (polyaromatic hydrocarbons).

WHO. WHO Air quality guidelines for particulate matter, ozone, nitrogen dioxide and sulfur dioxide. Global update 2005. Copenhagen: World Health Organization; 2005.

Table 15.8 Air pollutants and their health effects

	Average concentration	Poor air quality	Susceptible individuals	Mechanisms of health effects
Sulphur dioxide (SO₂)	5–15 ppb	>125 ppb	Asthmatics	Bronchoconstriction through neurogenic mechanism
Ozone (O₃)	10–30 ppb	>90 ppb	All affected, particularly during exercise	Restrictive lung defect Airway inflammation Enhanced response to allergen
Nitrogen dioxide (NO₂)	25–40 ppb	>100 ppb	Allergic individuals	Airway inflammation Enhanced response to allergen
Particulate matter PM ₁₀	25–30 µg/m ³	>65 µg/m ³	Elderly Allergic individuals	Airway and alveolar inflammation Enhanced production selectively of the allergy antibody (IgE)
PM _{2.5}	3–5 µg/m ³	>25 µg/m ³	With cardiac and respiratory disease	Airway inflammation
ppb, parts per billion.				

Although it has been proposed that air pollution may cause asthma and other allergic diseases, there is no current evidence for this (Table 15.8). However, air pollution does adversely affect lung development in teenage children, while both NO₂ and ozone enhance the nasal and lung airway responses to inhaled allergen in people with established allergic disease.

Management

When air quality is poor, asthmatics are advised to avoid exercising outdoors and to increase their anti-inflammatory medication (i.e. inhaled corticosteroids).

Short- and long-term measures are required to reduce air pollution, particularly diesel particulates (which are predicted to increase as more diesel engines are used). Such measures include increased motor engine efficiency, catalytic converters, diesel particulate traps and decreased reliance on cars and trucks.

DISEASES OF THE UPPER RESPIRATORY TRACT

The common cold (acute coryza)

This highly infectious illness causes a mild systemic upset and prominent nasal symptoms. It is due to infection by a wide range of respiratory viruses, of which the rhinoviruses are the most common. Other common cold viruses include coronaviruses and adenoviruses. Infectivity from close personal contact (nasal mucus on hands) or droplets is high in the early stages of the infection, and spread is facilitated by overcrowding and poor ventilation. There are at least 100 different antigenic strains of rhinovirus, making it difficult for the immune system to confer protection. On average, individuals suffer two to three colds per year, but the incidence lessens with age, presumably as a result of accumulating immunity to different virus strains. The incubation period varies from 12 hours to 5 days.

The clinical features are tiredness, slight pyrexia, malaise and a sore nose and pharynx. Sneezing and profuse, watery nasal discharge are followed by thick mucopurulent secretions which may persist for up to a week. Secondary bacterial infection occurs only in a minority of cases.

Sinusitis (see p. 1052)

Rhinitis

Rhinitis is defined clinically as sneezing attacks, nasal discharge or blockage occurring for more than an hour on most days:

- For a limited period of the year (seasonal or intermittent rhinitis)
- Throughout the whole year (perennial or persistent rhinitis).

Seasonal rhinitis

This is the commonest allergic disorder. It is often called 'hayfever' but as this implies that only grass pollen is responsible, it is better described as seasonal (or intermittent) allergic rhinitis. Worldwide prevalence rates vary from 2% to 20%. Prevalence is maximal in the 2nd decade, and up to 30% of UK teenagers and young adults are affected each June and July.

Nasal irritation, sneezing and watery rhinorrhoea are the most troublesome symptoms, but many also suffer from itching of the eyes and soft palate and occasionally even itching of the ears because of the common innervation of the pharyngeal mucosa and the ear. In addition, approximately 20% suffer from seasonal wheezing. The common seasonal allergens are shown in Figure 15.17. Since pollination of plants that give rise to high pollen counts varies from country to country, seasonal rhinoconjunctivitis and accompanying wheeze may occur at different times of year in different regions.

Perennial rhinitis

Patients with perennial rhinitis rarely have symptoms that affect the eyes or throat. Half have symptoms predominantly of sneezing and watery rhinorrhoea, whilst the other half complain mostly of nasal blockage. The patient may lose the sense of smell and taste. Sinusitis occurs in about 50% of cases, due to mucosal swelling that obstructs drainage from the sinuses. Perennial rhinitis is most frequent in the 2nd and 3rd decades, decreasing with age, and can be divided into four main types.

Perennial allergic rhinitis

The commonest cause is allergy to the faecal particles of the house-dust mite *Dermatophagoides pteronyssinus* or

Figure 15.17 Seasonal allergic rhinitis. Bar graph showing the proportion of patients whose symptoms are worst in the month or months indicated. The causative agents are also shown.

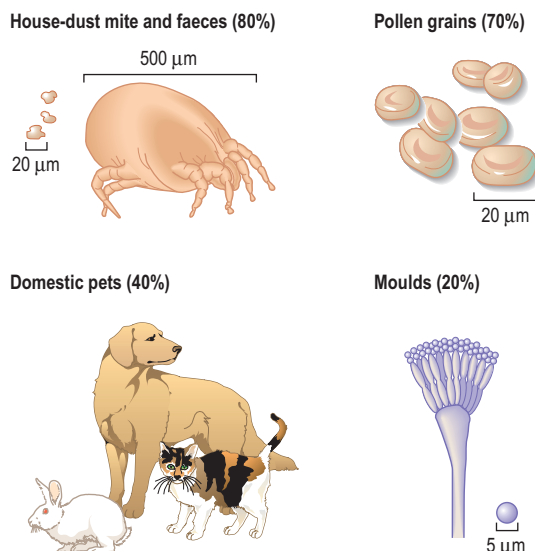

Figure 15.18 Common allergens causing allergic rhinitis and asthma. The house-dust mite, faeces of house-dust mites, pollen grains, domestic pets and moulds. Percentages are those of positive skin-prick tests to these allergens in patients with allergic rhinitis.

D. farinae; these are under 0.5 mm in size, invisible to the naked eye (Fig. 15.18), and found in dust throughout the house, particularly in older, damp dwellings. Mites live off desquamated human skin scales and the highest concentrations (4000 mites/g of surface dust) are found in human bedding. Their faecal particles are approximately 20 µm in diameter (Fig. 15.18), and impact in the nose rather than the lungs, unless the patient breathes through their mouth.

The next most common allergens come from domestic pets (especially cats) and are proteins derived from urine or saliva spread over the surface of the animal as well as skin protein. Allergy to urinary protein from small mammals is a major cause of morbidity among laboratory workers.

Industrial dust, vapours and fumes cause occupationally related perennial rhinitis more often than asthma.

The presence of perennial rhinitis makes the nose more reactive to nonspecific stimuli such as cigarette smoke, washing powders, household detergents, strong perfumes and traffic fumes. Although patients often think they are allergic to these stimuli, these are irritant responses and do not involve antibodies.

Perennial non-allergic rhinitis with eosinophilia

No extrinsic allergic cause can be identified, either from the history or on skin testing, but eosinophilic granulocytes are present in nasal secretions. Most of these patients are intolerant of aspirin/NSAIDs.

Vasomotor rhinitis

These patients with perennial rhinitis have no demonstrable allergy or nasal eosinophilia. Watery secretions and nasal congestion are triggered by, for example, cold air, smoke, perfume, newsprint, possibly because of an imbalance of the autonomic nerves controlling the erectile tissue (sinusoids) in the nasal mucosa.

Nasal polyps

These are round, smooth, soft, semi-translucent, pale or yellow, glistening structures attached to the sinus mucosa by a relatively narrow stalk or pedicle, occurring in patients with allergic or vasomotor rhinitis. The mechanism(s) of their formation is not known. They contain mast cells, eosinophils and mononuclear cells in large numbers and cause nasal obstruction, loss of smell and taste, and mouth breathing, but rarely sneezing, since the mucosa of the polyp is largely denervated.

Pathogenesis

Sneezing, increased secretion and changes in mucosal blood flow are mediated both by efferent nerve fibres and by released mediators (see p. 827). Mucus production results largely from parasympathetic stimulation. Blood vessels are under both sympathetic and parasympathetic control. Sympathetic fibres maintain tonic contraction of blood vessels, keeping the sinusoids of the nose partially constricted with good nasal patency. Stimulation of the parasympathetic system dilates these blood vessels. This stimulation varies spontaneously in a cyclical fashion so that air intake alternates slowly over several hours from one nostril to the other. The erectile cavernous nasal sinusoids can be influenced by emotion, which, in turn, can affect nasal patency.

B cells produce IgE antibody against the allergen. IgE binds to mast cells via high affinity cell surface receptors, causing degranulation and release of histamine, proteases (tryptase, chymase), prostaglandins (PGDs), cysteinyl leukotrienes (LTC₄, LTD₄, LTE₄), and cytokines. This causes the acute symptoms of sneezing, itch, rhinorrhoea and nasal congestion. Sneezing results from stimulation of afferent nerve endings (mostly via histamine) and begins within minutes of the allergen entering the nose. This is followed by nasal exudation and secretion and eventually nasal blockage peaking 15–20 minutes after contact with the allergen. These latter symptoms are driven by increased epithelial permeability, mostly due to histamine.

Additionally, allergens are also presented to T cells via antigen presenting cells (dendritic cells). This causes a release of IL-4 and IL-13 which further stimulate the B cells and also IL-5, IL-9 and GM-CSF, switching from a Th1 to a Th2 response to activate and recruit eosinophils, basophils, neutrophils and T lymphocytes. These cause chronic swelling

and irritation, leading to nasal obstruction, hyper-reactivity and anosmia.

Investigations and diagnosis

The allergic factors causing rhinitis can usually be identified from the history. Skin-prick testing is used to support the history. A positive test does not necessarily mean that the particular allergen producing the wheal causes the respiratory disease. However, if there is a compatible clinical history, a causative role is likely. Allergen-specific IgE antibodies can be measured in blood but such tests are much more expensive than skin tests and should only be used in patients who cannot be skin tested for some reason (e.g. dermatographism, active eczema or inability to stop antihistamines for 3 days before skin tests).

Treatment

Allergen avoidance

Removal of a household pet or total enclosure of industrial processes releasing sensitizing agents can lead to cure of rhinitis and, indeed, asthma.

Pollen avoidance is impossible. Contact may be diminished by wearing sunglasses, driving with the car windows shut, avoiding walks in the countryside (particularly in the late afternoon when the number of pollen grains is highest at ground level), and keeping the bedroom window shut at night. These measures are rarely sufficient in themselves to control symptoms. Exposure to pollen is generally lower in coastal regions, where sea breezes keep pollen grains inland.

The house-dust mite infests most areas of the house, but particularly the bedroom. Mite allergen exposure can be reduced by enclosing bedding in fabric specifically designed to prevent the passage of mite allergen, while allowing water vapour through. This is both comfortable and reduces symptoms. Acaricides are less effective and cannot be recommended. Increased room ventilation and reduced soft furnishings including carpets, curtains and soft toys are all helpful in reducing the mite load. However, a meta-analysis has questioned the value of house-dust mite control measures in asthma (p. 829).

H₁ antihistamines

Antihistamines remain the most common therapy for rhinitis, and many can be purchased directly over the counter in the UK. They are particularly effective against sneezing and itching of the eyes and palate, but are less effective against rhinorrhoea and have little influence on nasal blockage. First-generation antihistamines (chlorphenamine, hydroxyzine) cause sedation and loss of concentration in all patients (including those who are not aware of the problem) and should no longer be used. Second-generation drugs such as loratadine (10 mg once daily), desloratadine (5 mg daily), cetirizine (10 mg daily), and fexofenadine (120 mg daily) are at least as potent and they do not cause sedation.

Decongestants

Drugs with sympathomimetic activity (α -adrenergic agents) are widely used to treat nasal obstruction. They may be taken orally or more commonly as nasal drops or sprays (e.g. ephedrine nasal drops). Xylometazoline and oxymetazoline are widely used because they have a prolonged action and tachyphylaxis does not develop. Secondary nasal hyperaemia can occur some hours later as a rebound effect and rhinitis medicamentosa can develop if patients take increasing quantities of decongestant to overcome this phenomenon. Although local decongestants are an effective treatment

for vasomotor rhinitis, patients must be warned about rebound nasal obstruction and should use the drugs carefully. Usually, such preparations should be prescribed for only a limited period to open the nasal airways and allow better access for other local therapy, such as topical corticosteroids.

Anti-inflammatory drugs

Sodium cromoglycate and nedocromil sodium act by blocking an intracellular chloride channel and influence mast cell and eosinophil activation and nerve function. Topical sodium cromoglycate and nedocromil sodium can be very effective in allergic conjunctivitis but are of limited value in allergic rhinitis.

Corticosteroids

The most effective treatment for rhinitis is a topical corticosteroid preparation (e.g. beclometasone, fluticasone propionate, fluticasone furoate or mometasone furoate spray). Topical steroids should be started before the beginning of seasonal symptoms. The combination of a topical corticosteroid with a non-sedating antihistamine taken regularly is particularly effective. Patients should be carefully instructed in how to use the nasal steroid device to achieve optimal drug deposition. In selected cases, an α -adrenergic agonist may help to decongest the nose prior to taking the topical corticosteroid. Patients often worry about possible side-effects: nasal steroids can cause epistaxis, but the amount used is insufficient to cause systemic effects.

If other therapy has failed, seasonal and perennial rhinitis respond readily to a short course (max. 2 weeks) of treatment with oral prednisolone 5–10 mg daily. Nasal polyps may respond to oral corticosteroids and their recurrence may be prevented by continuous use of topical corticosteroids.

Leukotriene antagonists

In patients who do not respond to antihistamines or topical steroids, a leukotriene antagonist (e.g. montelukast 10 mg daily in the evening) may be helpful, especially in those with a history of NSAID sensitivity or concomitant asthma.

Immunotherapy

This is used for patients with seasonal allergic rhinitis who have not responded to the above. Both oral and injectable vaccines are available (p. 69). Other forms of desensitizing vaccines are under development.

Pharyngitis

The most common viruses causing pharyngitis are adenoviruses, of which there are about 32 serotypes. Endemic adenovirus infection causes the common sore throat, in which the oropharynx and soft palate are reddened and the tonsils are inflamed and swollen. Within 1–2 days the tonsillar lymph nodes enlarge. Occasionally, localized epidemics due to adenovirus serotype 8 occur, particularly in schools during summer, with episodes of fever, conjunctivitis, pharyngitis and lymphadenitis of the neck glands. The disease is self-limiting and only requires symptomatic treatment without antibiotics.

Over several decades, the proportion of sore throats due to bacterial infections, e.g. haemolytic streptococcus, has fallen. Many different pathogens have been implicated in pharyngitis but most do not require specific treatment. Persistent and severe tonsillitis should be treated with phenoxymethylpenicillin 500 mg four times a day or cefaclor 250 mg three times daily. Amoxicillin and ampicillin should

be avoided if there is a possibility of infectious mononucleosis (p. 100).

Acute laryngotracheobronchitis

Acute laryngitis is an occasional but striking complication of upper respiratory tract infections, particularly those caused by parainfluenza viruses and measles. The condition is most severe in children under the age of 3 years. Inflammatory oedema extends to the vocal cords and the epiglottis, causing narrowing of the airway; there may be associated *tracheitis* or *tracheobronchitis*. The voice becomes hoarse, with a barking cough (croup) and there is audible stridor. Progressive airways obstruction may occur, with recession of the soft tissue of the neck and abdomen during inspiration and, in severe cases, central cyanosis. Steam inhalations are not helpful. Nebulized adrenaline (epinephrine) gives short-term relief. Oral or i.m. corticosteroids (e.g. dexamethasone) should be given with oxygen and adequate fluids. If steroids are used, endotracheal intubation is rarely necessary. Rarely, a tracheostomy is required.

Acute epiglottitis

H. influenzae type b (Hib) can cause life-threatening infection of the epiglottis, usually in children under 5 years of age. The child becomes extremely ill with a high fever, and severe airflow obstruction may rapidly occur. This is a life-threatening emergency and requires urgent endotracheal intubation and intravenous antibiotics (e.g. ceftazidime 25–150 mg/kg). Chloramphenicol (50–100 mg/kg) can also be used. The epiglottis, which is red and swollen, should not be inspected until facilities to maintain the airways are available.

Other manifestations of Hib infection are meningitis, septic arthritis and osteomyelitis. A highly effective vaccine is now available, which is given to infants at 2, 3 and 4 months, with their primary immunizations against diphtheria, tetanus and pertussis (DTP). This programme has reduced death rates from Hib infections virtually to zero in many countries.

Influenza (see also p. 108)

The influenza virus belongs to the orthomyxovirus group and exists in two main forms, A and B. Influenza B is associated with localized outbreaks of mild disease, whereas influenza A causes worldwide pandemics (see p. 108).

Clinical features

The incubation period of influenza is usually 1–3 days. The illness starts abruptly with a fever, shivering and generalized aching in the limbs. This is associated with severe headache, soreness of the throat and a dry cough that can persist for several weeks. Diarrhoea occurs in 70% of cases of H5N1. Influenza infection can be followed by a prolonged period of debility and depression that may take weeks or months to clear.

Complications

Secondary bacterial infection is common following influenza virus infection, particularly with *Strep. pneumoniae* and *H. influenzae*. Secondary pneumonia caused by *Staph. aureus* is rarer, but more serious, and carries a mortality of up to 20%. Post-infectious encephalomyelitis is rare after influenza infection.

Diagnosis and treatment

Laboratory diagnosis is not usually necessary, but a definitive diagnosis can be established by demonstrating a four-fold

increase in complement-fixing antibody or the haemagglutinin antibody measured at onset and after 1–2 weeks or by demonstrating the virus in throat or nasal secretions.

Treatment is by bed rest and paracetamol, with antibiotics to prevent secondary infection in those with chronic bronchitis, cardiac or renal disease.

Neuraminidase inhibitors help to shorten the duration of symptoms in patients with influenza, if given within 48 h of the first symptom. The cost-benefit of zanamivir and oseltamivir remains unproven but these are currently recommended in the UK for patients with suspected influenza over the age of 65 and 'at-risk' adults, as part of a strategy to reduce admissions to hospital when influenza is circulating in the community.

Prophylaxis

Protection by influenza vaccines is only effective in about 70% of people and only lasts for about a year. Influenza vaccine should not be given to individuals who are allergic to egg protein as some are manufactured in chick embryos. New vaccines have to be prepared to cover each change in viral antigenicity and are therefore in limited supply at the start of an epidemic. Nevertheless, routine vaccination is recommended for all individuals over 65 years of age and also for younger people with chronic heart disease, chronic lung disease (including asthma), chronic kidney disease, diabetes mellitus and those who are immunosuppressed. During pandemics, key hospital and health service personnel should also be vaccinated.

Inhalation of foreign bodies

Children inhale foreign bodies, e.g. peanuts, more commonly than do adults. In adults, inhalation may occur after excess alcohol or under general anaesthesia (loose teeth or dentures).

When the foreign body is large it may impact in the trachea. The person chokes and then becomes silent; death ensues unless the material is quickly removed (see **Emergency Box 15.1**).

More often, impaction occurs in the right main bronchus and produces:

- Choking
- Persistent monophonic wheeze
- Persistent suppurative pneumonia
- Lung abscess (common).

Emergency Box 15.1

Treatment of inhaled foreign bodies (Heimlich manoeuvre)

Emergency

The Heimlich manoeuvre is used to expel the obstructing object:

1. Stand behind the patient.
2. Encircle your arms around the upper part of the abdomen just below the patient's rib cage.
3. Give a sharp, forceful squeeze, forcing the diaphragm sharply into the thorax. This should expel sufficient air from the lungs to force the foreign body out of the trachea.

Non-emergency

Rigid bronchoscopy should be performed.

DISEASES OF THE LOWER RESPIRATORY TRACT

Lower respiratory tract infection accounts for approximately 10% of the worldwide burden of morbidity and mortality. Some 75% of all antibiotic usage is for these diseases, despite the fact that they are mainly due to viruses.

Acute bronchitis

Acute bronchitis in previously healthy subjects is often viral. Bacterial infection with *Strep. pneumoniae* or *H. influenzae* is a common sequel to viral infections, and is more likely to occur in cigarette smokers or people with chronic obstructive pulmonary disease (COPD).

The illness begins with an irritating, non-productive cough, together with discomfort behind the sternum. There may be associated chest tightness, wheezing and shortness of breath. Later the cough becomes productive, with yellow or green sputum. There is a mild fever and a neutrophil leucocytosis; wheeze with occasional crackles can be heard on auscultation. In otherwise healthy adults the disease improves spontaneously in 4–8 days without the patient becoming seriously ill.

Antibiotics are often given (e.g. amoxicillin 250 mg three times daily), but it is not known whether this hastens recovery in otherwise healthy individuals.

Chronic obstructive pulmonary disease (COPD)

COPD is predicted to become the third most common cause of death and fifth most common cause of disability worldwide by 2020.

The term COPD was introduced to bring together a variety of clinical syndromes associated with airflow obstruction and destruction of the lung parenchyma. The older terms 'chronic obstructive airways disease' and 'chronic obstructive lung disease' are synonymous with COPD. Prior to 1979, patients with COPD were often classified by symptoms (chronic bronchitis, chronic asthma), by pathological changes (emphysema) or by physiological correlates (pink puffers, blue bloaters). Recognition that these entities overlapped and often co-existed led to introduction of the term COPD.

COPD is associated with a number of co-morbidities, e.g. ischaemic heart disease, hypertension, diabetes, heart failure and cancer, suggesting that it may be part of a generalized systemic inflammatory process.

Definition of COPD

COPD has been described as 'a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases'.

Epidemiology and aetiology

COPD is caused by long-term exposure to toxic particles and gases. In developed countries, cigarette smoking accounts for over 90% of cases. In developing countries other factors, such as the inhalation of smoke from biomass fuels used in heating and cooking in poorly ventilated areas, are also implicated. However, only 10–20% of heavy smokers develop COPD, indicating individual susceptibility. The development of COPD is proportional to the number of cigarettes smoked per day; the risk of death from COPD in patients smoking 30

cigarettes daily is 20 times that of a non-smoker. Autopsy studies have shown substantial numbers of centri-acinar emphysematous spaces in the lungs of 50% of British smokers over the age of 60 years independent of whether significant respiratory disease was diagnosed before death.

Climate and air pollution are lesser causes of COPD, but mortality from COPD increases dramatically during periods of heavy atmospheric pollution (p. 341). Urbanization, social class and occupation may also play a part in aetiology, but these effects are difficult to separate from that of smoking. Some animal studies suggest that diet could be a risk factor for COPD, but this has not been proven in humans.

The socioeconomic burden of COPD is considerable. In the UK, COPD causes approximately 18 million lost working days annually for men and 2.1 million lost working days for women, accounting for approximately 7% of all days of absence from work due to sickness. Nevertheless, the number of COPD admissions to UK hospitals has been falling steadily over the last 30 years.

Pathophysiology

The most consistent pathological finding in COPD is increased numbers of mucus-secreting goblet cells in the bronchial mucosa, especially in the larger bronchi (Fig. 15.19). In more advanced cases, the bronchi become overtly inflamed and pus is seen in the lumen.

Microscopically, there is infiltration of the walls of the bronchi and bronchioles with acute and chronic inflammatory cells; lymphoid follicles may develop in severe disease. In contrast to asthma, the lymphocytic infiltrate is predominantly CD8⁺. The epithelial layer may become ulcerated and, with time, squamous epithelium replaces the columnar cells. The inflammation is followed by scarring and thickening of the walls which narrows the small airways (Fig. 15.20).

The small airways are particularly affected early in the disease, initially without the development of any significant breathlessness. This initial inflammation of the small airways is reversible and accounts for the improvement in airway function if smoking is stopped early. In later stages the inflammation continues, even if smoking is stopped.

Further progression of the airways disease leads to progressive squamous cell metaplasia, and fibrosis of the

Figure 15.20 Pathological changes in the airways in COPD.

bronchial walls. The physiological consequence of these changes is the development of airflow limitation. If the airway narrowing is combined with emphysema (causing loss of the elastic recoil of the lung with collapse of small airways during expiration) the resulting airflow limitation is even more severe.

Emphysema is defined as abnormal, permanent enlargement of air spaces distal to the terminal bronchiole, accompanied by destruction of their walls and without obvious fibrosis. Recent evidence suggests that the enlargement of the distal air spaces (i.e. emphysema) is a secondary result of small airway inflammation and destruction. It is classified according to the site of damage:

- **Centri-acinar emphysema.** Distension and damage of lung tissue is concentrated around the respiratory bronchioles, whilst the more distal alveolar ducts and alveoli tend to be well preserved. This form of emphysema is extremely common; when of modest extent, it is not necessarily associated with disability. Severe centri-acinar emphysema is associated with substantial airflow limitation.
- **Pan-acinar emphysema.** This is less common. Distension and destruction affect the whole acinus, and in severe cases the lung is just a collection of bullae. Severe airflow limitation and \dot{V}_A/\dot{Q} mismatch occur. α_1 -Antitrypsin deficiency is associated with this type of emphysema (see p. 341).
- **Irregular emphysema.** There is scarring and damage affecting the lung parenchyma patchily independent of acinar structure.

Emphysema leads to expiratory airflow limitation and air trapping. The loss of lung elastic recoil results in an increase in TLC. Premature closure of airways limits expiratory flow while the loss of alveoli decreases capacity for gas transfer.

\dot{V}_A/\dot{Q} mismatch is partly due to damage and mucus plugging of smaller airways from chronic inflammation, and partly due to rapid closure of smaller airways in expiration owing to loss of elastic support. The mismatch leads to a fall in P_{aO_2} and increased work of respiration.

CO_2 excretion is less affected by \dot{V}_A/\dot{Q} mismatch and many patients have low normal P_{aCO_2} values due to increasing alveolar ventilation in an attempt to correct their hypoxia. Other patients fail to maintain their respiratory effort and then their P_{aCO_2} levels increase. In the short term, this rise in CO_2 leads to stimulation of respiration but in the longer term, these patients often become insensitive to CO_2 and come

Figure 15.21 Influence of smoking on airflow limitation.

(From Fletcher CM, Peto R. The natural history of chronic airflow obstruction. *British Medical Journal* 1977; 1:1645.)

to depend on hypoxaemia to drive their ventilation. Such patients appear less breathless and because of renal hypoxia they start to retain fluid and increase erythrocyte production (leading eventually to polycythaemia). In consequence they become bloated, plethoric and cyanosed, the typical appearance of the 'blue bloater'. Attempts to abolish hypoxaemia by administering oxygen can make the situation much worse by decreasing respiratory drive in these patients who depend on hypoxia to drive their ventilation.

The classic Fletcher and Peto studies (Fig. 15.21) show that there is a loss of 50 mL per year in FEV_1 in patients with COPD compared with 20 mL per year in healthy people. A recent study has shown a 40 mL loss per year but only in 38% of the patients studied. Biomarkers to indicate the rate of decline have been unhelpful although CC16 (Clare cell secretory protein 16) was shown to be a reasonable indicator in a study.

In summary, three mechanisms have been suggested for this limitation of airflow in small airways (<2 mm in diameter).

- Loss of elasticity and alveolar attachments of airways due to emphysema. This reduces the elastic recoil and the airways collapse during expiration.
- Inflammation and scarring cause the small airways to narrow.
- Mucus secretion, which blocks the airways.

Each of these narrows the small airways and causes air trapping leading to hyperinflation of the lungs, \dot{V}_A/\dot{Q} mismatch, increased work of breathing and breathlessness.

Pathogenesis

Cigarette smoking

Bronchoalveolar lavage and biopsies of the airways of smokers show increased numbers of neutrophil granulocytes. These granulocytes can release elastases and proteases, which may help to produce emphysema. It has been suggested that an imbalance between protease and antiprotease activity causes the damage. α_1 -Antitrypsin is a major serum antiprotease which can be inactivated by cigarette smoke (see below).

Mucous gland hypertrophy in the larger airways is thought to be a direct response to persistent irritation resulting from the inhalation of cigarette smoke. The smoke has an adverse effect on surfactant, favouring overdistension of the lungs.

Infections

Patients with COPD cope badly with respiratory infections, which are often the precipitating cause of acute exacerbations of the disease. However, it is less clear whether

infection is responsible for the progressive airflow limitation that characterizes disabling COPD. Prompt use of antibiotics and routine vaccinations against influenza and pneumococci are appropriate.

α_1 -Antitrypsin deficiency

α_1 -Antitrypsin (see also p. 341) is a proteinase inhibitor which is produced in the liver, secreted into the blood and diffuses into the lung. Here it inhibits proteolytic enzymes such as neutrophil elastase, which are capable of destroying alveolar wall connective tissue.

More than 75 alleles of the α_1 -antitrypsin gene have been described. The three main phenotypes are MM (normal), MZ (heterozygous deficiency) and ZZ (homozygous deficiency). About 1 child in 5000 in Britain is born with the homozygous deficiency, but not all develop chest disease. Those who do develop breathlessness under the age of 40 years have radiographic evidence of basal emphysema and are usually, but not always, cigarette smokers. Hereditary deficiency of α_1 -antitrypsin accounts for about 2% of emphysema cases. A small minority develop liver disease (see p. 341).

Clinical features

Symptoms

The characteristic symptoms of COPD are productive cough with white or clear sputum, wheeze and breathlessness, usually following many years of a smoker's cough. Colds seem to 'settle on the chest' and frequent infective exacerbations occur, with purulent sputum. Symptoms can be worsened by cold, foggy weather and atmospheric pollution. With advanced disease, breathlessness is severe even after mild exercise such as getting dressed. Apart from the pulmonary features, there are systemic effects including hypertension, osteoporosis, depression, weight loss and reduced muscle mass with general weakness.

Signs

In mild COPD, there may be no signs or just quiet wheezes throughout the chest. In severe disease, the patient is tachypnoeic, with prolonged expiration. The accessory muscles of respiration are used and there may be intercostal indrawing on inspiration and pursing of the lips on expiration (see p. 792). Chest expansion is poor, the lungs are hyperinflated, and there is loss of the normal cardiac and liver dullness.

Patients who remain responsive to CO_2 are usually breathless and rarely cyanosed. Heart failure and oedema are rare features except as terminal events. In contrast, patients who become insensitive to CO_2 are often oedematous and cyanosed but not particularly breathless. Those with hypercapnia may have peripheral vasodilatation, a bounding pulse, and when the $P_a\text{CO}_2$ is above about 10 kPa, a coarse flapping tremor of the outstretched hands. Severe hypercapnia

causes confusion and progressive drowsiness. Papilloedema may be present but this is neither specific nor sensitive as a diagnostic feature.

Respiratory failure

The later stages of COPD are characterized by the development of respiratory failure. For practical purposes this is said to occur when there is either a $P_a\text{O}_2 < 8$ kPa (60 mmHg) or a $P_a\text{CO}_2 > 7$ kPa (55 mmHg).

Chronic alveolar hypoxia and hypercapnia leads to constriction of the pulmonary arterioles and pulmonary hypertension. Cardiac output is normal or increased but salt and fluid retention occurs as a result of renal hypoxia.

Pulmonary hypertension (cor pulmonale)

Patients with advanced COPD may develop cor pulmonale, which is defined as symptoms and signs of fluid overload secondary to lung disease. The fluid retention and peripheral oedema is due to failure of excretion of sodium and water by the hypoxic kidney rather than heart failure. It is characterized by pulmonary hypertension and right ventricular hypertrophy. On examination, the patient is centrally cyanosed (owing to the lung disease) and later becomes more breathless and develops ankle oedema. Initially there may be a prominent parasternal heave, due to right ventricular hypertrophy, and a loud pulmonary second sound. In very severe pulmonary hypertension, the pulmonary valve becomes incompetent. With severe fluid overload, tricuspid incompetence may develop with a greatly elevated jugular venous pressure (JVP), ascites and upper abdominal discomfort due to liver swelling.

Diagnosis

This is usually clinical (Table 15.9) and based on a history of breathlessness and sputum production in a chronic smoker. In the absence of a history of cigarette smoking asthma is a more likely explanation unless there is a family history suggesting α_1 -antitrypsin deficiency.

No individual clinical feature is diagnostic. The patient may have signs of hyperinflation and typical pursed lip respiration. There may be signs of overinflation of the lungs (e.g. loss of liver dullness on percussion), but this also occurs in other diseases such as asthma. Conversely, centri-acinar emphysema may be present without signs of overinflation. The chest may become 'barrel-shaped' but this can also result from osteoporosis of the spine in older men without emphysema.

Investigations

- **Lung function tests** show evidence of airflow limitation (see Figs 15.7 and 15.12). The FEV_1 : FVC ratio is reduced and the PEFR is low. In many patients the

Table 15.9 Classification of severity of Airflow limitation in COPD (2011)

Gold stage	FEV_1/FVC	% Predicted
1. Mild	$<70\%$	$\geq 80\%$
2. Moderate	$<70\%$	$<80\%$
3. Severe	$<70\%$	$<50\%$
4. Very severe	$<70\%$	$<30\%$

Modified from Global Initiative for Chronic Obstructive Lung Disease, 2011. www.goldcopd.com.

airflow limitation is partly reversible (usually a change in FEV₁ of <15%), and it can be difficult to distinguish between COPD and asthma. Lung volumes may be normal or increased; carbon monoxide gas transfer factor is low when significant emphysema is present.

- **Chest X-ray** is often normal, even when the disease is advanced. The classic features are overinflation of the lungs with low, flattened diaphragms, and sometimes the presence of large bullae. Blood vessels may be 'pruned' with large proximal vessels and relatively little blood visible in the peripheral lung fields.
- **High-resolution CT scans** are useful, particularly when the plain chest X-ray is normal.
- **Haemoglobin level and PCV** can be elevated as a result of persistent hypoxaemia (secondary polycythaemia, see p. 404).
- **Blood gases** are often normal at rest, but patients desaturate on exercise. In more advanced cases there is resting hypoxaemia and there may also be hypercapnia.
- **Sputum examination** is not useful in ordinary cases. *Strep. pneumoniae* and *H. influenzae* are the only common organisms to produce acute exacerbations. Occasionally, *Moraxella catarrhalis* may cause infective exacerbations.
- **Electrocardiogram** is often normal. In advanced pulmonary hypertension the P wave is tall (P pulmonale) and there may be right bundle branch block and evidence of right ventricular hypertrophy (see p. 764).
- **Echocardiogram** is useful to assess cardiac function where there is disproportionate dyspnoea.
- **α_1 -Antitrypsin** levels and genotype are worth measuring in premature disease or lifelong non-smokers.

Management

See Figure 15.22 for management strategies.

Smoking cessation

The single most useful measure is to persuade the patient to stop smoking. Even in advanced disease this may slow down the rate of deterioration and prolong the time before disability and death occur (see Fig. 15.22). Smoke from burning biomass fuels in poorly ventilated homes should also be reduced or get to non-smoking facilities if possible.

Drug therapy

This is used both for the short-term management of exacerbations and for the long-term relief of symptoms. Many of the drugs used are similar to those used in asthma (see p. 829).

Bronchodilators

- **β -Adrenergic agonists.** Many patients with mild COPD feel less breathless after inhaling a β -adrenergic agonist such as salbutamol (200 μ g every 4–6 hours). In more severe airway limitation (moderate and severe COPD), a long-acting β_2 agonist should be used, e.g. formoterol 12 μ g powder inhaled twice daily or salmeterol 50 μ g twice daily. Indacaterol 150–300 μ g daily is also effective.
- **Antimuscarinic drugs.** More prolonged and greater bronchodilatation is achieved with antimuscarinic agents: tiotropium (long-acting) (18 μ g daily), ipratropium (40 μ g four times daily) or oxitropium (200 μ g twice daily). Tiotropium improves function and quality of life but does not affect the decline in FEV₁. Compound bronchodilators, a selective β_2 agonist and an antimuscarinic agent, are used. If patients find inhalers difficult to use, spacer devices improve delivery. Objective evidence of improvement in peak flow rate or FEV₁ may be small and decisions to continue or stop therapy are based mainly on the patient's reported symptoms.
- **Theophyllines.** Long-acting preparations of theophylline are of little benefit in COPD.

Phosphodiesterase type 4 inhibitors

Roflumilast is an inhibitor with anti-inflammatory properties. It is used as an adjunct to bronchodilators for the maintenance treatment of COPD patients.

Corticosteroids

In symptomatic patients with moderate/severe COPD, a trial of corticosteroids is always indicated, since a proportion of patients have a large, unsuspected, reversible element to their disease and airway function may improve considerably. Prednisolone 30 mg daily should be given for 2 weeks, with measurements of lung function before and after the treatment period. If there is objective evidence of a substantial degree of improvement in airflow limitation (FEV_1 increase >15%), prednisolone should be discontinued and replaced by inhaled corticosteroids (beclometasone 40 µg twice daily in the first instance, adjusted according to response). The long-term value of regular inhaled corticosteroids in all patients with COPD has not been proven.

Combination of a corticosteroid with a long-acting β_2 agonist may protect against lung function decline but does not improve overall mortality. High-dose inhaled steroids are not advised as they cause increased rates of respiratory infection

Antibiotics

Prompt antibiotic treatment shortens exacerbations and should always be given in acute episodes as it may prevent hospital admission and further lung damage. Patients can be given antibiotics to keep at home to start as soon as their sputum turns yellow or green. Although amoxicillin-resistant *H. influenzae* is increasing worldwide (occurring in about 20% of isolates from sputum) it is not a serious clinical problem. Resistance to cefaclor (500 mg 8-hourly) or cefixime (400 mg once daily) is significantly less frequent; co-amoxiclav is a useful alternative.

Long-term treatment with antibiotics remains controversial. They were once thought to be of no value, but eradication of infection and keeping the lower respiratory tract free of bacteria may help to prevent deterioration in lung function.

Antimucolytic agents

These reduce sputum viscosity and can reduce the number of acute exacerbations. A 4-week trial of carbocysteine 2.25 g daily can be tried.

Diuretic therapy (see p. 644)

This is necessary for all oedematous patients. Daily weights should be recorded during acute inpatient episodes.

Oxygen therapy

Two controlled trials (chiefly in males) have shown improved survival with the continuous administration of oxygen at 2 L/min via nasal prongs to achieve an oxygen saturation of greater than 90% for large proportions of the day and night. Survival curves from these two studies are shown in Figure 15.23.

Only 30% of those not receiving long-term oxygen therapy survived for more than 5 years. A fall in pulmonary artery pressure was achieved if oxygen was given for 15 hours daily, but substantial improvement in mortality was only achieved by the administration of oxygen for 19 hours daily. These results suggest that long-term continuous domiciliary oxygen therapy will benefit patients who have:

- P_{aO_2} of <7.3 kPa (55 mmHg) when breathing air. Measurements should be taken on two occasions at

Figure 15.23 Cumulative survival curves for patients receiving oxygen. Oxygen doses are in hours per day.

Box 15.1 Guidelines for domiciliary oxygen (Royal College of Physicians, 1999)

- Chronic obstructive pulmonary disease with P_{aO_2} <7.3 kPa when breathing air during a period of clinical stability
- Chronic obstructive pulmonary disease with P_{aO_2} 7.3–8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension
- Severe chronic asthma with a P_aCO_2 <7.3 kPa or persistent disabling breathlessness
- Diffuse lung disease with P_{aO_2} <8 kPa and in patients with P_{aO_2} >8 kPa with disabling dyspnoea
- Cystic fibrosis when P_{aO_2} <7.3 kPa or if P_{aO_2} 7.3–8 kPa in the presence of secondary polycythaemia, nocturnal hypoxaemia, pulmonary hypertension or peripheral oedema
- Pulmonary hypertension without parenchymal lung involvement when P_{aO_2} <8 kPa
- Neuromuscular or skeletal disorders, after specialist assessment
- Obstructive sleep apnoea despite continuous positive airways pressure therapy, after specialist assessment
- Pulmonary malignancy or other terminal disease with disabling dyspnoea
- Heart failure with daytime P_{aO_2} <7.3 kPa (on air) or with nocturnal hypoxaemia

least 3 weeks apart after appropriate bronchodilator therapy (Box 15.1).

- P_{aO_2} 7.3–8 kPa with secondary polycythaemia, nocturnal hypoxaemia, peripheral oedema or evidence of pulmonary hypertension.
- Carboxyhaemoglobin of <3% (i.e. patients who have stopped smoking).

Domiciliary oxygen is best provided by using an oxygen concentrator, which is considerably cheaper than using oxygen cylinders.

Nocturnal hypoxia

COPD patients with severe arterial hypoxaemia may experience profound nocturnal hypoxaemia which may drop the P_{aO_2} as low as 2.5 kPa (19 mmHg), particularly during the rapid eye movement (REM) phase of sleep.

Because patients with COPD are already hypoxic, the fall in P_{aO_2} produces a much larger fall in oxygen saturation

FURTHER READING

Martinez FJ et al. The future of COPD treatment – difficulties of and basics to drug development. *Lancet* 2011; 378: 1027–1037.

Rabe KF, Wedzicha JA. Controversies in the treatment of chronic obstructive pulmonary disease. *Lancet* 2011; 378:1038–1047.

(owing to the shape of the oxygen-haemoglobin dissociation curve) and desaturation of up to 50% occurs. The mechanism is alveolar hypoventilation due to:

- Inhibition of intercostal and accessory muscles in REM sleep
- Shallow breathing in REM sleep, which reduces ventilation, particularly in severe COPD
- An increase in upper airway resistance because of a reduction in muscle tone.

These nocturnal hypoxaemic episodes are associated with a further rise in pulmonary arterial pressure owing to vasoconstriction. Most deaths in patients with COPD occur at night, possibly from cardiac arrhythmias due to hypoxaemia. Secondary polycythaemia may be exacerbated by the severe nocturnal hypoxaemia.

Each episode of desaturation is usually terminated by arousal from sleep, so the amount of normal sleep is reduced and patients suffer from daytime sleepiness.

Treatment. Patients with arterial hypoxaemia should not be given sleeping tablets, as these will further depress respiratory drive. Treatment is with nocturnal administration of oxygen and ventilatory support.

Non-invasive positive-pressure ventilation can be administered with a tightly fitting nasal mask and bilevel positive airway pressure (BiPAP) – inspiratory to provide inspiratory assistance and expiratory to prevent alveolar closure, each adjusted independently. This improves ventilation during sleep and allows respiratory muscles to rest at night. BiPAP helps prevent hypoxaemic damage at night in COPD but it does not improve daytime respiratory function, respiratory muscle strength, exercise tolerance or breathlessness.

Pulmonary rehabilitation

Exercise training can modestly increase exercise capacity with a diminished sense of breathlessness and improved general wellbeing. Regular training periods can be instituted at home; climbing stairs or walking fixed distances can be combined with regular clinic visits for encouragement. Breathing exercises are probably of less value. Quality-of-life can be improved by a multidisciplinary approach involving physiotherapy, exercise and education, although this does not alter life expectancy or the rate of decline in lung function; stopping smoking is still the most useful thing patients can do to help themselves. Nutritional advice, psychological, social and behavioural interventions are also helpful.

Additional measures

- **Vaccines.** Patients with COPD should receive a single dose of the polyvalent pneumococcal polysaccharide vaccine and yearly influenza vaccinations.
- **α_1 -Antitrypsin replacement.** Weekly or monthly infusions of α_1 -antitrypsin have been recommended for patients with serum levels below 310 mg/L and abnormal lung function. Whether this modifies the long-term progression of the disease remains to be determined.
- **Heart failure** should be treated (p. 718).
- **Secondary polycythaemia** requires venesection if the PCV is >55%.
- **Pulmonary hypertension** can be partially relieved by the use of oral β -adrenergic agonists such as salbutamol (4 mg three times daily), but the long-term value is unknown.
- The **sensation of breathlessness** can be reduced by either promethazine 125 mg daily or dihydrocodeine

1 mg/kg by mouth. Although opiates are the most effective treatment for intractable breathlessness they depress ventilation and carry the risk of increasing respiratory failure.

- **Antileukotriene agents** have been tried but are rarely effective (p. 831).
- **Air travel.** Commercial aircraft are pressurized to the equivalent of 2000–2400 m altitude. In healthy people, this causes P_{aO_2} to fall from 13.5 to 10 kPa, causing a trivial 3% drop in oxygen saturation, but patients with moderate COPD may desaturate significantly. The desaturation associated with air travel can be simulated by breathing 15% oxygen at sea level. Patients whose saturation drops below 85% within 15 minutes should be advised to contact their airline to request supplemental oxygen during flight.
- **Surgery.** Some patients have large emphysematous bullae which reduce lung capacity. Surgical bullectomy can enable adjacent areas of collapsed lung to re-expand and start functioning again. In addition, carefully selected patients with severe COPD ($FEV_1 < 1$ L) have been treated with lung volume reduction surgery. This increases elastic recoil, which reduces the expiratory collapse of the airway and decreases expiratory airflow limitation. It also enables the diaphragm to work at a better mechanical advantage. Initial studies suggested that ventilation was improved and patients felt less breathless, although mortality was unchanged. However, a controlled trial in severe emphysema found increased mortality and no improvement in the patients' condition. **Single lung transplantation** (see p. 822) is used for end-stage emphysema, with 3-year survival rates of 75%. The principal benefit is improved quality of life but it does not extend survival.

Acute respiratory failure in COPD

- **Oxygen therapy.** COPD is by far the commonest cause of respiratory failure (Fig. 15.24). In managing respiratory failure the main goal is to improve the P_{aO_2} by continuous oxygen therapy. In type II respiratory failure the P_{aCO_2} is elevated and the patient is dependent on hypoxic drive. In this setting, giving additional oxygen will nearly always cause a further rise in P_{aCO_2} . Small increases in P_{aCO_2} can be tolerated but the pH should not be allowed to fall below 7.25; if it does, increased ventilation must be achieved either by artificial ventilation or by using a respiratory stimulant. In COPD exacerbations, a fixed-percentage mask (Venturi mask; Fig. 15.25) is used to deliver controlled concentrations of oxygen. Initially, 24% oxygen is given, and the concentration of inspired oxygen can be gradually increased provided the P_{aCO_2} does not rise unacceptably.
- **Removal of retained secretions.** Patients should be encouraged to cough up secretions. Physiotherapy is helpful. If this fails, secretions can be aspirated by bronchoscopy or via an endotracheal tube
- **Respiratory support** (see p. 895). Non-invasive ventilatory techniques can be very helpful in avoiding the need for endotracheal intubation. The best current technique uses tight-fitting facial masks to deliver bilevel positive airway pressure ventilatory support (BiPAP). Assisted ventilation with an endotracheal tube is occasionally used for patients with COPD with severe respiratory failure but only when there is a clear

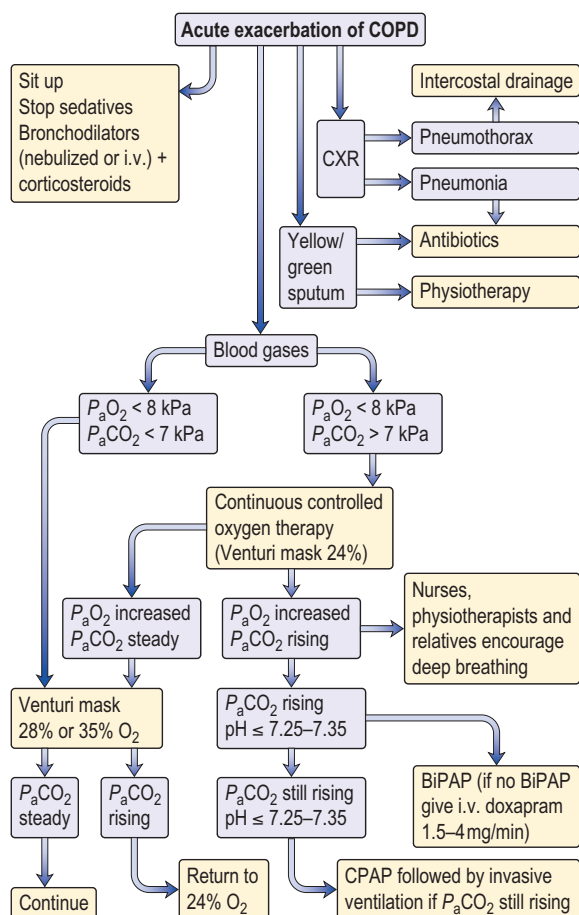

Figure 15.24 Algorithm for the treatment of respiratory failure in COPD. LVF, left ventricular failure; CPAP, continuous positive airway pressure; BiPAP, bilevel positive airway pressure; CXR, chest X-ray.

Figure 15.25 'Fixed-performance' device for administration of oxygen to spontaneously breathing patients (Venturi mask). Oxygen is delivered through the injector of the Venturi mask at a given flow rate. A fixed amount of air is entrained and the inspired oxygen can be predicted accurately. Masks are available to deliver 24%, 28% and 35% oxygen.

precipitating factor and the overall prognosis is reasonable. Assessing the likelihood of reversibility in an acute setting can present a difficult ethical problem.

- **Respiratory stimulants.** Respiratory stimulants such as doxapram were widely used in the past, but have fallen out of favour due to improvements in non-invasive ventilation.
- **Corticosteroids, antibiotics and bronchodilators** should be administered in the acute phase of respiratory

Box 15.2 BODE index (body mass index, degree of airflow obstruction, dyspnoea and exercise capacity)

Variable	Points on BODE index			
	0	1	2	3
FEV ₁ (% of predicted)	≥65	50–64	36–49	≤35
Distance walked in 6 min (metres)	≥350	250–349	150–249	≤149
MMRC dyspnoea scale	0–1	2	3	4
Body mass index	>21	≤21		

Scores on the modified Medical Research Council (MMRC) dyspnoea scale range from 0 to 4, with a score of 4 indicating that the patient is breathless when dressing.

Table 15.10 Symptoms of obstructive sleep apnoea

	(%)
Loud snoring	95
Daytime sleepiness	90
Unrefreshed sleep	40
Restless sleep	40
Morning headache	30
Nocturnal choking	30
Reduced libido	20
Morning drunkenness	5
Ankle swelling	5

failure but decisions on long-term use should wait until the patient has recovered (see above).

Prognosis of COPD

Predictors of a poor prognosis are increasing age and worsening airflow limitation, i.e. decreasing FEV₁. A predictive index (BODE: Body mass index, degree of airflow Obstruction, Dyspnoea and Exercise capacity) is shown in Box 15.2.

A patient with a BODE index of 0–2 has a 4-year mortality rate of 10%, compared with an 80% rate in one with a BODE index of 7–10.

Obstructive sleep apnoea

OSA affects 1–2% of the population and occurs most often in overweight middle-aged men. It can occur in children, particularly those with enlarged tonsils. The major symptoms and their frequency are listed in Table 15.10. During sleep, activity of the respiratory muscles is reduced, especially during REM sleep when the diaphragm is virtually the only active muscle. Apnoeas occur when the airway at the back of the throat is sucked closed when breathing in during sleep. When awake, this tendency is overcome by the action of opening muscles of the upper airway, the genioglossus and palatal muscles, but these become hypotonic during sleep (Fig. 15.26). Partial narrowing results in snoring, complete occlusion causes apnoea and critical narrowing causes hypopnoeas. Apnoea leads to hypoxia and increasingly strenuous respiratory efforts until the patient overcomes the resistance. The combination of the central hypoxic stimulation and the effort to overcome obstruction wakes the patient from sleep. These awakenings are so brief that the patient remains unaware of them but may be woken hundreds of times per night leading to sleep deprivation, especially a reduction in REM sleep, with consequent daytime sleepiness

Figure 15.26 Section through head, showing pressure changes (in kPa) in (a) the normal situation and (b) obstructive sleep apnoea. There is a pressure drop during inspiration as air is sucked through the turbinates. In patients with obstructive sleep apnoea this is sufficient to collapse the pharynx, obstructing inspiration.

Table 15.11 Epworth sleepiness scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent time. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = would never doze

1 = slight chance of dozing

2 = moderate chance of dozing

3 = high chance of dozing

Situation	Chance of dozing
Sitting and reading	_____
Watching TV	_____
Sitting and inactive in a public place (theatre or meeting)	_____
As a passenger in a car for an hour without a break	_____
Lying down to rest in the afternoon when circumstances permit	_____
Sitting and talking to someone	_____
Sitting quietly after lunch (without alcohol)	_____
In a car, while stopped for a few minutes in the traffic	_____
TOTAL	_____
Normal 5 ± 4	
Severe obstructive sleep apnoea $16 (\pm 4)$	
Narcolepsy 17	

and impaired intellectual performance. Contributory factors are obesity, narrow pharyngeal opening and co-existent COPD.

Correctable factors occur in about one-third of cases and include:

- **Encroachment on pharynx** – obesity, acromegaly, enlarged tonsils
- **Nasal obstruction** – nasal deformities, rhinitis, polyps, adenoids
- **Respiratory depressant drugs** – alcohol, sedatives, strong analgesics.

Diagnosis

Relatives often provide a good history of the snore-silence-snore cycle. The Epworth Sleepiness Scale (Table 15.11) helps

discriminate OSA from simple snoring. The diagnosis is supported by overnight pulse oximetry performed at home. Characteristically, oxygen saturation falls in a cyclical manner giving a sawtooth appearance to the tracing. If oximetry is negative or equivocal, inpatient assessment with oximetry and video-recording is indicated, preferably in a room specifically adapted for sleep studies. Full polysomnographic studies are rarely needed for clinical diagnosis but are useful in research labs. These involve oximetry, direct measurements of thoracic and abdominal movement to assess breathing, and electroencephalography to record patterns of sleep and arousal. Some centres also measure oronasal airflow.

The diagnosis of sleep apnoea/hypopnoea is confirmed if there are more than 10–15 apnoeas or hypopnoeas in any 1 hour of sleep. There is, however, overlap with *central sleep apnoea* (see p. 1069).

Management

Management consists of correction of treatable factors (see above) with, if necessary, nasal continuous positive airway pressure (CPAP) delivered by a nasal mask during sleep. Such systems raise the pressure in the pharynx by about 1 kPa, keeping the walls apart. Nasal CPAP improves symptoms, quality of life, daytime alertness and survival. However, up to 50% of OSA patients cannot tolerate CPAP. Modafinil (a CNS stimulant) is a useful short-term alternative.

Bronchiectasis

This term describes abnormal and permanently dilated airways. Bronchial walls become inflamed, thickened and irreversibly damaged. The mucociliary transport mechanism is impaired and frequent bacterial infections ensue. Clinically, the disease is characterized by productive cough with large amounts of discoloured sputum, and dilated, thickened bronchi, detected on CT.

Aetiology

Cystic fibrosis is the most common cause in developed countries. For other causes see Table 15.12.

Clinical features

Patients with mild bronchiectasis only produce yellow or green sputum after an infection. Localized areas of the lung may be particularly affected, in which case sputum production will vary with position. As the condition worsens, patients suffer persistent halitosis, recurrent febrile episodes with malaise, and episodes of pneumonia. Clubbing occurs, and coarse crackles can be heard over the infected areas, usually the lung bases. When the condition is severe there is continuous production of foul-smelling, thick, khaki-coloured sputum. Haemoptysis can occur either as blood-stained sputum or as a massive haemorrhage. Breathlessness may result from airflow limitation.

Investigations

- **Chest X-ray** may show dilated bronchi with thickened bronchial walls and sometimes multiple cysts containing fluid, but can be normal.
- **High-resolution CT scanning** (see p. 791) reveals thickened, dilated bronchi and cysts at the end of the bronchioles (Fig. 15.27). Characteristically the airways are larger than their associated blood vessels.
- **Sputum** examination and culture are essential for adequate treatment. The major pathogens are *Staph. aureus*, *Pseudomonas aeruginosa*, *H. influenzae* and anaerobes. Other pathogens include *Strep.*

pneumoniae and *Klebsiella pneumoniae*. *Aspergillus fumigatus* can be isolated from 10% of sputum specimens in cystic fibrosis, but the role of this organism in producing infection is uncertain. *Mycobacterium avium-intracellulare* complex (MAI) is being increasingly found.

- **Sinus X-rays.** 30% of bronchiectasis patients also have rhinosinusitis.
- **Serum immunoglobulins.** Up to 10% of adults with bronchiectasis have antibody class or subclass deficiency (mainly IgA). Some have normal antibody

class levels but fail to respond to respiratory pathogens. Responses to Hib and pneumococcal vaccines may be impaired.

- **Sweat electrolytes** – if cystic fibrosis is suspected (see p. 821).
- **Mucociliary clearance** (nasal clearance of saccharin). A 1 mm cube of saccharin is placed on the inferior turbinate and the time to taste measured (normally <30 minutes).

Treatment**Postural drainage**

Postural drainage is valuable. Patients must be trained by physiotherapists to tip themselves so that the affected lobe(s) are uppermost at least three times daily for 10–20 minutes. Most patients find that lying over the side of the bed with head and thorax down is effective.

Antibiotics

Experience from the treatment of cystic fibrosis suggests that bronchopulmonary infections need to be eradicated if progression of the disease is to be halted. In mild cases, intermittent chemotherapy with cefaclor 500 mg three times daily or ciprofloxacin 500 mg twice daily may be sufficient. Flucloxacillin 500 mg 6-hourly is needed if *Staph. aureus* is isolated.

If the sputum remains yellow or green despite regular physiotherapy and intermittent chemotherapy, or if lung function deteriorates despite treatment with bronchodilators, it is likely that there is infection with *Pseudomonas aeruginosa*. Treatment requires parenteral or aerosol chemotherapy at regular 3-month intervals. Ceftazidime 2 g intravenously 8-hourly or by inhalation (1 g twice daily) has been shown to be effective. Ciprofloxacin 750 mg twice daily orally may work in the short term, but resistance can develop rapidly. High sputum levels of some antibiotics, e.g. colistin or tobramycin, can be achieved by inhalation.

Treatment for aspergillus is described on page 852 and MAI on page 192.

Bronchodilators

Bronchodilators are useful in patients with demonstrable airflow limitation.

Anti-inflammatory agents

Inhaled or oral steroids can decrease the rate of progression.

Surgery

Unfortunately, it is rare for bronchiectasis to be sufficiently localized for resection to be practical. Lung or heart-lung transplantation is sometimes required.

Complications

The incidence of complications has fallen with antibiotic therapy. Pneumonia, pneumothorax, empyema and metastatic cerebral abscess can occur. Severe, life-threatening haemoptysis can also occur, particularly in patients with cystic fibrosis.

Massive haemoptysis originates from the high-pressure systemic bronchial arteries and has a mortality of 25%. Other causes of massive haemoptysis are pulmonary tuberculosis (most common), aspergilloma, lung abscess and primary and secondary malignant tumours.

Treatment of the haemoptysis consists of bed rest and antibiotics, when most stop bleeding. Blood transfusion is given if required. Urgent fiberoptic bronchoscopy is

occasionally necessary to detect the source of bleeding. If the haemoptysis does not settle rapidly, the treatment of choice is bronchial artery embolization. Surgical resection may be required if embolization fails.

Prognosis

The advent of effective antibiotic therapy has greatly improved the prognosis. Ultimately, most patients with severe bronchiectasis will develop respiratory failure or cor pulmonale, but those with mild disease have normal life expectancy. Of the pathogens that cause infective episodes, the most difficult to eradicate are *Pseudomonas aeruginosa*, *Aspergillus fumigatus* and MAI.

Cystic fibrosis

In cystic fibrosis (CF) there is an alteration in the viscosity and tenacity of mucus produced at epithelial surfaces. The classical form of the syndrome includes bronchopulmonary infection and pancreatic insufficiency, with a high sweat sodium and chloride concentration. It is an autosomal recessive inherited disorder with a carrier frequency in Caucasians of 1 in 22 (see p. 43). There is a gene mutation on the long arm of chromosome 7 in the region of 7q31.2. The commonest abnormality is a specific deletion at position 508 in the amino acid sequence [ΔF_{508}] – which results in a defect in a transmembrane regulator protein (see p. 44). This is the cystic fibrosis transmembrane conductance regulator (CFTR), which is a critical chloride channel (Fig. 15.28). The mutation alters the secondary and tertiary structure of the protein, leading to a failure of opening of the chloride channel in response to elevated cyclic AMP in epithelial cells. This results in decreased excretion of chloride into the airway lumen and an increased reabsorption of sodium into the epithelial cells. With less excretion of salt there is less excretion of water and increased viscosity and tenacity of airway secretions. A possible reason for the high salt content of sweat is that there is a CFTR-independent mechanism of chloride secretion in the sweat gland with an impaired reabsorption of sodium chloride in the distal end of the duct. Many genetic variants are known. The frequency of ΔF_{508} mutation in CF is 70% in the USA and UK, under 50% in southern Europe and 30% in Ashkenazi families. A further mutation G551D-CFTR reaches the cell surface but fails to open VX-770 allows it to open momentarily (see p. 811)

Clinical features

Respiratory effects

Although the lungs of babies born with CF are structurally normal at birth, frequent respiratory infections soon develop and are often the presenting feature. CF is the commonest cause of recurrent bronchopulmonary infection in childhood, and is a major cause in early adult life. Sinusitis is almost universal and nasal polyps are common. Breathlessness and haemoptysis occur in the later stages as airflow limitation and bronchiectasis develop. Spontaneous pneumothorax may occur. Respiratory failure and cor pulmonale eventually develop.

Gastrointestinal effects

About 85% of patients have symptomatic steatorrhea owing to pancreatic dysfunction (see p. 366). Children may be born with meconium ileus owing to the viscid consistency of meconium in CF; later in life they may develop the meconium ileus equivalent syndrome, a form of small intestinal obstruction unique to CF. Cholesterol gallstones occur with increased frequency. Cirrhosis develops in about 5% of older patients and there are increased incidences of peptic ulceration and gastrointestinal malignancy.

Nutritional effects

Many patients suffer from malnutrition due to a combination of malabsorption and maldigestion. Poor nutrition is associated with increased risk of pulmonary sepsis.

Other features

Puberty and skeletal maturity are delayed in most CF patients. Males are almost always infertile owing to failure of development of the vas deferens and epididymis. Females are able to conceive, but often develop secondary amenorrhoea as the disease progresses. Arthropathy and diabetes mellitus occur in 11% of adults with CF.

Diagnosis

The diagnosis of CF in older children and adults is based on the clinical history and:

- a family history of the disease
- a high sweat sodium concentration over 60 mmol/L (meticulous technique by laboratories performing regular

sweat analysis is essential, but the test is still difficult to interpret in adults)

- blood DNA analysis of gene defect
- radiology showing features seen in bronchiectasis (see p. 819)
- absent vas deferens and epididymis
- blood immunoreactive trypsin levels – these are not useful diagnostically but may be useful in screening.

Treatment

CF patients should be managed by multidisciplinary specialized teams. The overall care involves education to improve their quality of life, good nutrition and the prompt treatment of exacerbations to avoid hospitalization.

- **General care** should include stopping smoking, vaccination with influenza and pneumococcal vaccines and pulmonary rehabilitation (p. 817).
- **Oxygen therapy** should be given as necessary (Box 15.1).
- **Antibiotic treatment** for respiratory infections is as described under bronchiectasis on page 820.
- Seventy per cent of adults with CF have *Pseudomonas* infection in their sputum. Nebulized anti-pseudomonal antibiotic therapy improves lung function and decreases the risk of infective exacerbations and hospitalization.
- **Drug therapy:** β_2 agonists (p. 830) and inhaled corticosteroids (p. 831) may provide symptomatic relief but have no effect on long-term survival.
- **Airway clearance.** Inhalation of recombinant DNase (dornase alfa 2.5 mg daily) has been shown to improve FEV₁ by 20% in some patients. Hypertonic saline by inhalation (in concentrations of up to 7%) gives short-term benefit. Amiloride, which inhibits sodium transport, has been used but no overall benefit has been shown in meta-analysis. Acetylcysteine has been shown in vitro to liquefy CF sputum by cleaving disulfide bonds in mucus glycoproteins but clinical studies have been disappointing.
- **Non-invasive ventilation** (p. 895) improves symptoms in chronic respiratory failure but there is no evidence of a survival benefit. It acts as a bridge to lung transplantation (p. 822).
- Treatment for pancreatic insufficiency (p. 366) and malnutrition (p. 203).
- Human experimental studies have been conducted on the delivery to the epithelium of the normal CFTR gene using, as a vector, a replication-deficient adenovirus containing normal human CFTR complementary DNA which is trophic for epithelial cells. Gentamicin can suppress premature termination codons, and nasal administration has been shown to correct the physiological abnormality. These studies are in their early stages.
- Targeted genetic therapy – see page 44.

Prognosis and screening

Almost all CF patients develop progressive respiratory failure but the prognosis has improved considerably over the years. Some 90% of children now survive into their teens and the median survival for those born after 1990 is estimated at 40 years. A major problem is sputum infection with *Burkholderia cepacia* which is associated with accelerated disease and rapid death. Multiple antibiotic resistance is common and spread occurs from person to person. Strategies to limit

transmission include rigid segregation of both inpatients and outpatients and advice to CF sufferers not to socialize together. Sadly, groups formed for mutual support and education have had to be dissolved, leading to considerable distress.

Genetic screening is available for the 20 commonest mutations and this identifies 85–95% of carriers. Screening for the carrier state should be offered to persons or couples with a family history of CF, together with counselling (see p. 43).

Chronic cough (see p. 798)

Pathological coughing results from two mechanisms:

- Stimulation of sensory nerves in the epithelium by secretions, foreign bodies, cigarette smoke and tumours
- Sensitization of the cough reflex with abnormal increase in the sensitivity of the cough receptors.

Sensitization of the cough reflex can be demonstrated by inhalation of capsaicin or saline solution and presents clinically as a persistent tickling sensation in the throat with paroxysms of coughing induced by changes in air temperature, aerosol sprays, perfumes and cigarette smoke. It is found in association with viral infections, oesophageal reflux, post-nasal drip, cough-variant asthma, and in 15% of patients taking angiotensin-converting enzyme (ACE) inhibitors. The association with ACE inhibitors implicates neuropeptides, prostaglandins E₂ and F₂ and bradykinin as causes of the cough. In some patients no cause can be found (idiopathic cough). In the absence of chest X-ray abnormalities, possible investigations include:

- ENT examination (p. 1051) and sinus CT for post-nasal drip
- Lung function tests and histamine bronchial provocation testing (p. 829) for cough-variant asthma
- Ambulatory oesophageal pH monitoring and manometry for oesophageal reflux
- Fiberoptic bronchoscopy for inhaled foreign body or tumour
- ECG, echocardiography and exercise testing and impedance for cardiac causes
- Hyperventilation testing
- Psychiatric appraisal.

Symptomatic management of unexplained cough can be difficult. Morphine depresses the sensitized cough reflex but its unwanted effects limit its long-term use. Dihydrocodeine linctus may help some patients. Demulcent preparations and cough sweets only provide temporary relief. Patients who cough while taking ACE inhibitors should switch to an angiotensin-II receptor antagonist, e.g. losartan (see p. 719), which does not block bradykinin breakdown.

Lung and heart-lung transplantation

Indications and donor selection

The main diseases treated by transplantation are:

- Pulmonary fibrosis
- Primary pulmonary hypertension
- Cystic fibrosis
- Bronchiectasis
- Emphysema – particularly α_1 -antitrypsin inhibitor deficiency
- Eisenmenger's syndrome.

Patients selected for transplantation are usually under 60 years with a life expectancy of less than 18 months, no underlying cancer and no serious systemic disease.

Davis PB. Therapy for cystic fibrosis – the end of the beginning. *N Engl J Med* 2011; 365:1734–1735.

FURTHER READING

Garpestad E, Brennan J, Hill NS. Non-invasive ventilation for critical care. *Chest* 2007; 132:711–720.

Donor organs are taken from donors under 40 years, with good cardiac and lung function, and chest measurements slightly smaller than those of the recipient. Matching for ABO blood group is essential, but rhesus blood group compatibility is not essential. Since donor material is limited, single lung transplantation is preferred to double lung or heart-lung transplantation and can be successfully undertaken in pulmonary fibrosis, pulmonary hypertension and emphysema. Bilateral lung transplantation is required in infective conditions to prevent spillover of bacteria from the diseased lung to a single lung transplant. Eisenmenger's syndrome requires heart-lung transplant.

Complications and their treatment

- **Early post-transplant pulmonary oedema** requires diuretics and ventilatory support.
- **Infections**, particularly within first 3 months:
 - Bacterial pneumonia – antibiotics
 - Cytomegalovirus – ganciclovir
 - Herpes simplex – aciclovir.
 - *P. jiroveci* – prophylactic co-trimoxazole.
- **Immunosuppression** is with ciclosporin (inhaled formulation has shown benefit) or tacrolimus, azathioprine or mycophenolate mofetil and prednisolone.
- **Rejection:**
 - Early (first few weeks) – high-dose i.v. corticosteroids
 - Late (after 3 months) – high-dose i.v. corticosteroids are sometimes effective in obliterative bronchiolitis. Post-transplant lymphoproliferative disease may respond to rituximab, an anti-B-cell monoclonal antibody.

Prognosis

Several studies show a major improvement in overall quality of life. One year survival rates have improved with a yearly mortality rate of about 10%. Death is mainly due to bronchiolitis. Actual survival varies with the original diagnosis but the median survival is approximately four years.

ASTHMA

Asthma is a common chronic inflammatory condition of the airways whose cause is incompletely understood. Symptoms include wheeze, chest tightness, cough and shortness of breath, often worse at night. Asthma commonly starts in childhood between the ages of 3 and 5 years and may either worsen or improve during adolescence. Classically asthma has three characteristics:

- **Airflow limitation** which is usually reversible spontaneously or with treatment
- **Airway hyperresponsiveness** to a wide range of stimuli (see below)
- **Bronchial inflammation** with T lymphocytes, mast cells, eosinophils with associated plasma exudation, oedema, smooth muscle hypertrophy, matrix deposition, mucus plugging and epithelial damage.

In chronic asthma, inflammation may be accompanied by irreversible airflow limitation as a result of airway wall remodelling that may involve large and small airways and mucus impaction.

Prevalence

In many countries, the prevalence of asthma is increasing. This increase is particularly marked in children and young adults where this disease may affect up to 15% of the

population. There is also geographical variation, with asthma being commoner in more developed countries. Some of the highest rates are in the UK, New Zealand and Australia, with much lower rates in Far Eastern countries such as China and Malaysia, Africa and Central and Eastern Europe. Long-term follow-up in developing countries suggests that asthma may become more frequent as individuals adopt a more 'westernized' lifestyle, but the environmental factors accounting for this remain unknown. Studies of occupational asthma suggest that a large proportion of the workforce (15–20%) may become asthmatic if exposed to potent sensitizers. Worldwide, approximately 300 million people have asthma and this is expected to rise to 400 million by 2025.

Classification

Asthma is a complex disorder of the conducting airways that was often classified into extrinsic and intrinsic asthma but there is considerable overlap.

Extrinsic asthma occurs most frequently in atopic individuals: i.e. those with positive skin-prick reactions to common inhalant allergens such as dust mite, animal danders, pollens and fungi; 90% of children and 70% of adults with persistent asthma have positive skin-prick tests to inhalant allergens. Childhood asthma is often accompanied by eczema (atopic dermatitis) (see p. 1206). Sensitization to chemicals or biological products in the workplace is a frequently overlooked cause of late-onset asthma in adults.

Intrinsic asthma often starts in middle age. Nevertheless, many patients with adult-onset asthma show positive allergen skin tests and on close questioning some of these will give a history of childhood respiratory symptoms suggesting they have extrinsic asthma.

Non-atopic individuals may develop asthma in middle age from extrinsic causes such as sensitization to occupational agents such as toluene diisocyanate, intolerance to non-steroidal anti-inflammatory drugs such as aspirin or because they were given β -adrenoceptor-blocking agents for concurrent hypertension or angina that block the protective effect of endogenous adrenergic agonists. Extrinsic causes must be considered in all cases of asthma and, where possible, avoided.

Aetiology and pathogenesis

The two major factors involved in the development of asthma and many other stimuli that can precipitate attacks are shown in Figure 15.29.

Atopy and allergy

The term 'atopy' was coined in the early twentieth century to describe a group of disorders, including asthma and hay-fever, which appeared:

- to run in families
- to have characteristic wealing skin reactions to common allergens in the environment
- to have circulating allergen-specific antibodies (later shown to be IgE).

Allergen-specific IgE is present in 30–40% of the UK population, and there is a link between serum IgE levels and both the prevalence of asthma and airway hyperresponsiveness. Genetic and environmental factors affect serum IgE levels.

Genetic

There is no single gene for asthma, but several genes, in combination with environmental factors, appear to influence the development of asthma.

Figure 15.29 Causes and triggers of asthma. RSV, respiratory syncytial virus; NSAIDs, non-steroidal anti-inflammatory drugs.

- Genes controlling the production of the cytokines IL-3, IL-4, IL-5, IL-9, IL-13 and GM-CSF – which in turn affect mast and eosinophil cell development and longevity as well as IgE production – are present in a cluster on chromosome 5q31-33 (the IL-4 gene cluster).
- Polymorphic variation in proteins along the IL-4/-13 signalling pathway is strongly associated with allergy and asthma.
- Novel asthma genes identified by positional cloning from whole genome scans are the PHF11 locus on chromosome 2 (that includes genes SETDB2 and RCBTB1) and transcription factors, which are implicated in IgE synthesis and associated more with atopy than asthma.
- ADAM 33 (a disintegrin and metalloproteinase) on chromosome 20p13 is associated with airway hyperresponsiveness and tissue remodelling.
- Other genes associated with asthma are those that encode neuropeptide S receptor (GPRA or GPR154) on chromosome 7p15, HLA-G on chromosome 6p21, dipeptidyl peptidase 10 on chromosome 2q14 and ORMDL3, a member of a gene family that encodes transmembrane proteins anchored in the endoplasmic reticulum, on chromosome 17q21.

Environmental factors

Early childhood exposure to allergens and maternal smoking has a major influence on IgE production. Much current interest focuses on the role of intestinal bacteria and childhood infections in shaping the immune system in early life. It has been suggested that growing up in a relatively 'clean' environment may predispose towards an IgE response to allergens (the 'hygiene hypothesis'). Conversely, growing up in a 'dirtier' environment may allow the immune system to avoid developing allergic responses. Components of bacteria (e.g. lipopolysaccharide endotoxin, immunostimulatory CpG DNA sequences, flagellin), viruses (e.g. SS- and DS-RNA) and

fungi (e.g. chitin, a cell wall component) stimulate various toll-like receptors (TLRs) expressed on immune and epithelial cells to direct the immune and inflammatory response away from the allergic (Th2) towards protective (Th1 and Treg) pathways. Th1 immunity is associated with antimicrobial protective immunity whereas regulatory T cells are strongly implicated in tolerance to allergens. Thus early life exposure to inhaled and ingested products of microorganisms, as occurs in livestock farming communities and developing countries, may reduce the subsequent risk of a child becoming allergic and/or developing asthma.

The allergens involved in allergic asthma are similar to those implicated in rhinitis although pollens are relatively less implicated in asthma. Most allergic asthmatics are sensitized to house-dust mite allergens. Cockroach allergy has been implicated in asthma in US inner-city children, while allergens from furry pets (especially cats) are increasingly common causes. The fungal spores from *Aspergillus fumigatus* cause a range of lung disorders, including asthma (see p. 852). Many allergens, including those from *Aspergillus*, have intrinsic biological properties, e.g. enzymes with proteolytic function which may increase their sensitizing capacity.

Increased responsiveness of the airways of the lung (airway hyperresponsiveness)

Bronchial hyperresponsiveness (BHR) is a characteristic feature of asthma and can be demonstrated by asking patients to inhale gradually increasing concentrations of histamine or methacholine (*bronchial provocation tests*). This induces transient airflow limitation in susceptible individuals (approximately 20% of the population); the severity of BHR can be graded according to the provocation dose (PD) or concentration (PC) of the agonist that produces a 20% fall in FEV₁ (PD₂₀ FEV₁ or PC₂₀ FEV₁). Patients with clinical symptoms of asthma respond to very low doses of methacholine, i.e. they have a low PD₂₀ FEV₁. BHR can also be assessed by exercise testing or inhalation of cold dry air, mannitol or hypertonic saline. These are indirect tests that release endogenous mediators such as histamine, prostaglandins and leukotrienes which then cause bronchoconstriction. Indirect measures of BHR correlate more closely with symptoms and diurnal peak expiratory flow rate (PEFR) variation than PC₂₀ histamine or methacholine: both are useful in diagnosing asthma if there is doubt and in guiding controller treatment.

Some patients also react to methacholine but at *higher* doses, e.g. those with:

- attacks of asthma only on extreme exertion, e.g. winter sports enthusiasts
- wheezing or prolonged periods of coughing following a viral infection
- seasonal wheeze during the pollen season
- allergic rhinitis, but not complaining of lower respiratory symptoms until specifically questioned
- and some subjects with no respiratory symptoms.

Although the degree of BHR can be influenced by allergic mechanisms (see p. 826 and Fig. 15.32), its pathogenesis and mode of inheritance involve a combination of airway inflammation and tissue remodelling.

Precipitating factors

Occupational sensitizers (Table 15.13)

Over 250 materials encountered at the workplace can cause occupational asthma, which accounts for about 15% of all

Table 15.13 Occupational asthma

Cause	Source/Occupation
Low molecular weight (non-IgE related)	
Isocyanates	Polyurethane varnishes Industrial coatings Spray painting
Colophony fumes	Soldering/welders Electronics industry
Wood dust	
Drugs	
Bleaches and dyes	
Complex metal salts, e.g. nickel, platinum, chromium	
High molecular weight (IgE related)	
Allergens from animals and insects	Farmers, workers in poultry and seafood processing industry; laboratory workers
Antibiotics	Nurses, health industry
Latex	Health workers
Proteolytic enzymes	Manufacture (but not use) of 'biological' washing powders
Complex salts of platinum	Metal refining
Acid anhydrides and polyamine hardening agents	Industrial coatings

asthma cases. These are recognized occupational diseases in the UK, and patients in insurable employment are eligible for statutory compensation provided they apply within 10 years of leaving the occupation in which the asthma developed.

Asthma can be due to:

- Low molecular weight compounds, e.g. reactive chemicals such as isocyanates and acid anhydrides that bond chemically to epithelial cells to activate them as well as provide haptens recognized by T cells.
- High molecular weight compounds, e.g. flour, organic dusts and other large protein molecules involving specific IgE antibodies

The risk of developing some forms of occupational asthma increases in smokers. The proportion of employees developing occupational asthma depends primarily upon the level of exposure. Proper enclosure of industrial processes or appropriate ventilation greatly reduces the risk. Atopic individuals develop occupational asthma more rapidly when exposed to agents causing the development of specific IgE antibody. Non-atopic individuals can also develop asthma when exposed to such agents, but after a longer period of exposure.

Nonspecific factors

The characteristic feature of BHR in asthma means that, as well as reacting to specific antigens, the airways will also respond to a wide variety of nonspecific direct and indirect stimuli.

Cold air and exercise

Most asthmatics wheeze after prolonged exercise or inhaling cold dry air. Typically, the attack does not occur while exercising but afterwards. Exercise-induced wheeze is driven by release of histamine, prostaglandins (PGs) and leukotrienes (LTs) from mast cells as well as stimulation of neural reflexes when the epithelial lining fluid of the bronchi becomes

hyperosmolar owing to drying and cooling during exercise. The phenomenon can be shown by exercise, cold air and hypertonic (e.g. saline or mannitol) provocation tests.

Atmospheric pollution and irritant dusts, vapours and fumes

Many patients with asthma experience worsening of symptoms on contact with tobacco smoke, car exhaust fumes, solvents, strong perfumes or high concentrations of dust in the atmosphere. Major epidemics have been recorded when large amounts of allergens are released into the air, e.g. soybean dust in Barcelona. Asthma exacerbations increase during summer and winter air pollution episodes associated with climatic temperature inversions. Epidemics of asthma have occurred in the presence of high concentrations of ozone, particulates and NO₂ in the summer and particulates, NO₂ and SO₂ in the winter.

Diet

Increased intakes of fresh fruit and vegetables have been shown to be protective, possibly owing to the increased intake of antioxidants or other protective molecules such as flavonoids. Genetic variation in antioxidant enzymes is associated with more severe asthma.

Emotion

It is well known that emotional factors may influence asthma both acutely and chronically, but there is no evidence that patients with the disease are any more psychologically disturbed than their non-asthmatic peers. An asthma attack is a frightening experience, especially when of sudden and unexpected onset. Patients at special risk of life-threatening attacks are understandably anxious.

Drugs

Non-steroid anti-inflammatory drugs (NSAIDs). NSAIDs, particularly aspirin and propionic acid derivatives, e.g. indometacin and ibuprofen, are implicated in triggering asthma in approximately 5% of patients. NSAID intolerance is especially prevalent in those with both nasal polyps and asthma and is not infrequently associated with rhinitis and flushing on drug exposure. NSAIDs inhibit arachidonic acid metabolism via the cyclo-oxygenase (COX) pathway, preventing the synthesis of certain prostaglandins. In aspirin-intolerant asthma there is reduced production of PGE₂ which, in a sub-proportion of genetically susceptible subjects, induces the overproduction of cysteinyl leukotrienes by eosinophils, mast cells and macrophages. In such patients there is evidence for genetic polymorphisms involving the enzymes and receptors of the leukotriene generating pathway (Fig. 15.30). Interestingly, asthma in intolerant patients is not precipitated by COX-2 inhibitors, indicating that it is blockade of the COX-1 isoenzyme that is linked to impaired PGE₂ production.

Beta-blockers. The airways have a direct parasympathetic innervation that tends to produce bronchoconstriction. There is no direct sympathetic innervation of the smooth muscle of the bronchi, and antagonism of parasympathetically induced bronchoconstriction is critically dependent upon circulating epinephrine (adrenaline) acting through β_2 -receptors on the surface of smooth muscle cells. Inhibition of this effect by β -adrenoceptor-blocking drugs such as propranolol leads to bronchoconstriction and airflow limitation, but only in asthmatic subjects. Selective β_1 -adrenergic-blocking drugs such as atenolol may still induce attacks of asthma; ideally alternative drugs should be used to treat hypertension or angina in asthmatic patients.

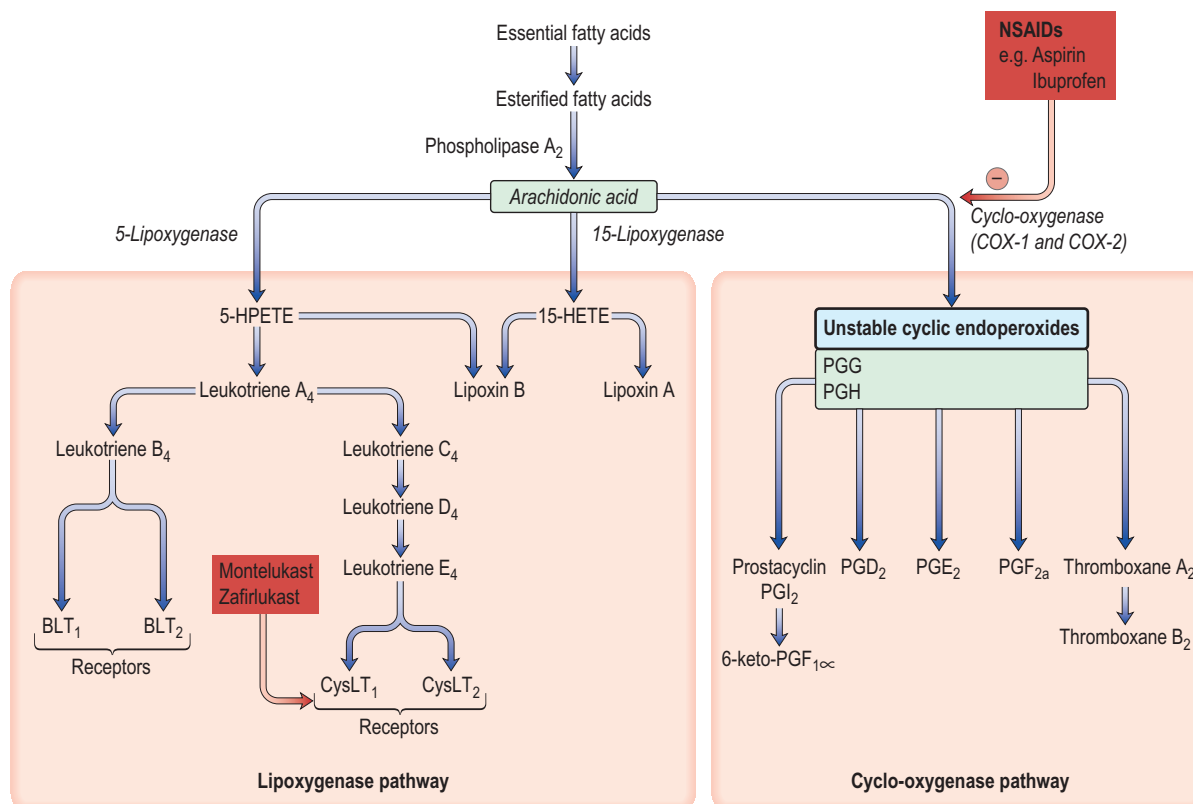

Figure 15.30 Arachidonic acid metabolism and the effect of drugs. The sites of action of NSAIDs (e.g. aspirin, ibuprofen) are shown. The enzyme cyclo-oxygenase occurs in three isoforms, COX-1 (constitutive), COX-2 (inducible) and COX-3 (in brain). PG, prostaglandin; BLT, B leukotriene receptor; CysLT, cysteinyl leukotriene receptor.

Allergen-induced asthma

The experimental inhalation of allergen by atopic asthmatic individuals leads to the development of different types of reaction, as illustrated in Figure 15.31. Much of our knowledge of asthma mechanisms comes from studies of allergen inhalation, but it must always be remembered this is only a model of the disease.

Immediate asthma (early reaction). Airflow limitation begins within minutes of contact with the allergen, reaches its maximum in 15–20 minutes and subsides by 1 hour.

Dual and late-phase reactions. Following an immediate reaction many asthmatics develop a more prolonged and sustained attack of airflow limitation that responds less well to inhalation of bronchodilator drugs such as salbutamol. Isolated late-phase reactions with no preceding immediate response can occur after the inhalation of some occupational sensitizers such as isocyanates. BHR increases during and for several weeks after the exposure, which may explain persisting symptoms after allergen exposure.

Pathogenesis

The pathogenesis of asthma is complex and not fully understood. It involves a number of cells, mediators, nerves and vascular leakage that can be activated by several different mechanisms, including exposure to allergens (Fig. 15.32). The varying clinical severity and chronicity of asthma is dependent on an interplay between airway inflammation and airway wall remodelling. The inflammatory component is driven by Th2-type T lymphocytes which facilitate IgE synthesis through production of IL-4 and eosinophilic inflammation through IL-5 (Fig. 15.32). However, as the disease

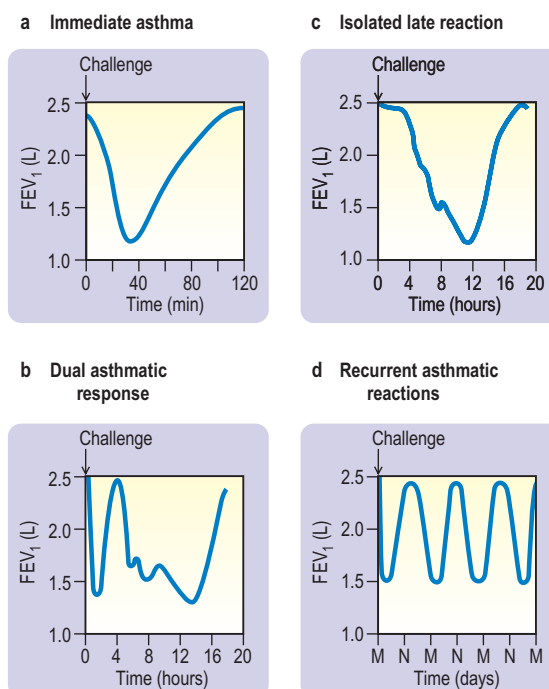

Figure 15.31 Different types of asthmatic reactions following challenge with allergen. M, midnight; N, noon.

becomes more severe and chronic and loses its sensitivity to corticosteroids, there is greater evidence of a Th1 response with release of mediators such as TNF- α and associated tissue damage, mucous metaplasia and aberrant epithelial and mesenchymal repair.

Figure 15.32 Inflammatory and remodelling responses in asthma with activation of the epithelial mesenchymal trophic unit. Epithelial damage alters the set point for communication between bronchial epithelium and underlying mesenchymal cells, leading to myofibroblast activation, an increase in mesenchymal volume, and induction of structural changes throughout airway wall. (Adapted from Holgate ST, Polosa R. The mechanisms, diagnosis, and management of severe asthma in adults. *Lancet* 2006; 368: 780–793, with permission from Elsevier.)

Inflammation

Several key cells are involved in the inflammatory response that characterizes all types of asthma.

Mast cells (see also p. 53). These are increased in the epithelium, smooth muscle and mucous glands in asthma and release powerful preformed and newly generated mediators that act on smooth muscle, small blood vessels, mucus-secreting cells and sensory nerves, such as histamine, tryptase, PGD_2 and cysteinyl leukotrienes, which cause the immediate asthmatic reaction. Mast cells are inhibited by sodium cromoglycate and β_2 agonists, which may partly explain their ability to prevent acute bronchoconstriction triggered by indirect challenges. Mast cells also release an array of cytokines, chemokines and growth factors that contribute to the late asthmatic response and more chronic aspects of asthma.

Eosinophils. These are found in large numbers in the bronchial wall and secretions of asthmatics. They are attracted to the airways by the eosinophilopoietic cytokines IL-3, IL-5 and GM-CSF as well as by chemokines which act on type 3 C-C chemokine receptors (CCR-3) (i.e. eotaxin, RANTES, MCP-1, MCP-3 and MCP-4). These mediators also prime eosinophils for enhanced mediator secretion. When activated, eosinophils release LTC_4 , and basic proteins such as major basic

protein (MBP), eosinophil cationic protein (ECP) and eosinophils peroxidase (EPX) that are toxic to epithelial cells. Both the number and activation of eosinophils are rapidly decreased by corticosteroids. Sputum eosinophilia is of diagnostic help as well as providing a biomarker of response to therapy

Dendritic cells and lymphocytes. These cells are abundant in the mucous membranes of the airways and the alveoli. Dendritic cells have a role in the initial uptake and presentation of allergens to lymphocytes. T helper lymphocytes (CD4^+) show evidence of activation (Fig. 15.32) and the release of their cytokines plays a key part in the migration and activation of mast cells (IL-3, IL-4, IL-9 and IL-13) and eosinophils (IL-3, IL-5, GM-CSF). In addition, production of IL-4 and IL-13 helps maintain the proallergic Th2 phenotype, favouring switching of antibody production by B lymphocytes to IgE. In mild/moderate asthma there is selective upregulation of Th2 T cells with reduced evidence of the Th1 phenotype (producing gamma-interferon, $\text{TNF-}\alpha$ and IL-2), although Th1 cells are more prominent in more severe disease. This polarization is mediated by dendritic cells and involves a combination of antigen presentation, co-stimulation and exposure to polarizing cytokines. The activity of both macrophages and lymphocytes is influenced by corticosteroids but not β_2 -adrenoceptor agonists.

FURTHER READING

Tschumperlin DJ. Physical forces and airway remodelling in asthma. *N Engl J Med* 2011; 364:2058–2057.

Remodelling

A characteristic feature of chronic asthma is an alteration of structure and functions of the formed elements of the airways. Together, these structural changes interact with inflammatory cells and mediators to cause the characteristic features of the disease. Deposition of matrix proteins, swelling and cellular infiltration expand the submucosa beneath the epithelium so that for a given degree of smooth muscle shortening there is excess airway narrowing. Swelling outside the smooth muscle layer spreads the retractile forces exerted by the surrounding alveoli over a greater surface area so that the airways close more easily. Several factors contribute to these changes.

The epithelium. In asthma the epithelium of the conducting airways is stressed and damaged with loss of ciliated columnar cells. Metaplasia occurs with a resultant increase in the number and activity of mucus-secreting goblet cells. The epithelium is a major source of mediators, cytokines and growth factors that enhance inflammation and promote tissue remodelling (Fig. 15.32). Damage and activation of the epithelium make it more vulnerable to infection by common respiratory viruses (e.g. rhinovirus, coronavirus) and to the effects of air pollutants. Increased production of nitric oxide (NO), due to the increased expression of inducible NO synthase, is a feature of epithelial damage and activation. Measurement of exhaled NO is proving useful as a non-invasive test of continuing inflammation (p. 829).

Epithelial basement membrane. A pathognomonic feature of asthma is the deposition of repair collagens (types I, III and V) and proteoglycans in the lamina reticularis beneath the basement membrane. This, along with the deposition of other matrix proteins such as laminin, tenascin and fibronectin, causes the appearance of a thickened basement membrane observed by light microscopy in asthma. This collagen deposition reflects activation of an underlying sheath of fibroblasts that transform into contractile myofibroblasts which also have an increased capacity to secrete matrix. Aberrant signalling between the epithelium and underlying myofibroblasts is thought to be the principal cause of airway wall remodelling, since the cells are prolific producers of a range of tissue growth factors such as epidermal growth factor (EGF), transforming growth factor (TGF)- α and - β , connective tissue-derived growth factor (CTGF), platelet-derived growth factor (PDGF), endothelin (ET), insulin-like growth factors (IGF), nerve growth factors and vascular endothelial growth factors (Fig. 15.32). The same interaction between epithelium and mesenchymal tissues is central to branching morphogenesis in the developing fetal lung. It has been suggested that these mechanisms are reactivated in asthma, but instead of causing airway growth and branching, they lead to thickening of the airway wall (remodelling, Fig. 15.32). Increased deposition of collagens, proteoglycans and matrix proteins creates a microenvironment which encourages ongoing inflammation since these molecules also possess cell-signalling functions, which aid cell movement, prolong inflammatory cell survival and prime them for mediator secretion.

Smooth muscle. Another prominent feature of asthma is hyperplasia of the helical bands of airway smooth muscle. In addition to increasing in amount, the smooth muscle alters in function so it contracts more easily and stays contracted because of a change in actin–myosin cross-link cycling. These changes allow asthmatic airways to contract too much and too easily at the least provocation. Asthmatic smooth muscle also secretes a wide range of cytokines, chemokines and growth factors that help sustain the chronic inflammatory response. The asthma gene *ADAM33* has been

implicated in driving increased airway smooth muscle and other features of remodelling through increased availability of growth factors.

Nerves. Neural reflexes, both central and peripheral, contribute to the irritability of asthmatic airways. Central reflexes involve stimulation of nerve endings in the epithelium and submucosa with transmission of impulses via the spinal cord and brain back down to the airways where release of acetylcholine from nerve endings stimulates M_3 receptors on smooth muscle causing contraction. Local neural reflexes involve antidromic neurotransmission and the release of a variety of neuropeptides. Some of these are smooth muscle contractants (substance P, neurokinin A), some are vasoconstrictors (e.g. calcitonin gene-related peptide, CGRP) and some vasodilators (e.g. neuropeptide Y, vasoactive intestinal polypeptide). A polymorphism of the neuropeptide S receptor (GPR 154) is associated with asthma susceptibility. Bradykinin generated by tissue and serum proteolytic enzymes (including mast cell tryptase and tissue kallikrein) is also a potent stimulus of local neural reflexes involving (nonmyelinated) nerve fibres.

Clinical features

The principal symptoms of asthma are wheezing attacks and episodic shortness of breath. Symptoms are usually worst during the night, especially in uncontrolled disease. Cough is a frequent symptom that sometimes predominates, especially in children in whom nocturnal cough can be a presenting feature. Attacks vary greatly in frequency and duration. Some patients only have one or two attacks a year that last for a few hours, while others have attacks lasting for weeks. Some patients have chronic persistent symptoms, on top of which there are fluctuations. Attacks may be precipitated by a wide range of triggers (Fig. 15.29). Asthma is a major cause of impaired quality of life with impact on work and recreational, as well as physical activities, and emotions.

Investigations

There is no single satisfactory diagnostic test for all patients with asthma.

Lung function tests

Peak expiratory flow rate (PEFR) measurements on waking, prior to taking a bronchodilator and before bed after a bronchodilator, are particularly useful in demonstrating the variable airflow limitation that characterizes the disease (Fig. 15.14). The diurnal variation in PEFR is a good measure of asthma activity and is of help in the longer-term assessment of the patient's disease and its response to treatment.

Spirometry is useful, especially in assessing reversibility. Asthma can be diagnosed by demonstrating a greater than 15% improvement in FEV_1 or PEFR following the inhalation of a bronchodilator. However, there may be less reversibility when asthma is in remission or in severe chronic asthma when little reversibility can be demonstrated or if the patient is already being treated with long-acting bronchodilators.

The carbon monoxide (CO) transfer test is normal in asthma.

Exercise tests

These have been widely used in the diagnosis of asthma in children. Ideally, the child should run for 6 minutes on a treadmill at a workload sufficient to increase the heart rate above 160 beats per minute. Alternative methods use cold air challenge, isocapnic hyperventilation (forced

overbreathing with artificially maintained P_{ACO_2}) or aerosol challenge with hypertonic solutions. A negative test does not automatically rule out asthma.

Histamine or methacholine bronchial provocation test (see p. 824)

This test indicates the presence of airway hyperresponsiveness, a feature found in most asthmatics, and can be particularly useful in investigating those patients whose main symptom is cough. The test should not be performed on individuals who have poor lung function ($\text{FEV}_1 < 1.5 \text{ L}$) or a history of 'brittle' asthma. In children, controlled exercise testing as a measure of BHR is often easier to perform.

Trial of corticosteroids

All patients who present with severe airflow limitation should undergo a formal trial of corticosteroids. Prednisolone 30 mg orally should be given daily for 2 weeks with lung function measured before and immediately after the course. A substantial improvement in FEV_1 ($>15\%$) confirms the presence of a reversible element and indicates that the administration of inhaled steroids will prove beneficial to the patient. If the trial is for ≤ 2 weeks, the oral corticosteroid can be withdrawn without tailing off the dose, and should be replaced by inhaled corticosteroids in those who have responded.

Exhaled nitric oxide (NO)

A measure of airway inflammation and an index of corticosteroid response; used in children to assess the efficacy of corticosteroids.

Blood and sputum tests

Patients with asthma sometimes have increased numbers of eosinophils in peripheral blood ($>0.4 \times 10^9/\text{L}$) but sputum eosinophilis is a more specific diagnostic finding.

Chest X-ray

There are no diagnostic features of asthma on the chest X-ray, although overinflation is characteristic during an acute episode or in chronic severe disease. A chest X-ray may be helpful in excluding a pneumothorax, which can occur as a complication, or in detecting the pulmonary infiltrates associated with allergic bronchopulmonary aspergillosis.

Skin tests

Skin-prick tests (SPT) should be performed in all cases of asthma to help identify allergic trigger factors. Allergen-specific IgE can be measured in serum if SPT facilities are not available, if the patient is taking antihistamines or no suitable allergen extracts are available.

Allergen provocation tests

Allergen inhalation challenge is a useful research tool, and is required when investigating of patients with suspected occupational asthma, but not in ordinary asthma.

Management

The aims of treatment are to:

- Abolish symptoms
- Restore normal or best possible lung function
- Reduce the risk of severe attacks
- Enable normal growth to occur in children
- Minimize absence from school or employment.

This involves:

- Patient and family education about asthma
- Patient and family participation in treatment

- Avoidance of identified causes where possible
- Use of the lowest effective doses of convenient medications to minimize short-term and long-term side-effects.

Many asthmatics join self-help groups whose aim is in order to improve their understanding of the disease and to foster self-confidence and fitness.

Control of extrinsic factors

Measures must be taken to avoid causative allergens such as pets, moulds and certain foodstuffs (see allergic rhinitis), particularly in childhood. Avoidance of house-dust mite is very difficult. There is little evidence for the effectiveness of current physical or chemical measures to control house-dust mite levels. The use of covers for bedding and changes to living accommodation has no beneficial effect on outcomes. Active and passive smoking should be avoided, as should beta-blockers in either tablet or eye drop form. Individuals intolerant to aspirin should avoid NSAIDs, although they may tolerate COX-2 inhibitors. Other agents (e.g. preservatives and colouring materials such as tartrazine) should be avoided if shown to be a causative factor. About one-third of individuals sensitized to occupational agents may be cured if they are kept permanently away from exposure. The remaining two-thirds will continue to have symptoms, and in half of these the symptoms may be as severe as when exposed to materials at work, especially if they were symptomatic for a long time before the diagnosis was made.

This emphasizes that:

- The rapid identification of extrinsic causes of asthma and their removal is necessary wherever possible (e.g. occupational agents, family pets).
- Once extrinsic asthma is initiated, it may become self-perpetuating, possibly by non-immune mechanisms.

Drug treatment

The mainstay of asthma therapy is the use of therapeutic agents delivered as aerosols or powders directly into the lungs (see [Practical Box 15.3](#)). The advantages of this method

Practical Box 15.3

Inhaled therapy

Patients should be taught how to use inhalers and their technique checked regularly.

Use of a metered-dose inhaler

1. The canister is shaken.
2. The patient exhales to functional residual capacity (not residual volume), i.e. normal expiration.
3. The aerosol nozzle is placed to the open mouth.
4. The patient simultaneously inhales rapidly and activates the aerosol.
5. Inhalation is completed.
6. The breath is held for 10 seconds if possible. Even with good technique, only 15% of the contents is inhaled and 85% is deposited on the wall of the pharynx and ultimately swallowed.

Spacers

These are plastic cones or spheres inserted between the patient's mouth and the inhaler. Some inhalers have a built-in spacer extension. These are designed to reduce particle velocity so that less drug is deposited in the mouth. Spacers also diminish the need for coordination between aerosol activation and inhalation. They are useful in children and in the elderly and reduce the risk of candidiasis.

Box 15.3 The stepwise management of asthma

Step	PEFR	Treatment
1. Occasional symptoms; less frequent than daily	100% predicted	As-required short-acting β_2 agonists If used more than once daily, move to step 2
2. Daily symptoms	<80% predicted	Regular inhaled preventer therapy: Anti-inflammatory drugs: inhaled low-dose corticosteroids up to 800 μg daily Leukotriene receptor antagonists (LTRA), theophylline and sodium cromoglycate are less effective If not controlled, move to step 3
3. Severe symptoms	50–80% predicted	Inhaled corticosteroids and long-acting inhaled β_2 agonist Continue inhaled corticosteroid Add regular inhaled long-acting β_2 agonist (LABA) Still not controlled, add either LTRA, modified release oral theophylline or β_2 agonist If not controlled, move to step 4
4. Severe symptoms uncontrolled with high-dose inhaled corticosteroids	50–80% predicted	High-dose inhaled corticosteroid and regular bronchodilators Increase high-dose inhaled corticosteroids up to 2000 μg daily Plus regular long-acting β_2 agonists Plus either LTRA or modified release theophylline or β_2 agonist
5. Severe symptoms deteriorating	$\leq 50\%$ predicted	Regular oral corticosteroids Add prednisolone 40 mg daily to step 4
6. Severe symptoms deteriorating in spite of prednisolone	$\leq 30\%$ predicted	Hospital admission
Short-acting bronchodilator treatment <i>taken at any step on an as-required basis.</i>		

of administration are that drugs are delivered direct to the airways and first-pass metabolism in the liver is avoided; thus lower doses are necessary and systemic unwanted effects are minimized.

Both national and international guidelines have been published on the stepwise treatment of asthma (Box 15.3), based on three principles:

- Asthma self-management with regular asthma monitoring using PEF meters and individual treatment plans that are discussed with each patient and written down.
- The appreciation that asthma is an inflammatory disease and that anti-inflammatory (controller) therapy should be started even in mild cases.
- Use of short-acting inhaled bronchodilators (e.g. salbutamol and terbutaline) only to relieve breakthrough symptoms. Increased use of bronchodilator treatment to relieve increasing symptoms is an indication of deteriorating disease.

A list of drugs used in asthma is shown in Box 15.4. These are given in a stepwise fashion as indicated in Box 15.3.

Once asthma is brought under control, for at least 2–3 months, the drug regimen should be reassessed in order to reduce the dosage of inhaled steroids.

β_2 -Adrenoceptor agonists

The most widely used bronchodilator preparations contain β_2 -adrenoceptor agonists that are selective for the respiratory tract and do not stimulate the β_1 adrenoceptors of the myocardium. These drugs are potent bronchodilators because they relax the bronchial smooth muscle. They are very effective in relieving symptoms but do little for the underlying airways inflammation. Their usage is as follows:

- **Mildest asthmatics with intermittent attacks.** Only these people should rely on bronchodilator treatment alone. Short-acting β agonists (SABAs) such as salbutamol (100 μg), (called albuterol in the USA), or

Box 15.4 Drugs used in asthma

Short-acting relievers

- Inhaled β_2 agonists (e.g. salbutamol (albuterol in USA), terbutaline)

Long-acting relief/disease controllers

- Inhaled long-acting β_2 agonists (e.g. salmeterol, formoterol)
- Inhaled corticosteroids (e.g. beclomethasone, budesonide, fluticasone)
- Compound inhaled salmeterol and fluticasone
- Sodium cromoglycate
- Leukotriene modifiers (e.g. montelukast, zafirlukast, zileuton)

Other agents with bronchodilator activity

- Inhaled antimuscarinic agents (e.g. ipratropium, oxitropium)
- Theophylline preparations
- Oral corticosteroids (e.g. prednisolone 40 mg daily)

Steroid-sparing agents

- Methotrexate
- Ciclosporin
- Intravenous immunoglobulin
- Anti-IgE monoclonal antibody – omalizumab
- Etanercept (p. 72), infliximab, lebrikizumab

terbutaline (250 μg) should be prescribed as 'two puffs as required'. Some patients use nebulizers at home for self-administration of salbutamol or terbutaline. Such treatment is effective, but patients should not rely on repeated home administration of nebulized β_2 -adrenoceptor agonists for worsening asthma, and should seek medical advice urgently if their condition does not improve. Excessive use of SABAs was linked to two epidemics of asthma mortality in the 1960s and 1980s.

- **SABAs** can be taken at any step, as and when required from **step 1 to step 5** (see above).

- **Poorly controlled asthmatics** on standard doses of inhaled steroids. These patients require salmeterol or formoterol, which are highly selective and potent long-acting β_2 -adrenoceptor agonists (LABAs) effective by inhalation for up to 12 hours, thereby reducing the need for administration to once or twice daily. LABAs improve symptoms and lung function and reduce exacerbations in patients. They should never be used alone but always in combination with an inhaled corticosteroid. Increasingly, these drugs are administered as fixed-dose combinations with corticosteroids (salmeterol/fluticasone and formoterol/budesonide) in the same inhaler (**step 3**).

To help those who cannot coordinate activation of the aerosol and inhalation, several breath-activated or dry powder devices have been developed.

Antimuscarinic bronchodilators

Muscarinic receptors are found in the respiratory tract; large airways contain mainly M_3 receptors whereas the peripheral lung tissue contains M_3 and M_1 receptors (see p. 793). Non-selective muscarinic antagonists – ipratropium bromide (20–40 μ g three or four times daily) or oxitropium bromide (200 μ g twice daily) – by aerosol inhalation can be useful during asthma exacerbations, but they are less useful in stable asthma.

Anti-inflammatory drugs

Sodium cromoglycate and nedocromil sodium prevent activation of many inflammatory cells, particularly mast cells, eosinophils and epithelial cells, but not lymphocytes, by blocking a specific chloride channel which in turn prevents calcium influx. These drugs are effective in patients with *milder asthma* (**step 2**) but have fallen out of favour in recent years.

Inhaled corticosteroids

All patients who have regular persistent symptoms (even mild symptoms) need regular treatment with inhaled corticosteroids delivered in a stepwise fashion (**from step 2 upwards**) or as a high dose followed by a reduction to maintenance levels. Beclometasone dipropionate (BDP) is the most widely used inhaled steroid and is available in doses of 50, 100, 200 and 250 μ g per puff. Other inhaled steroids include budesonide, fluticasone, mometasone and triamcinolone.

Much of the inhaled dose does not reach the lung but is either swallowed or exhaled. Deposition in the lung varies between 10% and 25% depending on inhaler technique and the technical characteristics of the aerosol device. Drug which is deposited in the airways reaches the systemic circulation directly, through the bronchial circulation, while any drug that is swallowed has to pass through the liver before it can reach the systemic circulation. Gram for gram, fluticasone and mometasone are more potent than beclometasone with considerably less systemic bioavailability, owing to their greater sensitivity to hepatic metabolism. Absorption of beclometasone and budesonide does not seem to present a risk at doses up to 800 μ g/day, but fluticasone or mometasone may be preferred because of their lower bioavailability when high-dose inhaled steroids are needed. The dose-response curve for inhaled corticosteroids is flat beyond 800 μ g beclometasone or equivalent, and in patients with moderate asthma who are taking this daily, addition of a LABA is more effective than doubling the dose of inhaled corticosteroid.

Unwanted effects of inhaled corticosteroids include oral candidiasis (5% patients), and hoarseness. Subcapsular cataract formation is rare but can occur in the elderly.

Osteoporosis is less likely than with oral steroids but can occur with high-dose inhaled corticosteroids (beclometasone or budesonide >800 μ g daily). In children, inhaled corticosteroids at doses >400 μ g daily have been shown to retard short-term growth, but final heights are not affected. Inhaled corticosteroid use should be stepped down once asthma comes under control (p. 830). Candidiasis and GI absorption can be reduced by using spacers, mouthwashing and teeth cleaning after use. Inhaled corticosteroids that are esterified in the lung, thereby reducing systemic effects, are also used (e.g. ciclesonide 80 μ g daily).

Asthmatic patients who smoke are less responsive to inhaled corticosteroids due to induction of a range of genes and proteins in their respiratory epithelium. Assistance with smoking cessation should be offered, and additional therapy, e.g. with leukotriene receptor antagonists or theophylline, is required.

A functional GLCC11 variant is associated with a decreased response to inhaled corticosteroids.

Many patients with anything more than mild/moderate asthma benefit from combination LABA/corticosteroid therapy and there is some evidence that the two drugs interact therapeutically.

Oral corticosteroids and steroid-sparing agents

Oral corticosteroids are needed for individuals not controlled on inhaled corticosteroids (**step 5**). The dose should be kept as low as possible to minimize side-effects. The effect of short-term treatment with prednisolone 30 mg daily is shown in Figure 15.14 (p. 804). Some patients require continuing treatment with oral corticosteroids. Several studies suggest that treatment with low doses of methotrexate (15 mg weekly) can significantly reduce the dose of prednisolone needed to control the disease in some patients, and ciclosporin also improves lung function in some steroid-dependent asthmatics. Several other steroid-sparing strategies including ciclosporin and immunoglobulin have also been tried, but with varying success.

Cysteinyl leukotriene receptor antagonists (LTRAs)

This class of anti-asthma therapy targets one of the principal asthma mediators by inhibiting the cysteinyl LT_1 receptor. A second receptor (cyst LT_2) has been identified on inflammatory cells. Montelukast, pranlukast (only available in South-east Asia) and zafirlukast are given orally and are effective in a subpopulation of patients. However, it is not possible to predict which individuals will benefit: a 4-week trial of LTRA therapy is recommended before a decision is made to continue or stop. LTRAs should be tried in any patient who is not controlled on low to medium doses of inhaled steroids (**step 2**). Their action is additive to that of long-acting β_2 agonists. LTRAs are particularly useful in patients with aspirin-intolerant asthma, in those patients requiring high-dose inhaled or oral corticosteroids and in asthmatic smokers. Because these drugs are orally active they are helpful in asthma combined with rhinitis and in young children with asthma and/or virus-associated wheezing.

Monoclonal antibodies

Omalizumab, a recombinant humanized monoclonal antibody directed against IgE, chelates free IgE and downregulate the number and activity of mast cells and basophils. It is given subcutaneously every 2–4 weeks, depending on total serum IgE level and body weight. Although expensive, it is cost-effective in patients with frequent exacerbations

requiring hospital admission. Proof-of-concept trials have shown that anti-TNF therapy (infliximab or etanercept) may be helpful in severe corticosteroid-refractory asthma. There is still a need to examine other biological agents as potential new controller therapies for the 5–10% of patients with severe disease, who account for a high proportion of the health costs of asthma.

Lebrikizumab, a monoclonal antibody to IL-3, showed improvement in lung function in one recent study.

Antibiotics

Although wheezing frequently occurs in infective exacerbations of COPD, there is little evidence that antibiotics are helpful in managing patients with asthma. During acute exacerbations, yellow or green sputum containing eosinophils and bronchial epithelial cells may be coughed up. This is normally due to viral rather than bacterial infection and antibiotics are not required. Occasionally, mycoplasma and *Chlamydia* infections can cause chronic relapsing asthma and macrolide antimicrobials may be helpful if a bacterial diagnosis has been established by culture or serology.

Asthma attack

Although these may occur spontaneously, asthma exacerbations are most commonly caused by lack of treatment adherence, respiratory virus infections associated with the common cold, and exposure to allergen or triggering drug, e.g. an NSAID. Whenever possible, patients should have a written personalized plan that they can implement in anticipation of or at the start of an exacerbation that includes the early use of a short course of oral corticosteroids. If the PEFR is >150 L/min, patients may improve dramatically on nebulized therapy and may not require hospital admission. Their regular treatment should be increased, to include treatment for 2 weeks with 30–60 mg of prednisolone followed by substitution by an inhaled corticosteroid preparation. Short courses of oral prednisolone can be stopped abruptly without tailing down the dose.

Acute severe asthma

The term acute severe asthma is used to mean an exacerbation of asthma that has not been controlled by the use of standard medication.

Patients with *acute severe asthma* typically have:

- the inability to complete a sentence in one breath
- a respiratory rate of ≥ 25 breaths/min
- Tachycardia ≥ 110 beats/min (pulsus paradoxus is not useful as it is only present in 45% of cases)
- PEFR <50% of predicted normal or best.

Features of life-threatening attacks are:

- A silent chest, cyanosis or feeble respiratory effort
- Exhaustion, confusion or coma
- Bradycardia or hypotension
- PEFR <30% of predicted normal or best (approximately 150 L/min in adults).

Arterial blood gases should always be measured in asthmatic patients requiring admission to hospital, with particular attention paid to the $P_a\text{CO}_2$. Pulse oximetry is useful in monitoring oxygen saturation during the admission and can reduce the need for repeated arterial puncture. Features suggesting very severe life-threatening attacks are:

- a high $P_a\text{CO}_2 > 6$ kPa
- severe hypoxaemia $P_a\text{O}_2 < 8$ kPa despite treatment with oxygen
- a low and falling arterial pH.

Emergency Box 15.2

Treatment of severe asthma

At home

1. The patient is assessed. Tachycardia, a high respiratory rate and inability to speak in sentences indicate a severe attack.
2. If the PEFR is <150 L/min (in adults), an ambulance should be called. (All doctors should carry peak flow meters.)
3. Nebulized salbutamol 5 mg or terbutaline 10 mg is administered.
4. Hydrocortisone sodium succinate 200 mg i.v. is given.
5. Oxygen 40–60% is given if available.
6. Prednisolone 60 mg is given orally.

At hospital

1. The patient is reassessed.
2. Oxygen 40–60% is given.
3. The PEFR is measured using a low-reading peak flow meter, as an ordinary meter measures only from 60 L/min upwards.
Measure O_2 saturation with a pulse oximeter.
4. Nebulized salbutamol 5 mg or terbutaline 10 mg is repeated and administered 4-hourly.
5. Add nebulized ipratropium bromide 0.5 mg to nebulized salbutamol/terbutaline.
6. Hydrocortisone 200 mg i.v. is given 4-hourly for 24 hours.
7. Prednisolone is continued at 60 mg orally daily for 2 weeks.
8. Arterial blood gases are measured; if the $P_a\text{CO}_2$ is >7 kPa, ventilation may be required.
9. A chest X-ray is performed to exclude pneumothorax.
10. One of the following intravenous infusions is given if no improvement is seen:
Salbutamol 3–20 $\mu\text{g}/\text{min}$, or
Terbutaline 1.5–5.0 $\mu\text{g}/\text{min}$, or
Magnesium sulphate 1.2–2 g over 20 min.
11. No improvement – urgent; transfer to ITU

Treatment (Emergency Box 15.2) consists of nebulized short-acting bronchodilators; nebulized antimuscarinics (e.g. ipratropium bromide) are also helpful. A chest X-ray is useful to exclude pneumothorax and other causes of dyspnoea. Intravenous hydrocortisone is useful, and in very severe cases, β_2 -adrenoceptor agonists and/or magnesium sulphate are also given intravenously. Oral prednisolone (40–60 mg daily) should be given orally. Ventilation is required for patients who deteriorate despite this initial regimen.

Depending on progress, patients may go home after receiving nebulized therapy. More severe cases should be kept in hospital for 2–5 days with regular monitoring of oxygen saturation and peak flow rates. Downstream assessment of patients admitted with asthma should address trigger factors and aim to reduce the risk of readmission. Bronchial thermoplasty is a novel approach for moderate to severe persistent asthma. This bronchoscopic procedure reduces the mass of airway smooth muscle, reducing bronchoconstriction, and is being evaluated.

Management of catastrophic sudden severe asthma (brittle asthma)

A small minority of patients with asthma suffer sudden life-threatening attacks despite being well controlled between attacks. These attacks may occur within hours or even minutes, and can cause sudden death. Such patients require a carefully worked out management plan agreed by patient, primary care physician hospital emergency services and the respiratory physician, which may include:

- Optimization of standard therapy
- Emergency supplies of medications at home, in the car and at work
- Oxygen and resuscitation equipment at home and at work
- Nebulized β_2 -adrenoceptor agonists at home and at work
- Self-injectable adrenaline (epinephrine): two autoinjectors of 0.3 mg adrenaline at home, at work and to be carried by the patient at all times
- Prednisolone tablets 60 mg
- Medic Alert bracelet.

On developing wheeze, the patient should attend the nearest hospital immediately. Direct admission to intensive care may be required.

Prognosis of asthma

Although asthma often improves in children as they reach their teens, the disease frequently returns in the 2nd, 3rd and 4th decades. In the past, the data indicating a natural decrease in asthma through teenage years have led to childhood asthma being treated as an episodic disorder. However, airway inflammation is present continuously from an early age and usually persists even if the symptoms resolve. Moreover, airways remodelling accelerates the process of decline in lung function over time. This has led to a reappraisal of the treatment strategy for asthma, mandating the early use of controller drugs and environmental measures from the time asthma is first diagnosed.

PNEUMONIA

Pneumonia is defined as inflammation of the substance of the lungs. It is usually caused by bacteria but can also be caused by viruses and fungi. Clinically, it usually presents as an acute illness with cough, purulent sputum, breathlessness and fever together with physical signs or radiological changes compatible with consolidation of the lung (Fig. 15.33). However, it can present with more subtle symptoms, particularly in the elderly. About 50% of pneumonia is pneumococcal.

Figure 15.33 Chest X-ray showing lobar pneumonia.

Pneumonia is usually classified by the setting in which the person has contracted their infection, e.g.

- In the community setting or community-acquired pneumonia (CAP) by a person with no underlying immunosuppression or malignancy
- In a hospital or other institution such as a nursing home – hospital-acquired pneumonia (HAP)
- In a patient whose immune system is compromised, through either genetic defect, immunosuppressive medication, or acquired immunodeficiency such as HIV infection.

Community-acquired pneumonia (CAP)

Community-acquired pneumonia occurs across all ages, but is commoner at the extremes of age. There has been an increase in rates of hospital admission due to community-acquired pneumonia over the last 10 years, reflecting changes in clinical practice and an ageing population, rather than a true increase in incidence.

Pneumonia can be classified either according to the organism responsible for infection or by the site of disease; *Pneumococcus* is the commonest cause overall; however, in 30–50% cases no organisms is identifiable while in about 20% of cases more than one organism is present. Infection can be localized with the whole of one or more lobes affected ('lobar pneumonia') or diffuse, when the lobules of the lung are mainly affected, often due to infection centred on the bronchi and bronchioles ('bronchopneumonia').

Pathophysiology

Several different microorganisms commonly cause CAP. Infection is spread by respiratory droplets. Both the clinical presentation and the range of causative organisms vary with age and with the effectiveness of the host's immune response and innate defence mechanisms. Factors which increase the risk of developing CAP are shown in Box 15.5.

Other causes of pneumonitis are listed below:

- **Chemical insult**, such as in the aspiration of vomit (see p. 838)
- **Radiotherapy** (see p. 838)
- **Allergic mechanisms** (see p. 852).

Clinical features of CAP

The clinical presentation varies according to the immune state of the patient and the infecting agent.

- **Cough**: this may be dry or productive and haemoptysis can occur. In pneumococcal pneumonia, sputum is characteristically rust-coloured.

Box 15.5 Risk factors for community-acquired pneumonia

- **Age**: <16 or >65 years
- **Co-morbidities**: HIV infection, diabetes mellitus, chronic kidney disease, malnutrition, recent viral respiratory infection
- **Other respiratory conditions**: cystic fibrosis, bronchiectasis, COPD, obstructing lesion (endoluminal cancer, inhaled foreign body)
- **Lifestyle**: cigarette smoking, excess alcohol, intravenous drug use
- **Iatrogenic**: immunosuppressant therapy (including prolonged corticosteroids)

Pneumonia

SIGNIFICANT WEBSITE

Scottish Intercollegiate Guidelines Network. Guideline No. 101. British Guideline on the Management of Asthma. 2011 update: <http://www.sign.ac.uk/guidelines/fulltext/101/index.html>

- **Breathlessness:** the alveoli become filled with pus and debris, impairing gas exchange. Coarse crackles are often heard on auscultation, due to consolidation of the lung parenchyma. Bronchial breath sounds may be heard over areas of consolidated lung.
- **Fever:** this can be as high as 39.5–40°C. If swinging fevers are present this often indicates empyema (see *Complications*).
- **Chest pain:** this is commonly pleuritic in nature and is due to inflammation of the pleura. A pleural rub may be heard early on in the illness.
- **Extrapulmonary features** (Box 15.6): these are more common in certain infections and are not universal. Sometimes the presence of these symptoms gives a clinical clue as to the aetiology.
 - Haemolysis due to cold agglutinins occurs (in approximately 50% cases of *Mycoplasma pneumoniae*). Thrombocytopenia is relatively common.
- **Other features:** in the elderly, CAP can present with confusion or nonspecific symptoms such as recurrent falls. CAP should always be considered in the differential diagnosis of sick elderly patients given their frequently atypical presentation.
- Where symptoms have been present for several weeks or have failed to respond to standard antibiotics, the possibility of *tuberculosis* should always be remembered.

Investigation and management of CAP

The clinical presentation varies between different causative organisms, but there is considerable overlap. *Streptococcus pneumoniae* (pneumococcus) is the commonest single cause, and all treatment and investigation strategies need to cover this. The most likely causative pathogens must be treated while considering alternative less common infectious causes (such as tuberculosis) or an alternative pathology (e.g. lung cancer). The treatment plan can always be refined and focused later. Pneumonia caused by endobronchial obstruction due to lung cancer is the main underlying problem.

Initial assessment

The type and extent of investigation depends on the severity of the illness, which also guides where the patient should be managed and predicts their outcome. Diagnostic microbiological tests are not needed in mild infection, which should be treated at home with standard antibiotics (amoxicillin or

clarithromycin for those with a history of penicillin allergy). Where patients have mild disease, chest X-ray is not routinely recommended unless they fail to improve after 48–72 hours. Antibiotics can be administered orally.

Severity is commonly assessed by CURB-65 or the CRB-65 score (Box 15.7). These give a guide to the likely risk of fatal outcome but they are not mandatory and antibiotic choice must always be tempered by clinical assessment and judgement, taking into account other factors associated with increased rates of mortality (Box 15.8). The CRB-65 score is used in the community where the serum urea level is not usually available (Fig. 15.34). Other severity scores are available to predict mortality and where a patient should be cared for such as the Pneumonia Severity Index (PSI), which is used more widely in the USA. Figure 15.34 illustrates a suggested diagnostic and treatment algorithm in CAP. It incorporates treatment recommendations extracted both from the British Thoracic Society Guidance for the management of CAP (2009) and the Infectious Diseases Society of America/American Thoracic Society Guidance 2007.

Investigations

All patients admitted to hospital should have a chest X-ray, blood tests and microbiological tests.

Chest X-ray

This must be repeated 6 weeks after discharge unless complications occur to rule out an underlying bronchial malignancy predisposing to pneumonia by causing obstruction.

- ***Strep. pneumoniae*.** Consolidation with air bronchograms, effusions and collapse due to retention of secretions can all be seen. Radiological abnormalities can lag behind clinical signs. A normal chest X-ray on presentation should be repeated after 2–3 days where CAP is suspected
- ***Mycoplasma*.** Usually one lobe is involved but infection can be bilateral and extensive.
- ***Legionella*.** There is lobar and then multi-lobar shadowing, with the occasional small pleural effusion. Cavitation is rare.

Box 15.6 Extrapulmonary features of community-acquired pneumonia

- Myalgia, arthralgia and malaise are common, particularly in infections caused by *Legionella* and *Mycoplasma*
- Myocarditis and pericarditis are cardiac manifestations of infection, most commonly in *Mycoplasma pneumoniae*
- Headache is common in *Legionella pneumoniae*. Meningoencephalitis and other neurological abnormalities also occur but are much less common
- Abdominal pain, diarrhoea and vomiting are common. Hepatitis can be a feature of *Legionella pneumoniae*
- Labial herpes simplex reactivation is relatively common in pneumococcal pneumonia
- Other skin rashes such as erythema multiforme and erythema nodosum are found in *Mycoplasma pneumoniae*. Stevens–Johnson syndrome (p. 1231) is a rare and potentially life-threatening complication of pneumonia

Box 15.7 CURB-65 score

C: confusion present (abbreviated mental test score <8/10)
U: (plasma) urea level >7 mmol/L
R: respiratory rate >30/min
B: systolic BP <90 mmHg; diastolic BP <60 mmHg
65: age >65
 1 point for each of the above:
 Score 0–1: Treat as outpatient
 Score 2: Admit to hospital
 Score 3+: Often require ICU care
 Mortality rates increase with increasing score.

Box 15.8 Other markers of severe community-acquired pneumonia

- Chest X-ray: more than one lobe involved
- P_{aO_2} <8 kPa
- Low albumin (<35 g/L)
- White cell count (<4 × 10⁹/L or >20 × 10⁹/L)
- Blood culture – positive
- Other co-morbidities
- Absence of fever in the elderly

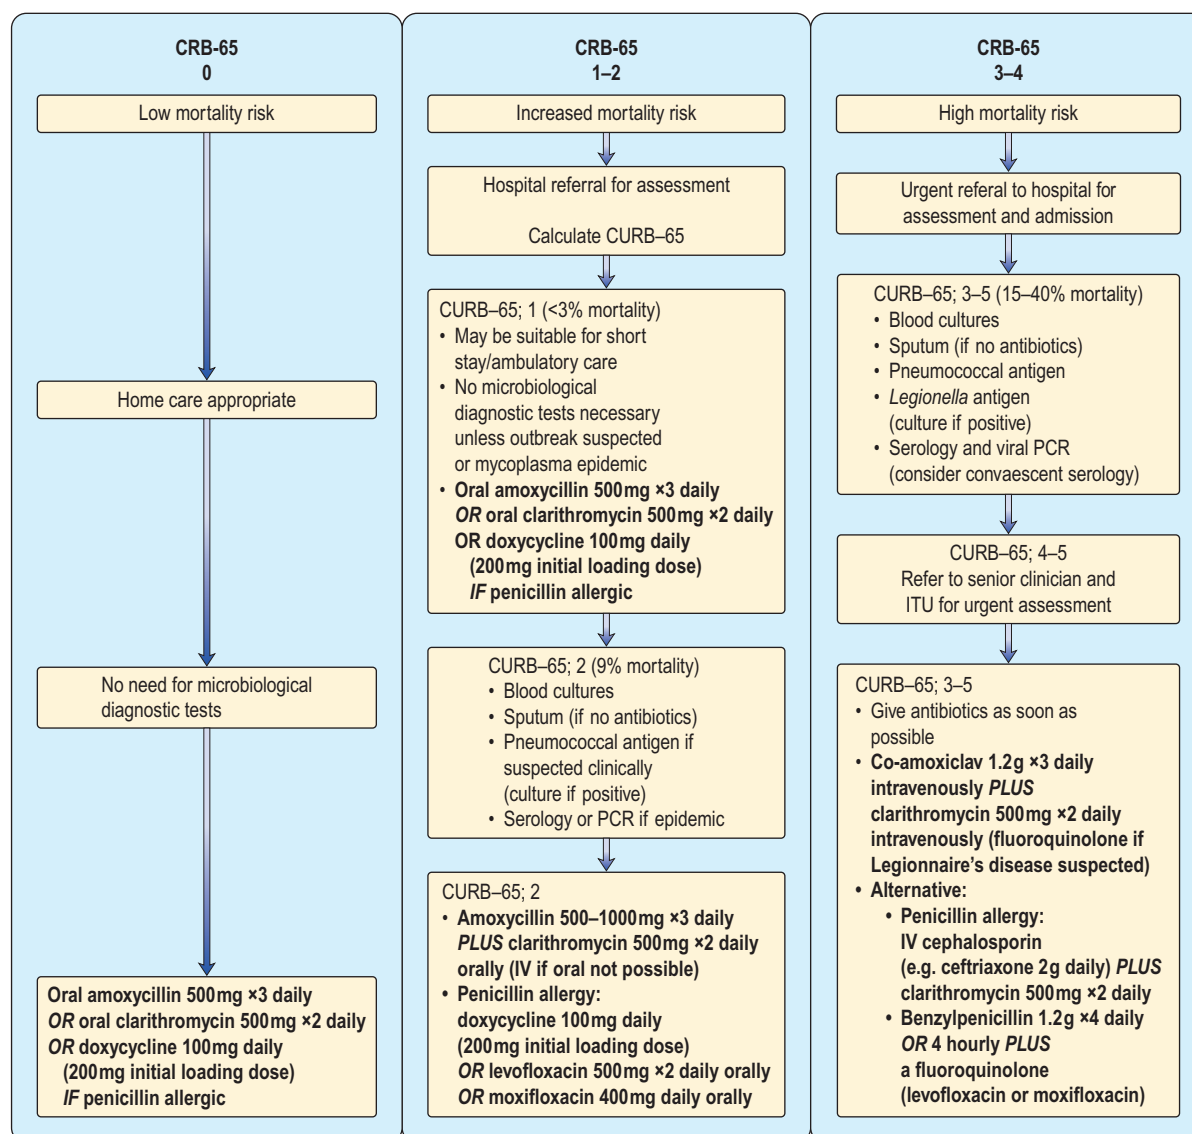

Figure 15.34 Algorithm for the assessment and treatment of CAP. CRB, confusion, respiratory rate, blood pressure.

Blood tests

Full blood count, urea and electrolytes, biochemistry and C-reactive protein are helpful.

- **Strep. pneumoniae.** White cell count is $>15 \times 10^9/L$ (90% polymorphonuclear leucocytosis); inflammatory markers significantly elevated: ESR >100 mm/hour; CRP >100 mg/L.
- **Mycoplasma.** White cell count is usually normal. In the presence of anaemia, haemolysis should be ruled out (direct Coombs' test and measurement of cold agglutinins).
- **Legionella.** There is lymphopenia without marked leucocytosis, hyponatraemia, hypoalbuminaemia and high serum levels of liver aminotransferases.

Other tests

The causative organism must be identified:

- Sputum culture and Gram-stain are required for all patients:
 - *S. pneumoniae*: Gram-positive diplococci
 - *S. aureus*: Gram-positive organisms commonly in clusters like a bunch of grapes

– Also diagnostic in infections caused by *S. aureus*, *H. influenzae*, *M. catarrhalis*, Gram-negative organisms

- Blood culture should be done for all patients who have moderate to severe CAP, ideally before antibiotics are administered. In *S. pneumoniae* infection, positive blood culture indicates more severe disease with greater mortality.

Table 15.14 highlights more specific diagnostic tests used to identify the causative organism in patients with moderate to severe CAP.

Pulse oximetry and arterial blood gas analysis is necessary if oxygen saturation is below 94%.

HIV testing: since pneumonia is a common initial presenting illness in patients with previously undiagnosed HIV infection, a test should be offered to all patients with pneumonia unless the patient is unable to give consent or comfort measures alone are implemented due to poor prognosis.

General management of pneumonia

- **Oxygen.** Supplemental oxygen should be administered to maintain saturations between 94% and 98% provided the patient is not at risk of carbon dioxide retention,

Table 15.14 Specific diagnostic tests in patients with moderate to severe community-acquired pneumonia (CAP)

Organism	Diagnostic confirmatory test
<i>Streptococcus pneumoniae</i>	Counter-immunoelectrophoresis (CIE) of sputum, urine and serum is 3–4 times more sensitive than sputum or blood cultures Urinary antigen test detects C-polysaccharide. This is rapid and unaffected by antibiotics; sensitivity is 65–80% and specificity about 80% Pneumococcal PCR (not routinely recommended as inferior to blood cultures and low sensitivity)
<i>Mycoplasma pneumoniae</i>	PCR of respiratory tract samples (throat swab/sputum/BAL fluid) – higher detection rates than serological assays PCR on serum under assessment and likely to become more available Complement fixation test (CFT) (though sensitivity and specificity low) – measure paired samples 10–14 days apart and look for rising titres or single level approximately 7 days after onset of illness
<i>Legionella</i> spp. (also termed Legionnaire's disease)	Urinary antigen test detects only serogroup 1, which accounts for most of these infections. Sensitivity (~80%) and specificity are high (almost 99%) Direct immunofluorescent staining of organism in the pleural fluid, sputum or bronchial washings is carried out Serum antibodies are less reliable. Paired serum antibody titres 10–14 days apart (or single level 7 days after onset of illness) Culture on special media is possible but takes up to 3 weeks. This gives valuable information on antibiotic sensitivity and should be performed if urinary antigen positive <i>Legionella</i> is not visible on Gram-staining
<i>Chlamydophila pneumoniae</i>	Paired serum antibody titres 10–14 days apart Antigen detection (DIF) on throat swabs/respiratory samples CFT usually only weakly positive and less reliable than in <i>C. psittaci</i>
<i>Chlamydophila psittaci</i>	Paired serum antibody titres 10–14 days apart CFT relatively sensitive and specific Antigen detection (DIF) not available for <i>C. psittaci</i>
<i>Coxiella burnetii</i> (Q fever)	Paired serum antibody titres 10–14 days apart
All respiratory viruses including influenza A and B	PCR of respiratory tract samples (throat swab/sputum/bronchoalveolar lavage, BAL fluid)

due to loss of hypoxic drive in COPD. In patients with known COPD, oxygen saturations should be maintained between 88% and 92%; normally with controlled oxygen via fixed percentage delivery mask.

- **Intravenous fluids.** Required in hypotensive patients showing any evidence of volume depletion.
- **Antibiotics.** The first dose of antibiotic should be administered within 4 hours of presentation in hospital and treatment should not be delayed while investigations are awaited.
 - Parenteral antibiotics should be switched to oral once the temperature has settled for a period of 24 hours, provided there is no contraindication to oral therapy.
 - If patients fail to respond to initial treatment, microbiological advice should be sought and alternative diagnoses considered (e.g. *S. aureus* pneumonia, which requires addition of flucloxacillin/fusidic acid, and possibly cover for MRSA infection. Causes of failure are shown in Table 15.15.
 - The antibiotic regimen should be adjusted specifically once culture and sensitivity results are available. There is an increased incidence of *Clostridium difficile* associated diarrhoea (CDAD) associated with some antibiotics, e.g. cephalosporins, which should be avoided if possible. The risk of MRSA increases with antibiotic overuse.
- **Thromboprophylaxis.** If admitted for >12 hours subcutaneous low molecular weight heparin should be prescribed unless contraindications exist and TED (thromboembolus deterrent) stockings fitted.
- **Physiotherapy.** Chest physiotherapy is not needed unless sputum retention is an issue.
- **Nutritional supplementation.** The need for this is assessed, particularly in severe disease, by a dietician.

Table 15.15 Causes of slow resolving pneumonia

Incorrect or incomplete antimicrobial treatment	Underlying antibiotic resistance Inadequate dose/duration Non-adherence Malabsorption
Complication of CAP	Parapneumonic pleural effusion (exudative) Empyema Lung abscess
Underlying neoplastic lesion or other lung disease	Obstructing lesion Bronchoalveolar cell carcinoma Bronchiectasis
Alternative diagnosis	Pulmonary thromboembolic disease Cryptogenic organizing pneumonia Eosinophilic pneumonia Pulmonary haemorrhage

- **Analgesia.** Simple analgesia such as paracetamol or non-steroidal anti-inflammatory medication helps treat pleuritic pain, thereby reducing the risk of further complications due to restricted breathing because of pain (e.g. sputum retention, atelectasis or secondary infection).

Complications

Complications of pneumonia must be excluded, especially if the patient does not respond quickly to initial treatment (see Table 15.17).

Prevention of further episodes

Cigarette smoking is an independent risk factor for CAP; if the patient still smokes, cessation advice and support should be given.

Vaccination against influenza is recommended for at-risk groups. All patients over the age of 65 who have not previously been vaccinated and are admitted with CAP should have the pneumococcal vaccine before discharge from hospital.

Types of pneumonia (Table 15.16)

The clinical presentation of pneumonia varies according to the causative organism but there is considerable overlap. Pneumococcal disease is typically acute in onset, with prominent respiratory symptoms and a high fever. Pneumonia due to the so-called atypical pathogens (*Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, *Legionella pneumophila*) tends to have a slower onset, often with more prominent extrapulmonary symptoms and complications.

The radiographic appearances are indistinguishable from those of CAP caused by pneumococcal pneumonia. The other atypical feature is that these organisms do not respond to penicillin, because they lack a cell wall. Erythromycin and tetracycline are usually effective.

Complications of pneumonia (Table 15.17)

Parapneumonic effusion and empyema

Effusions commonly occur with pneumonia and complicate around one-third to a half of cases of CAP. The majority of these are simple exudative effusions but empyema may also develop (where purulent fluid collects in the pleural space). Early indications of empyema are ongoing fever, and rising or persistently elevated inflammatory markers, despite appropriate antibiotic therapy.

Table 15.16 Types of pneumonia and their clinical features

Organism	Features
<i>Streptococcus pneumoniae</i>	Acute onset, often preceded by flu-like symptoms. Cough with rust coloured sputum High fevers and pleuritic chest pain common Bacteraemia more common in females, excess alcohol, dry cough and COPD, diabetes or HIV infection
<i>Mycoplasma pneumoniae</i>	Usually mild disease in young patient; occurs in cycles every 3–4 years Usually prominent extrapulmonary symptoms (headache, malaise, myalgia); complications common: haemolytic anaemia, erythema multiforme, hepatitis, meningoencephalitis
<i>Legionella</i> spp. (Legionnaire's disease)	Usually <i>Legionella pneumophila</i> but other species implicated in around 10% of cases Causes more severe disease with need for early intensive care Usually acquired by inhaling water mist containing bacteria Neurological symptoms frequently seen, along with GI involvement and deranged liver enzymes, elevated creatine kinase More common in smokers, males and in young people with no co-morbidities
<i>Staphylococcus aureus</i>	Evidence of recent influenza found in up to around 40–50% patients (increasing frequency with greater severity disease) Usually meticillin-sensitive strains (MSSA) but increasing incidence of meticillin-resistant disease (MRSA) which can produce Panton Valentine leucocidin (PVL) and result in necrotizing cavitating pneumonia and bilateral infiltrates
<i>Chlamydophila pneumoniae</i>	Unclear whether this is a causative or associated organism Generally causes mild disease but with prolonged prodrome
<i>Haemophilus influenzae</i> ; <i>Moraxella catarrhalis</i>	More common in pre-existing structural lung disease (CF, bronchiectasis, COPD) and the elderly
<i>Chlamydophila psittaci</i>	Acquired from birds (only 20% have positive history) Can be person-to-person spread; usually mild illness
<i>Coxiella burnetii</i> (Q fever)	Tends to occur more commonly in young men. History of dry cough and high fever Recognized cause of endocarditis
Gram-negative organisms <i>Klebsiella pneumoniae</i>	More common in men and those with history of excess alcohol (bacteraemia more likely), poor dental hygiene, diabetes and other co-morbidities; often present with low platelet and white cell count. Systemic upset is usual; high mortality
<i>Pseudomonas aeruginosa</i>	Cavitation and abscess formation seen Infection is associated with underlying lung disease (cystic fibrosis, bronchiectasis, COPD) or immune suppression
All respiratory viruses Varicella zoster Influenza A and B	Infection more likely in elderly with subsequent staphylococcal pneumonia Usually causes mild disease; not admitted to hospital Causes pneumonitis which heals leaving characteristic small calcified or non-calcified nodules Approximately 10% of adults with confirmed influenza infection have coincident <i>S. aureus</i> disease Fever, malaise and myalgia common
Other Influenza A (H5N1)	Does not usually affect humans Can be transmitted from poultry (causes avian flu) Fever, breathlessness, cough, diarrhoea Lymphopenia and thrombocytopenia High mortality

Table 15.17 Complications of pneumonia

General	Respiratory failure Sepsis – multi-system failure
Local	Pleural effusion Empyema Lung abscess Organizing pneumonia

Box 15.9 Common causative organisms in lung abscess

- *Klebsiella pneumoniae*
- *Staphylococcus aureus*
- Gram-negative enteric bacilli
- *Mycobacterium tuberculosis*
- *Streptococcus milleri*
- Anaerobic bacteria (post aspiration)
- *Haemophilus influenzae*

Thoracentesis should be performed to make a diagnosis. Fluid should be aspirated under ultrasound guidance and sent for Gram-stain, culture, fluid protein, glucose and LDH (with comparison to serum levels). Light's criteria (see p. 863) can be applied to assess whether an effusion is transudative or exudative. An exudative effusion with pleural fluid pH <7.2 is strongly suggestive of empyema. Pathogens are often detectable; sensitivity analysis will help guide antimicrobial therapy.

If an empyema develops, the fluid should be urgently drained to prevent further complications such as development of a thick pleural rind or prolonged hospital admission. The presence of empyema further increases mortality risk. The duration of antibiotic administration will usually need to be extended. Whenever possible, the choice of antimicrobial should be guided by the results of cultures. Thoracic surgical intervention is necessary in severe cases.

Lung abscess

This term is used to describe severe localized suppuration within the lung associated with cavity formation visible on the chest X-ray or CT scan, often with a fluid level (which always indicates an air-liquid interface).

There are several causes of lung abscess (Box 15.9).

- **Aspiration pneumonia:** rarely, abscesses develop as a complication of aspiration pneumonia. A history of excessive alcohol consumption or impaired swallowing in a patient with pneumonia suggests aspiration.
- **Tuberculosis:** see pages 839–841.
- **Pneumonia caused by certain species,** particularly *Staphylococcus aureus* or *Klebsiella pneumoniae*.
- **Septic emboli usually containing staphylococci:** these can cause multiple lung abscesses. The presence of multiple lung abscesses in an injecting drug user should prompt investigation for infective endocarditis of the tricuspid (or rarely pulmonary) valves. Infarcted areas of lung (due to pulmonary emboli) occasionally cavitate and become infected.
- **Spread from an amoebic liver abscess:** amoebic lung abscesses occasionally develop in the right lower lobe following transdiaphragmatic spread.
- **Bronchial obstruction by an endoluminal cancer**
- **Foreign body inhalation.**

Box 15.10 Organisms implicated in hospital-acquired pneumonia

- Gram-negative bacteria (*Pseudomonas* spp., *Escherichia* spp., *Klebsiella* spp.)
- Anaerobic bacteria (*Enterobacter* spp.)
- *Staphylococcus aureus* (including MRSA)
- *Acinetobacter* spp.

In the latter two, a fiberoptic bronchoscopy and CT scan are performed. Chronic or subacute lung abscesses may follow inadequate treatment of pneumonia.

Clinical features

The clinical features are usually persisting or worsening pneumonia associated with the production of large quantities of sputum, which is often foul-smelling owing to the growth of anaerobic organisms. There is usually a swinging fever; malaise and weight loss frequently occur. On examination, there may be little to find in the chest. Clubbing occurs in chronic suppuration. Patients have a normocytic anaemia and/or raised inflammatory markers (ESR/CRP).

Treatment

Treatment should be guided by available culture results or clinical judgement and is often prolonged (4–6 weeks). Surgical drainage is sometimes necessary.

Pneumonia in other settings**Hospital-acquired pneumonia (HAP)**

This is defined as new onset of cough with purulent sputum along with a compatible X-ray demonstrating consolidation, in patients who are beyond 2 days of their initial admission to hospital or who have been in a healthcare setting within the last 3 months (including nursing/residential homes as well as acute care facilities such as hospitals). HAP is the second most common form of hospital-acquired infection after urinary tract and carries a significant mortality risk, particularly in the elderly or those with co-morbidities such as stroke, respiratory disease or diabetes. In HAP, the causative organisms differ from those causing CAP (Box 15.10). Viral or fungal pathogens are not responsible in immunocompetent hosts. Aerobic Gram-negative bacilli are commonly involved (e.g. *P. aeruginosa*, *E. coli*, *Klebsiella pneumoniae* and *Acinetobacter* species). *Staphylococcus aureus* is increasingly recognized in HAP, particularly methicillin-resistant *S. aureus* (MRSA), both in Europe and the USA. HAP due to *S. aureus* is more common in patients with diabetes mellitus, head trauma, and patients in intensive care units. Empirical antimicrobial therapy should be tailored accordingly. Other conditions should be excluded, including aspiration of gastric contents due to impaired swallowing or bulbar weakness.

Elderly residents of long-term care facilities who develop pneumonia have a similar range of pathogens to those found in HAP. In the USA, *S. aureus*, Gram-negative rods, pneumococcus and *Pseudomonas* species are the commonest causes of pneumonia acquired in nursing homes. Pneumonia associated with ventilation has the same range of organisms as other forms of HAP (p. 894). Piperacillin-tazobactam is commonly used in severe HAP.

Aspiration pneumonia

Acute aspiration of gastric contents into the lungs can produce an extremely severe and sometimes fatal illness

owing to the intense destructiveness of gastric acid. This can complicate anaesthesia, particularly during pregnancy (Mendelson's syndrome). Because of the bronchial anatomy, the most usual sites for aspirated material to end up are the right middle lobe and apical or posterior segments of the right lower lobe. The persistent pneumonia is often due to anaerobes and progresses to lung abscess or even bronchiectasis if protracted. It is vital to identify any underlying problem, since without appropriate corrective measures aspiration will recur.

Treatment should be directed specifically against positive cultures if available. If not, then use co-amoxiclav for mild to moderate disease which covers Gram-negative and anaerobic bacteria. Treatment needs to be escalated where there is a lack of response or in severe cases.

Rare causes of pneumonia

Pneumonia can occur as a minor feature during infection by *Bordetella pertussis*, typhoid and paratyphoid bacillus, brucellosis, leptospirosis and a number of viral infections including measles, chickenpox and glandular fever. Details of these infections are described in [Chapter 4](#).

Pneumonia in Immunocompromised patients

Patients who are immunosuppressed (either iatrogenically or due to a defect in host defences) are at risk not only from all the usual organisms which can cause pneumonia but also opportunistic pathogens which would not be expected to cause disease. These opportunistic pathogens can be commonly occurring microorganisms (i.e. ubiquitous in the environment) or bacteria, viruses and fungi that are found less often (see [Table 4.56](#)). The symptom pattern may resemble CAP or be more nonspecific. A high degree of clinical suspicion is therefore necessary when assessing an ill patient who is immunocompromised.

Pneumocystis jiroveci

Pneumocystis pneumonia (PCP) is one of the most common opportunistic infections encountered in clinical practice. It affects patients on immunosuppressant therapy such as long-term corticosteroids, monoclonal antibody therapy or methotrexate for autoimmune disease, those on anti-rejection medication post-solid organ transplantation or following stem cell transplantation, and patients infected with HIV; those at particular risk have CD4 counts $<200/\text{mm}^3$. *Pneumocystis jiroveci* is found in the air, and pneumonia arises from re-infection rather than reactivation of persisting organisms acquired in childhood.

Clinically, the pneumonia is associated with a high fever, breathlessness and dry cough. A characteristic feature on examination is rapid desaturation on exercise or exertion. The typical radiographic appearance is of a diffuse bilateral alveolar and interstitial shadowing beginning in the perihilar regions and spreading out in a butterfly pattern. Other chest X-ray appearances include localized infiltration, nodules, cavitation or a pneumothorax. Empirical treatment is justified in very sick high-risk patients, but wherever possible the diagnosis should be confirmed by indirect immunofluorescence on induced sputum or bronchoalveolar lavage fluid. First-line treatment of PCP is with high-dose co-trimoxazole (see [p. 188](#)).

TUBERCULOSIS

Epidemiology

It is estimated that one-third of the world's population are infected with tuberculosis (see also [p. 135](#)). The World Health Organization (WHO) declared TB a world emergency in 1993. There were almost 9 million new and relapsed cases of TB worldwide in 2010. Its incidence had been increasing by around 1% per year to a peak in 2005, but since then the global incidence *per capita* has started to slowly decline. The majority of cases (around 65%) are seen in Africa and Asia (India and China). Co-infection with HIV remains a problem, not only because this is a huge health burden on resource-poor nations, but also because of the growing incidence of multi- and extremely-drug resistant strains and the high mortality of the two co-existent diseases. TB was responsible for 1.4 million deaths in 2010 and a quarter of these were in HIV co-infected individuals. There are a number of factors affecting the prevalence and risk of developing TB ([Box 15.11](#)).

Pathophysiology

Tuberculosis is caused by four main mycobacterial species collectively termed *Mycobacterium tuberculosis complex* (MTb):

- *Mycobacterium tuberculosis*
- *Mycobacterium bovis*
- *Mycobacterium africanum*
- *Mycobacterium microti*.

These are obligate aerobes and facultative intracellular pathogens, usually infecting mononuclear phagocytes. They are slow growing with a generation time of 12–18 hours. Due to high lipid content in the cell wall, they are relatively impermeable and stain only weakly with Gram-stain. Where stained with dye combined with phenol and washed with acidic organic solvents, they resist decolorization and therefore are termed 'acid-fast bacilli'.

Pathogenesis

Tuberculosis is an airborne infection spread via respiratory droplets. Only a small number of bacteria need to be inhaled to develop infection but not all those who are infected develop active disease. The outcome of exposure is dictated

Box 15.11 Factors affecting the prevalence and risk of developing tuberculosis in the developed world

- Contact with high-risk groups:
 - Originated from a high incidence country (defined as $>40/100\,000$)
 - Frequent travel to high incidence areas
- Immune deficiency
 - HIV infection
 - Corticosteroids or immunosuppressant therapy
 - Chemotherapeutic drugs
 - Nutritional deficiency (vitamin D)
 - Diabetes mellitus
 - Chronic kidney disease
 - Malnutrition/body weight $>10\%$ below ideal body weight
- Lifestyle factors:
 - Drug/alcohol misuse
 - Homelessness/hostels/overcrowding
 - Prison inmates
- Genetic susceptibility (twin studies of gene polymorphisms)

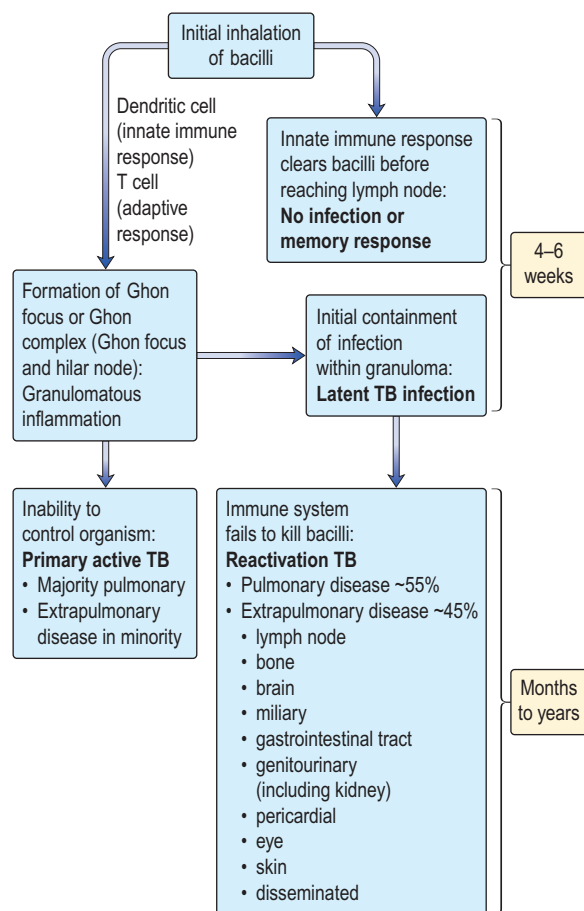

Figure 15.35 The consequences of exposure to TB.

by a number of factors including the host's immune response (Fig. 15.35).

Primary tuberculosis

'Primary tuberculosis' describes the first infection with MTb. Once inhaled into the lung, alveolar macrophages ingest the bacteria; the bacilli then proliferate inside the macrophages and cause the release of neutrophil chemo-attractants and cytokines, resulting in an inflammatory cell infiltrate reaching the lung and draining hilar lymph nodes. Macrophages present the antigen to the T lymphocytes with the development of a cellular immune response. A delayed hypersensitivity-type reaction occurs, resulting in tissue necrosis and formation of a granuloma.

Granulomatous lesions consist of a central area of necrotic material called caseation, surrounded by epithelioid cells and Langhans' giant cells with multiple nuclei, both cells being derived from the macrophage. Lymphocytes are present and there is a varying degree of fibrosis. Subsequently, the caseated areas heal completely and many become calcified. Some of these calcified nodules contain bacteria, which are contained by the immune system (and the hypoxic acidic environment created within the granuloma) and are capable of lying dormant for many years. The initial focus of disease is termed the 'Ghon focus'.

On a chest X-ray, the Ghon focus is evident as a small calcified nodule often within the upper parts of the lower lobes or the lower parts of the upper lobes, seen in the mid-zone. A focus can also develop within the regional draining lymph node (primary complex of Ranke).

Box 15.12 Factors implicated in the reactivation of latent TB

- HIV co-infection
- Immunosuppressant therapy (chemotherapy/monoclonal antibody treatment) including corticosteroids
- Diabetes mellitus
- End-stage chronic kidney disease
- Malnutrition
- Ageing

Table 15.18 Some features contrasting latent infection with active tuberculous disease

Latent infection	Active disease
Bacilli present in Ghon focus	Bacilli present in tissues or secretions
Sputum smear and culture negative	Sputum commonly smear and culture positive in pulmonary disease MTb can usually be cultured from infected tissue
Tuberculin skin test usually positive	Tuberculin skin test usually positive (and can ulcerate)
Chest X-ray normal (small calcified Ghon focus frequently visible)	Chest X-ray shows signs of consolidation/cavitation/effusion in pulmonary disease
Asymptomatic	Symptomatic – night sweats, fevers, weight loss and cough common
Not infectious to others	Infectious to others if bacilli detectable in sputum

Upon initial contact with infection <5% of patients develop active disease. This percentage increases to 10% within the first year of exposure.

Latent tuberculosis

In the majority of people who are infected by *Mycobacterium* spp., the immune system contains the infection and the patient develops cell-mediated immune memory to the bacteria. This is termed **latent tuberculosis**.

Reactivation tuberculosis

The majority of TB cases are due to reactivation of latent infection. The initial contact usually occurred many years or decades earlier. In patients with HIV infection newly acquired TB infection is also common. There are several factors implicated in the development of active disease. (Box 15.12). The clinical features of latent and reactivation TB are contrasted in Table 15.18.

Clinical features and diagnosis

Any of the manifestations of disease shown in Table 15.19 occur in primary or reactivation disease but extrapulmonary involvement is far less common in primary disease and is usually only seen in regions of high endemicity.

In all cases of suspected TB, substantial effort should be made to obtain tissue or fluid for microscopy, smear and culture to obtain information on sensitivities. Tissue samples should also be sent for histopathological examination.

Pulmonary TB

Patients are frequently symptomatic with a productive cough and occasionally haemoptysis along with systemic symptoms of weight loss, fevers and sweats (commonly at the end

of the day and through the night). Where there is laryngeal involvement, hoarse voice and a severe cough are found. If disease involves the pleura, then pleuritic pain is a frequent presenting complaint.

The chest X-ray (Fig. 15.36) demonstrates several findings: consolidation with or without cavitation, pleural effusion or thickening or widening of the mediastinum caused by hilar or paratracheal adenopathy.

Lymph node TB

The next commonest site for infection is lymph node TB. Extrathoracic nodes are more commonly involved than intrathoracic or mediastinal. Usually this presents as a firm

non-tender enlargement of a cervical or supraclavicular node. The node becomes necrotic centrally and can liquefy and be fluctuant if peripheral. The overlying skin is frequently indurated or there can be sinus tract formation with purulent discharge but characteristically there is no erythema (cold abscess formation). Nodes typically can be enlarged for several months prior to diagnosis. On CT imaging, the central area appears necrotic (see image).

Other forms of TB

Gastrointestinal

See page .833

TB of bone and spine

See pages 533 and 534

Miliary TB

- Miliary disease occurs through haematogenous spread of the bacilli to multiple sites, including the central nervous system in 20% cases.
- Systemic upset is the rule, with respiratory symptoms in the majority. Other findings are liver and splenic microabscesses with deranged liver enzymes or cholestasis and GI symptoms.
- The chest X-ray demonstrates multiple nodules which appear like millet seeds, hence the term 'miliary'.

Central nervous system TB

See this chapter.

Pericardial TB

Skin

See page 1198.

Figure 15.36 Chest X-ray showing tuberculosis of left upper lobe with cavitation.

Table 15.19 Common sites of TB infection with relevant radiological findings and appropriate diagnostic investigations

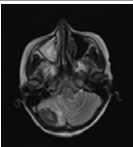

Common sites of TB infection with relevant radiological findings and appropriate diagnostic investigations		
Pulmonary, pleural and laryngeal 	Smear and culture of: <ul style="list-style-type: none"> ■ Sputum (≥ 2 samples increase diagnostic yield) Induced sputum (inhale hypertonic saline which induces coughing) diagnostic yield comparable to bronchoscopic samples ■ Bronchoalveolar lavage fluid if cough unproductive and induced sputum not possible ■ Aspiration of pleural fluid and pleural biopsy ■ Gastric aspirates may be useful in paediatric disease ■ Nasoendoscopic or bronchoscopic examination/biopsy of vocal cords with biopsy for smear/culture and histology in laryngeal disease 	
Miliary TB 	CNS TB 	Lymph node TB 
<ul style="list-style-type: none"> ■ Blood cultures ■ Bronchoalveolar lavage fluid (usually smear negative but culture-positive) ■ Lumbar puncture should be performed in all cases unless contraindicated to assess for CNS involvement (affects treatment duration) – see below Sampling of other involved organs often necessary	<ul style="list-style-type: none"> ■ Lumbar puncture if no contraindication. Characteristics of lumbar puncture: CSF protein may be very high (usually $>2-3$ g/L) CSF glucose $< \frac{1}{2}$ blood glucose CSF lymphocytosis	All samples should be sent for Histocytopathological examination as well as culture and smear: <ul style="list-style-type: none"> ■ Fine needle aspiration or biopsy of an involved lymph node usually under radiological guidance ■ Mediastinal nodal sampling (endobronchial ultrasound transbronchial needle aspiration, mediastinoscopy/mediastinotomy)

Table 15.20 Usual treatment and duration in fully sensitive TB

Site of disease	Duration of therapy	Drug choice
Pulmonary ^a Extrapulmonary (excluding CNS disease) Miliary (excluding CNS involvement)	6 months (may be extended to 9 months in certain situations): patient smear positive 2 months into treatment some patients with HIV co-infection high burden of disease	Fully sensitive strain: 2HRZE + 4HR ^b Or 2HRZE + 7HR
CNS TB	12 months	2HRZE + 10HR Plus Prednisolone (20–40 mg o.d.) weaning over 2–4 weeks
Latent TB	3 months Or 6 months	3RH Or 6H

CNS, central nervous system; E, ethambutol; H, isoniazid; R, rifampicin; Z, pyrazinamide.
^aFor pulmonary TB, 2HRZE + 4(HR)₃, i.e. 3x weekly for 4HR is acceptable.
^b2HRZE + 4HR, 2 months of HRZE + 4 months of HR.

Microbiological diagnosis

Rapid identification of the presence of bacteria by immediate stains is essential and should be performed within 24 hours; culture of the sample allows determination of the antibiotic sensitivity of the infecting strain.

Stains

Auramine-rhodamine staining is more sensitive (though less specific) than Ziehl–Neelsen; as a result it is more widely used. It requires fluorescence microscopy and highlights bacilli as yellow-orange on a green background.

Culture

The majority of the developed world uses liquid/broth culture of mycobacteria in addition to solid media (Lowenstein–Jensen slopes or Middlebrook agar) as time to culture is shorter than for solid culture (1–3 weeks compared with 3–8 weeks). Using liquid culture in the presence of anti-mycobacterial drugs (usually first-line therapy initially) establishes the drug sensitivity for that strain and usually takes approximately 3 weeks).

The use of microscopic-observation drug-sensitivity (MODS) assay allows detection of bacteria and susceptibility rapidly by comparing growth in multiple wells with anti-mycobacterial drugs within liquid media. This technique has the advantage of being relatively inexpensive (although is labour-intensive and operator dependent) and is therefore more widely used in resource-poor areas.

Nucleic acid amplification (NAA)

NAA is increasingly used for rapid identification of MTb complex and is useful in differentiating between MTb and non-tuberculosis mycobacteria (NTM) as well as identifying TB in smear-negative sputum specimens. Culture and staining is still necessary and should not be replaced by PCR. PCR is only useful at the initial stage of diagnosis as it frequently remains positive despite treatment due to the detection of dead organisms. This test has a high specificity and moderate sensitivity on cerebrospinal fluid and should be routinely looked for in suspected CNS TB.

The identification of mycobacterial DNA is becoming increasingly useful in facilitating rapid commencement of treatment and also rapid identification of drug resistance. Genetic mutations in bacterial DNA conferring rifampicin-resistance are highly predictive of multi-drug resistance. The development of a highly specific probe designed to detect this mutation thereby allows rapid identification of resistant

disease and appropriate therapy to be commenced sooner than waiting for cultures to complete (may take up to 8 weeks).

Molecular testing for drug resistance has also become possible using PCR to detect genetic mutations associated with rifampicin resistance.

Management

Patients with fully sensitive TB require 6 months of treatment, excluding TB of the central nervous system, for which the recommended duration is at least 12 months. Shorter duration courses are being studied, aiming at reducing the duration of treatment and increasing the armamentarium against resistant strains. In CNS and pericardial disease, corticosteroids are used as an adjunct at treatment initiation to reduce long-term complications. Table 15.20 summarizes standard recommended regimens.

Directly observed therapy (DOT) is widely recommended and employed with an aim to achieve treatment-completion rates of over 85%. DOT is defined as treatment supervised by a healthcare professional or family member where the person is observed swallowing their medication. WHO advocates universal DOT as one of their strategies to reduce the incidence of TB worldwide, partly because the majority of relapsed disease or treatment failure is due to lack of adherence, interrupted therapy or incorrect treatment (Box 15.13). Where used, the dosing frequency may be reduced to three-times per week to make DOT more convenient. Success rates are comparable for thrice-weekly DOT as for standard daily unsupervised therapy.

Unwanted effects of drug treatment

Rifampicin induces liver enzymes, which may be transiently elevated in the serum of many patients. The drug should be stopped only if the serum bilirubin becomes elevated or if transferases are >3 times elevated, which is uncommon. Induction of liver enzymes means that concomitant drug treatment may be made less effective (see Ch. 16). Thrombocytopenia has been reported. Rifampicin stains body secretions pink and the patients should be warned of the change in colour of their urine, tears (contact lens) and sweat. Oral contraception will not be effective, so alternative birth-control methods should be used. Rifabutin, a rifamycin, is similar and is used for prophylaxis against *M. avium-intracellulare* complex infection in HIV patients with CD4 counts <200 mm³.

Isoniazid has very few unwanted effects. At high doses it may produce a polyneuropathy due to a B₆ deficiency as isoniazid interacts with pyridoxal phosphate. This is extremely rare when the normal dose of 200–300 mg is given daily. Nevertheless, it is customary to prescribe pyridoxine 10 mg daily to prevent this. Occasionally, isoniazid gives rise to allergic reactions, e.g. a skin rash and fever, with hepatitis occurring in fewer than 1% of cases. The latter, however, may be fatal if the drug is continued.

Pyrazinamide may cause hepatic toxicity, though this is much rarer with present dosage schedules. Pyrazinamide reduces the renal excretion of urate and may precipitate hyperuricaemic gout.

Ethambutol can cause a dose-related optic retrobulbar neuritis that presents with colour blindness for green, reduction in visual acuity and a central scotoma (commoner at doses of 25 mg/kg). This usually reverses provided the drug is stopped when symptoms develop; patients should therefore be warned of its effects. All patients prescribed the drug should be seen by an ophthalmologist prior to treatment and doses of 15 mg/kg should be used.

Streptomycin can cause irreversible damage to the vestibular nerve. It is more likely to occur in the elderly and in those with renal impairment. Allergic reactions to streptomycin are more common than to rifampicin, isoniazid or pyrazinamide. This drug is used only if patients are very ill, have multidrug-resistant TB or are not responding adequately to therapy.

Box 15.13 Criteria for implementation of directly observed therapy for TB

- Patients thought unlikely to comply
 - History of serious mental illness
 - History of non-adherence to TB therapy in past or during current treatment course
- Street or shelter-dwelling homelessness
- Multi-drug resistant TB

Drug resistance

Worldwide, drug resistance is an increasing problem, with an estimated incidence of 444 000 cases in 2008, responsible for around 150 000 deaths (Fig. 15.37). It arises due to incomplete or incorrect drug treatment and can be spread from person to person. In developed countries, the incidence of multi-drug resistance (resistance to both rifampicin and isoniazid, termed MDR-TB) is relatively low (around 1%) and only a handful of extensively drug-resistant (XDR-TB) cases have been seen, though most countries have reported at least one case. XDR-TB is defined as high level resistance to rifampicin, isoniazid, fluoroquinolones and at least one injectable agent such as amikacin, capreomycin or kanamycin. Total drug resistance (TDR) has now been reported from Italy, Iran and Mumbai (India) in a few cases. Mono-resistance is reasonably common, for example the incidence is approximately 10% in the UK. A risk assessment for drug resistance should be routinely performed (Box 15.14).

TB in special situations

HIV co-infection

The increase in TB seen over recent decades has occurred to a considerable extent in association with the incidence of

Box 15.14 Factors associated with an increased risk of drug-resistant TB

- History of prior drug treatment of TB (particularly if unsupervised, self-administered treatment)
- Co-infection with advanced HIV and previous TB treatment
- Infection acquired in region with high rates of drug resistance
- Contact with a known case of resistant TB
- Failure to respond to empiric TB therapy despite documented adherence
- Exposure to multiple courses of fluoroquinolone antibiotics for presumed community acquired pneumonia
- Healthcare workers exposed to cases of resistant TB

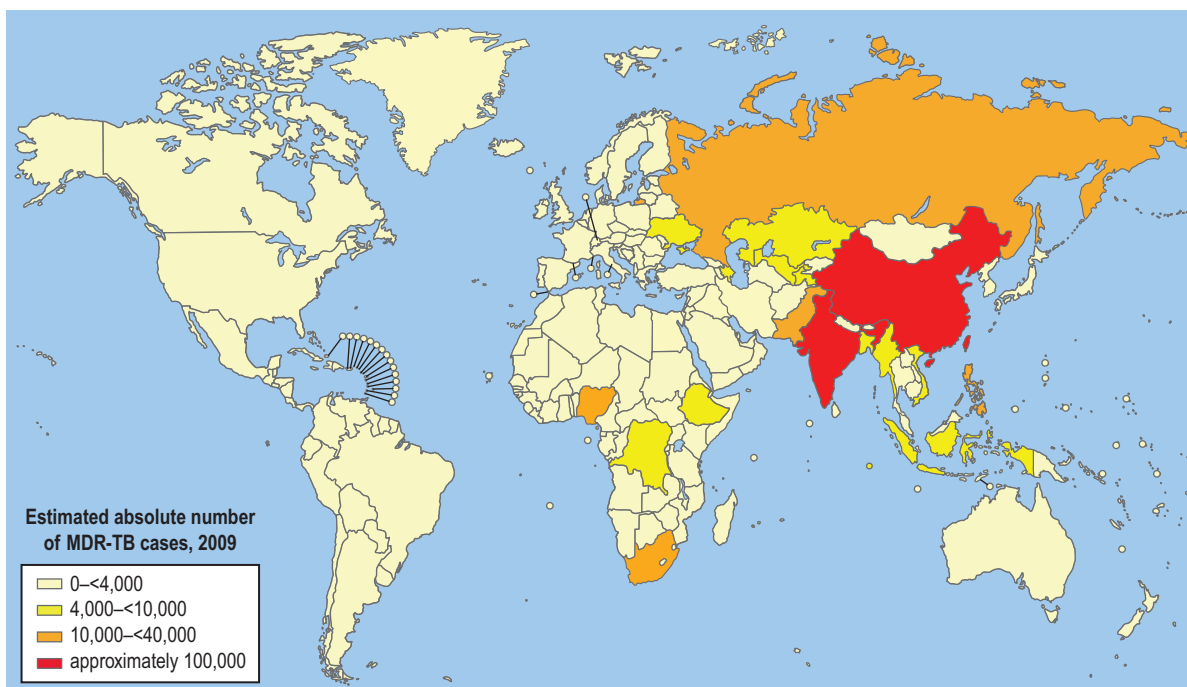

Figure 15.37 Worldwide incidence of MDR-TB, 2009. (Reproduced with permission from WHO.)

HIV infection, with high levels seen in Africa (particularly sub-Saharan Africa), the Indian subcontinent and parts of Eastern Europe and Russia. The incidence of HIV infection in TB worldwide is around 15% and TB is responsible for around one-quarter of AIDS-related deaths.

Alongside the increased morbidity and mortality of co-infection, there are specific issues relating to the treatment of TB in HIV: namely, the incidence of drug interactions and intolerance, the increased risk of treatment toxicity and the higher incidence of drug resistance. TB/HIV infection should be managed by experts in TB (respiratory or infectious disease physicians) alongside HIV specialists.

Chronic kidney disease (CKD)

CKD is a risk factor for reactivation of latent TB infection due to relative immune paresis. Patients due to undergo renal transplantation may need to be screened for LTBI and need to be given complete chemoprophylaxis if necessary before undergoing their procedure. The presence of chronic kidney disease also complicates the treatment regimen as there is an increased risk of toxicity due to altered pharmacokinetics, which necessitates dosage adjustments and therapeutic drug level monitoring. Management should be undertaken by TB specialists in conjunction with renal physicians.

Latent TB Infection

The diagnosis of latent TB infection (LTBI) involves demonstration of immune memory to mycobacterial proteins. Two tests are available.

Tuberculin skin test (TST)

A positive result is indicated by a delayed hypersensitivity reaction evident 48–72 hours after the intradermal injection of purified protein derivative (PPD) resulting in:

- A raised indurated lesion >6 mm diameter in non-vaccinated adults
- A raised indurated lesion >15 mm in BCG-vaccinated adults.

False negative (anergic) TSTs are common in immunosuppression due to HIV infection ($CD4^+ < 200/mm^3$), sarcoidosis, drugs (chemotherapy, anti-TNF therapy, steroids), at the extremes of age and in active disease. False positives occur due to cross-reactivity with non-tuberculous mycobacteria (NTM) and BCG vaccination.

Interferon-gamma release assays (IGRAs)

IGRAs detect T-cell secretion of interferon-gamma (IFN- γ) following exposure to *M. tuberculosis*-specific antigens (ESAT-6, CFP-10.). Where a person has been infected (previously or currently) with TB, activated T cells within their extracted whole-blood secrete quantifiable levels of interferon-gamma in response to re-exposure to TB-specific antigens. The test does not differentiate between active and latent infection. However, it is highly specific compared with the TST and has a similar or better sensitivity.

Global TB strategy

Part of the global strategy is an increase in the identification and treatment of latent TB infection (LTBI), thereby reducing the risk of conversion to active disease and transmission to others. In certain groups with LTBI, chemoprophylaxis is offered to reduce the risk of active infection (Box 15.15).

Active case finding forms part of a number of programmes:

Box 15.15 People who should be treated for latent TB infection (after excluding active TB)

- People aged ≤ 35 years with positive TST or IGRA
- Healthcare workers with positive TST or IGRA
- Patients commencing anti-TNF therapy with positive IGRA
- HIV-positive people with positive IGRA
- People with evidence of previous TB on chest X-ray and inadequate treatment.

- **Contact tracing:** carried out after diagnosis of a new case of TB; involves identifying close contacts who are at risk of infection or who may have active infection and not yet sought medical attention
- **Screening of healthcare workers:** as part of an occupational health programme, with BCG vaccination of those with no evidence of previous TB exposure
- **Screening of new entrants:** those arriving from a country of high incidence of TB should be offered screening for latent or active infection and vaccination if not infected and previously unvaccinated
- **Street-homeless or hostel dwellers:** these groups are at increased risk of active TB and should be offered opportunistic screening for active infection
- **Immunocompromised people:**
 - Patients due to commence monoclonal antibody therapy for autoimmune conditions should be screened for active or latent infection and should be given appropriate treatment before commencing immunosuppressive therapy as they are at a particularly high risk for reactivation of LTBI
 - People with HIV infection (see above)
 - People with underlying haematological malignancies or solid-organ transplants or undergoing chemotherapy require screening.

BCG vaccination

BCG is a live attenuated vaccine derived from *M. bovis* that has lost its virulence. It has variable efficacy but is still recommended in certain situations in developed countries (but not the USA), though no longer offered routinely to all due to the lack of cost-efficacy. It has been shown to reduce the risk of disseminated and CNS TB in babies and children and is therefore used worldwide. There are safety concerns in babies with HIV. Its efficacy in adults is very variable.

Non-tuberculous mycobacterial infection (NTM)

NTM occur in soil and water and are not usually pathogenic due to their lack of virulence. However, where there is a breach of the normal host defence mechanisms, certain strains have the potential to become pathogenic (Table 15.21). Factors associated with increased risk of pulmonary NTM infection are shown in Box 15.16. Treatment is suggested if there is a compatible clinical picture and (a) the organism is isolated from an invasive sample or (b) if an NTM is isolated from more than one sputum sample obtained at different times.

Table 15.21 Some non-tuberculous mycobacteria strains implicated in disease

Strain	Site of disease
<i>M. avium intracellulare complex</i> (MAC)	Pulmonary (nodular and interstitial infiltrates in middle lobe in women or fibrocavitary disease in smoking middle-aged males) Disseminated (usually in HIV) Hypersensitivity pulmonary disease ('hot-tub lung') Lymphadenitis in children
<i>M. kansasii</i>	Pulmonary (similar presentation to MTb, usually in middle-aged males) Disseminated disease (in HIV)
<i>M. abscessus</i>	Skin, soft tissue and bone disease Pulmonary (usually in bronchiectasis, older, non-smoking females)
<i>M. chelonae</i>	Skin, bone and soft tissue Pulmonary (similar to <i>M. abscessus</i>)
<i>M. fortuitum</i>	Pulmonary (similar to <i>M. abscessus</i>)
<i>M. gordonae</i>	Only rarely pathogenic (can be significant in immunocompromised host)
<i>M. xenopi</i>	Pulmonary (fibrocavitary disease in COPD) Contaminated surgical instruments causing bone/soft tissue infection
<i>M. malmoense</i>	Pulmonary Lymph node
<i>M. marinum</i>	Soft tissue, skin and bone
<i>M. szulgai</i>	Pulmonary (similar to TB)

Box 15.16 Factors associated with increased risk of pulmonary infection with non-tuberculous mycobacteria

- Structural lung disease:
 - COPD
 - Bronchiectasis
 - subgroup of women with bronchiectasis, scoliosis, pectus excavatum, mitral valve prolapse and hypermobile joints at particular risk
 - Cystic fibrosis
 - Prior TB
- HIV infection (CD4 <50/mm³)
- Genetic defects of interferon- γ /interleukin-12 pathway

Box 15.17 Diffuse parenchymal lung diseases (DPLDs)

- Granulomatous lung disease, e.g. sarcoid
- Granulomatous lung disease with vasculitis, e.g. Wegener, Churg–Strauss, microscopic vasculitis
- Pulmonary autoimmune rheumatic diseases, e.g. rheumatoid arthritis, systemic lupus erythematosus
- Idiopathic interstitial pneumonias, see [Box 15.18](#)
- Drugs, see [Table 15.22](#)
- Other forms:
 - Langerhans' cell histiocytosis
 - Goodpasture's syndrome
 - Diffuse alveolar haemorrhage
 - Idiopathic pulmonary haemosiderosis
 - Lymphangioleiomyomatosis
 - Pulmonary alveolar proteinosis

DIFFUSE DISEASES OF THE LUNG PARENCHYMA

Diffuse parenchymal lung disorders (DPLD, also referred to as interstitial lung diseases) are a heterogeneous group of disorders accounting for about 15% of respiratory clinical practice. There is diffuse lung injury and inflammation that can progress to lung fibrosis. The classification is shown in [Box 15.17](#).

Granulomatous lung disease

A granuloma is a mass or nodule composed of chronically inflamed tissue formed by the response of the mononuclear phagocyte system (macrophage/histiocyte) to an insoluble or slowly soluble antigen or irritant. If the foreign substance is inert (e.g. an inhaled dust), the phagocytes turn over slowly; if the substance is toxic or reproducing, the cells turn over faster, producing a granuloma. A granuloma is characterized by epithelioid multinucleate giant cells, as seen in tuberculosis. Granulomas are also seen in other infections, including fungal and helminthic, in sarcoidosis, and in hypersensitivity pneumonitis, and can also be due to foreign bodies (e.g. talc). Granulomatous lung disease with pulmonary vasculitis is discussed on [page 847](#).

Sarcoidosis

Sarcoidosis is a multisystem granulomatous disorder, commonly affecting young adults and usually presenting with bilateral hilar lymphadenopathy, pulmonary infiltration and skin or eye lesions. Beryllium poisoning can produce a clinical and histological picture identical to sarcoidosis, though contact with this element is now strictly controlled.

Epidemiology and aetiology

Sarcoidosis is a common disease of unknown aetiology that is often detected by routine chest X-ray. There is great geographical variation. The prevalence in the UK is approximately 19/100 000. Sarcoidosis is common in the USA but is uncommon in Japan. The course of the disease is much more severe in American blacks than in whites. The peak incidence is in the 3rd and 4th decades, with a female preponderance. There is no relation with any histocompatibility antigen, but 1st degree relatives (particularly in Caucasians) have an increased risk of developing sarcoidosis. Other proposed aetiological factors are an atypical mycobacterium or fungus, the Epstein–Barr virus, and occupational, genetic, social or other environmental factors (sarcoidosis is commoner in rural than in urban populations). None of these has been substantiated.

Immunopathology

- Typical sarcoid granulomas consist of focal accumulations of epithelioid cells, macrophages and lymphocytes, mainly T cells.
- There is depressed cell-mediated reactivity to tuberculin and other antigens such as *Candida albicans*.
- There is overall lymphopenia: circulating T lymphocytes are low but B cells are slightly increased.
- Bronchoalveolar lavage shows a great increase in the number of cells; lymphocytes are greatly increased (particularly CD4⁺ T-helper cells). The number of alveolar macrophages is increased but they represent a reduced percentage of the total number of bronchoalveolar lavage cells.
- Transbronchial biopsies show infiltration of the alveolar walls and interstitial spaces with leucocytes, mainly T cells, prior to granuloma formation.

It seems likely that the decrease in circulating T lymphocytes and changes in delayed hypersensitivity responses are the result of sequestration of lymphocytes within the lung. There is no evidence to suggest that patients with sarcoidosis suffer from an overall defect in immunity, since the frequency of fungal, viral and bacterial infections is not increased and there is no evidence of any increased risk of developing malignant neoplasms.

Clinical features

Sarcoidosis can affect many different organs of the body. The most common presentation is with respiratory symptoms or abnormalities found on chest X-ray (50%). Less common presentations include fatigue or weight loss (5%), peripheral lymphadenopathy (5%) and fever (4%). Neurological presentations are rare but well recognized and can mimic a variety of conditions. Chest X-ray may be normal in up to 20% of non-respiratory cases, though pulmonary lesions may be detected later.

There are four stages of pulmonary involvement based on radiological stage of the disease, which is helpful in prognosis:

- **Stage I:** bilateral hilar lymphadenopathy (BHL) alone
- **Stage II:** BHL with pulmonary infiltrates
- **Stage III:** pulmonary infiltrates without BHL
- **Stage IV:** fibrosis.

Bilateral hilar lymphadenopathy

This is a characteristic feature of sarcoidosis which is usually symptomless and only detected on chest X-ray. Occasionally, the bilateral hilar lymphadenopathy is associated with a dull ache in the chest, malaise and a mild fever.

Although the lung fields may appear normal on plain chest X-ray, the lung parenchyma is nearly always involved as shown by CT scanning (Fig. 15.38), transbronchial biopsies and bronchoalveolar lavage.

The differential diagnosis of bilateral hilar lymphadenopathy includes:

- **Lymphoma:** though this rarely affects only the hilar lymph nodes
- **Pulmonary tuberculosis:** though it is rare for the hilar lymph nodes to be symmetrically enlarged
- **Carcinoma of the bronchus** with malignant spread to the contralateral hilar lymph nodes: again this is rarely symmetrical.

Figure 15.38 HRCT scan in sarcoidosis. Note bilateral hilar lymphadenopathy and reticular shadowing.

Pulmonary infiltration

Parenchymal sarcoidosis may be asymptomatic. The combination of pulmonary infiltration and normal lung function tests is highly suggestive of sarcoidosis. Other cases are progressive leading to increasing effort dyspnoea and eventually cor pulmonale and death. The chest X-ray shows mottling in the mid-zones evolving over time to generalized fine nodular shadows. Eventually, widespread linear shadows develop, reflecting the underlying fibrosis. A honeycomb appearance can occasionally occur. In progressive disease, lung function tests show a typical restrictive defect with reduced gas transfer (see below).

The principal differential diagnoses are tuberculosis, pneumoconiosis, idiopathic pulmonary fibrosis and alveolar cell carcinoma.

Extrapulmonary manifestations

Skin and ocular sarcoidosis are the most common extrapulmonary presentations.

Skin lesions occur in 10% of cases. Sarcoidosis is the most common cause of erythema nodosum (see p. 1216). The association of bilateral symmetrical hilar lymphadenopathy with erythema nodosum occurs only in sarcoidosis. A chilblain-like lesion known as lupus pernio is also seen, as are skin nodules (see p. 1219).

Eye lesions. Anterior uveitis is common and presents with misting of vision, pain and a red eye, but posterior uveitis may present simply as progressive loss of vision. Although ocular sarcoidosis accounts for about 5% of uveitis presenting to ophthalmologists, asymptomatic uveitis may be found in up to 25% of patients with sarcoidosis. Conjunctivitis and retinal lesions have also been reported. *Uveoparotid fever* is a syndrome of bilateral uveitis and parotid gland enlargement together with occasional development of facial nerve palsy and is sometimes seen with sarcoidosis.

Keratoconjunctivitis sicca and lacrimal gland enlargement also occurs.

Metabolic manifestations. It is rare for sarcoidosis to present with problems of calcium metabolism, though hypercalcaemia is found in 10% of established cases. Hypercalcaemia and hypercalciuria can lead to the development of renal calculi and nephrocalcinosis. The cause of the hypercalcaemia is an increase in circulating 1,25-dihydroxyvitamin D₃, with 1 α -hydroxylation occurring in sarcoid macrophages in the lung in addition to that taking place in the kidney.

Central nervous system. CNS involvement is rare (2%) but can lead to severe neurological disease (see p. 1130).

Bone and joint involvement. Arthralgia without erythema nodosum is seen in 5% of cases. Bone cysts are found,

FURTHER READING

Iannuzzi MC, Rybicki BA, Teirstein AS. Sarcoidosis. *N Engl J Med* 2007; 357: 2153–2165.

particularly in the digits, with associated swelling. In the absence of swelling, routine X-rays of the hands are unnecessary.

Hepatosplenomegaly. Sarcoidosis is a cause of hepatosplenomegaly, though it is rarely of any clinical consequence. Liver biopsy is occasionally performed when the diagnosis is in doubt and will show granulomas.

Cardiac involvement is rare (3%) but can be serious. Ventricular dysrhythmias, conduction defects and cardiomyopathy with congestive cardiac failure are seen.

Investigations

- **Imaging.** Chest X-ray (see above). High-resolution CT is useful for assessment of diffuse lung parenchymal involvement.
- **Full blood count.** There may be a mild normochromic, normocytic anaemia with raised ESR.
- **Serum biochemistry.** Serum calcium is often raised and there is hypergammaglobulinaemia.
- **Transbronchial biopsy** is the most useful investigation, with positive results in 90% of cases of pulmonary sarcoidosis with or without X-ray evidence of lung parenchymal involvement. Pulmonary non-caseating granulomas are found in approximately 50% of patients with extrapulmonary sarcoidosis in whom the chest X-ray is normal.
- **Serum angiotensin-converting enzyme (ACE) level** is raised by two standard deviations above the normal mean value in over 75% of patients with untreated sarcoidosis. Raised (but lower) levels are also seen in patients with lymphoma, pulmonary tuberculosis, asbestosis and silicosis, limiting the diagnostic value of the test. However, the test is useful in assessing disease activity and response to treatment. Reduction of serum ACE during corticosteroid treatment does not, however, imply complete resolution of the disease.
- **Lung function tests** show a restrictive lung defect in patients with pulmonary infiltration or fibrosis. There is a decrease in TLC, FEV₁ and FVC, and gas transfer. Lung function is usually normal in patients who present with extrapulmonary disease or who only have hilar adenopathy on chest X-ray.

Treatment

Both the need to treat and the value of corticosteroid therapy are contested in many aspects of this disease. Hilar lymphadenopathy alone does not require treatment. Persisting infiltration visible on the chest X-ray with normal lung function tests should be monitored carefully. Patients with abnormal lung function tests are unlikely to improve without corticosteroid treatment. If the disease is not improving spontaneously 6 months after diagnosis, treatment should be started with prednisolone 30 mg for 6 weeks, reducing to alternate-day treatment with prednisolone 15 mg for 6–12 months. Although there have been no controlled trials of corticosteroids, they are indicated when there is continuing deterioration of lung function. Eye involvement or persistent hypercalcaemia are mandatory indications for systemic steroids.

If the erythema nodosum of sarcoidosis is severe or persistent it will respond rapidly to a 2-week course of prednisolone 5–15 mg daily, as will patients with uveoparotid fever. Myocardial sarcoidosis and neurological manifestations are also treated with prednisolone.

Prognosis

Sarcoidosis is a much more severe disease in certain racial groups, particularly American blacks, where death rates of up to 10% have been recorded. It is probable that the disease is fatal in fewer than 5% of cases in the UK, either as a result of respiratory failure and cor pulmonale or, more rarely, from myocardial sarcoidosis and renal damage. The initial chest X-ray provides a guide to prognosis. The disease remits within 2 years in over two-thirds of patients with hilar lymphadenopathy alone (*stage I*), in approximately one-half with hilar lymphadenopathy plus chest X-ray evidence of pulmonary infiltration (*stage II*), but in only one-third of patients with X-ray evidence of infiltration without any demonstrable lymphadenopathy (*stage III*). Lung volumes and gas transfer are the most useful way to monitor progression.

Granulomatous lung disease with vasculitis

The classification of pulmonary vasculitis and granulomatous disorders is unsatisfactory. In broad terms there are two main groups: the respiratory manifestations of systemic diseases, and disorders associated with the presence of anti-neutrophil cytoplasmic antibodies (ANCA).

Anti-neutrophil cytoplasmic antibodies (ANCA) (see also p. 587) are found in the acute phase of vasculitides, particularly Wegener's granulomatosis, Churg–Strauss syndrome and microscopic polyangiitis (polyarteritis) associated with neutrophil infiltration of the vessel wall.

Two major ANCA reactivities are recognized: proteinase-3 (PR₃) ANCA and myeloperoxidase (MPO) ANCA.

Some 10–15% cases of progressive glomerulonephritis with anti-glomerular basement membrane (GBM) antibodies Goodpasture's syndrome (see below) are also MPO-ANCA-positive and these are the most likely to suffer pulmonary haemorrhage.

Wegener's granulomatosis (granulomatosis with polyangiitis)

This granulomatous disease (see p. 544) of unknown aetiology predominantly affects small arteries. It is characterized by lesions involving the upper respiratory tract, lungs and kidneys. It often starts with severe rhinorrhoea, with subsequent nasal mucosal ulceration followed by cough, haemoptysis and pleuritic pain. Occasionally, the skin and nervous system are involved. Single or multiple nodular masses or pneumonic infiltrates with cavitation are seen on chest X-ray. These appear to migrate, with large lesions clearing in one area and new lesions appearing elsewhere. The typical histological changes are usually best seen on renal biopsy, which shows *necrotizing microvascular glomerulonephritis*. This disease responds well to treatment with cyclophosphamide 150–200 mg daily. Rituximab is also being used. A variant of Wegener's granulomatosis called 'midline granuloma' affects the nose and paranasal sinuses and is particularly mutilating; it has a poor prognosis.

Churg–Strauss syndrome

This condition classically occurs in males in their 4th decade, who present with rhinitis and asthma, eosinophilia and systemic vasculitis. The aetiology is uncertain, with some believing that it is an unusual progression of allergic disease while others regard it as a primary vasculitis which presents like asthma because of the involvement of eosinophils.

There is an eosinophilic infiltration with a characteristic high blood eosinophil count, vasculitis of small arteries and veins, and extravascular granulomas. Typically, it involves the

Figure 15.39 Respiratory manifestations of rheumatoid disease. Many drugs affect the lungs, see text, [page 1231](#).

lungs, peripheral nerves and skin, but renal involvement is uncommon. Transient patchy pneumonia-like shadows may occur, but sometimes these can be massive and bilateral. Skin lesions include tender subcutaneous nodules as well as petechial or purpuric lesions. ANCA is usually positive. The disease responds well to corticosteroids. Occasionally, Churg–Strauss syndrome is revealed when oral steroids are withdrawn in patients being treated for asthma. There is no evidence that anti-asthma drugs precipitate the condition.

Microscopic vasculitis (polyangiitis)

This involves the kidneys and the lungs where it results in recurrent haemoptysis. ANCA is usually positive.

Pulmonary autoimmune rheumatic disease

Rheumatoid disease (see also [p. 521](#))

The lungs can be affected by rheumatoid disease and also by some anti-rheumatic drugs used in its treatment ([Fig. 15.39](#)).

- **Pleural adhesions, thickening and effusions** are the most common lesions. The effusion is often unilateral and tends to be chronic. It has a low glucose content but this is not specific.

Several forms of parenchymal disease can occur in patients with rheumatoid arthritis. These include fibrosing alveolitis, rheumatoid nodules, cryptogenic organizing pneumonia, lymphoid interstitial pneumonia and bronchiectasis; other pulmonary problems include pulmonary hypertension and fibrosis ([Fig. 15.39](#)). Some patients will have modified presentations because they are already on disease-modifying drugs such as prednisolone or methotrexate for their arthritis.

- **Fibrosing alveolitis** occurring in rheumatoid arthritis can be considered as a variant of the cryptogenic form of the disease (see [p. 848](#)). The clinical features and gross appearance are the same but the disease is often more chronic.
- **Rheumatoid nodules** appear on the chest X-ray as single or multiple nodules ranging in size from a few millimetres to a few centimetres. The nodules frequently cavitate. They usually produce no symptoms but can give rise to a pneumothorax or pleural effusion.

- **Obliterative disease of the small bronchioles** is rare. It is characterized by progressive breathlessness and irreversible airflow limitation. Corticosteroids may prevent progression.
- **Cricoarytenoid joint involvement** by rheumatoid arthritis gives rise to dyspnoea, stridor, and hoarseness. Occasionally severe obstruction necessitates tracheostomy.
- **Caplan's syndrome** is due to a combination of dust inhalation and the disturbed immunity of rheumatoid arthritis. It occurs particularly in coal-worker's pneumoconiosis but it can occur in individuals exposed to other dusts, such as silica and asbestos. Typically the lesions appear as rounded nodules 0.5–5.0 cm in diameter, though sometimes they become incorporated into large areas of fibrosis that are indistinguishable radiologically from progressive massive fibrosis. There may not be much evidence of simple pneumoconiosis prior to the development of the nodule. These lesions may precede the development of the arthritis. Rheumatoid factor is always present in the serum.

Drugs used in the treatment of rheumatoid arthritis can cause pulmonary problems: e.g. pneumonitis with methotrexate, gold, NSAIDs; fibrosis, with methotrexate; bronchospasm with NSAIDs, aspirin; infections due to corticosteroids, methotrexate; reactivation of tuberculosis with anti-TNF therapy.

Systemic lupus erythematosus (see also [p. 536](#))

The most common respiratory manifestation of this disease is pleurisy, occurring in up to two-thirds of cases, with or without an effusion. Effusions are usually small and bilateral. Basal pneumonitis is often present, perhaps as a result of poor movement of the diaphragm, or restriction of chest movements because of pleural pain. Pneumonia also occurs because of either infection or the disease process itself. In contrast to rheumatoid arthritis, diffuse pulmonary fibrosis is rare.

Systemic sclerosis (see [pp.538](#) and [1218](#))

Autopsy studies have indicated that there is almost always some diffuse fibrosis of alveolar walls and obliteration of capillaries and the alveolar space. Severe changes result in nodular then streaky shadowing on the chest X-ray, followed by cystic changes, ending up with a honeycomb lung. Lung function tests reveal a restrictive defect and poor gas transfer. Dilation of the oesophagus increases the risk of aspiration pneumonia (see [p. 243](#)). Breathlessness may be worsened by restriction of chest wall movement owing to thickening and contraction of the skin and trunk.

Idiopathic interstitial pneumonia (IIP)

A current international classification is shown in [Box 15.18](#). IIP is characterized by diffuse inflammation and fibrosis in the lung parenchyma.

Idiopathic pulmonary fibrosis (IPF)

This is also known as *usual interstitial pneumonia* (UIP) and was previously known as cryptogenic fibrosing alveolitis (CFA).

It is relatively rare with a prevalence of about 20/100000 population, mean onset is in the late 60s and it is more common in males. The cause is unknown but possible contributory factors include cigarette smoking, chronic aspiration, antidepressants, wood and metal dusts and infections, e.g. Epstein–Barr virus.

Pathology

The key features are patchy fibrosis of the interstitium (often with intervening normal lung), subpleural and paraseptal changes, minimal or absent inflammation, acute fibroblastic proliferation and collagen deposition (fibroblastic foci) and honeycombing.

Pathogenesis

Several hypotheses have been proposed but it seems likely that injury results from repeated exogenous and endogenous unknown stimuli. It is now understood that inflammation plays little or no part. Multiple micro-injuries to the alveolar cells cause them to secrete growth factors that recruit fibroblasts in a fibrotic environment. These fibroblasts differentiate into myofibroblasts under the influence of TGF- β , synthesize collagen and aggregate to form 'fibrotic foci' (Fig. 15.40). In familial pulmonary fibrosis, several mutations have been identified, suggesting a genetic disposition. Genes over-expressed in IPF include matrix metalloproteinases (MMP1, 7), cyclin A₂ (CLNA₂), α -defensins, surfactant protein A1 and the gene encoding mucin5B (MUC5B). There is an absence of type 1 pneumocytes with a lack of differentiation of type 2 into type 1 pneumocytes resulting in a dysfunctional alveolar epithelium.

Clinical features

The main features are progressive breathlessness, a non-productive cough and cyanosis, which eventually lead to respiratory failure, pulmonary hypertension and cor pulmonale. Fine bilateral end-inspiratory crackles are heard on auscultation and gross finger clubbing occurs in two-thirds of cases. An acute form known as the Hamman-Rich syndrome occasionally occurs. Various autoimmune diseases are associated with IPF (see also Box 15.17). IPF has also been reported in association with coeliac disease, ulcerative colitis and renal tubular acidosis.

Investigations

- **Chest X-ray** initially shows a ground glass appearance, followed by irregular reticulonodular shadowing (often

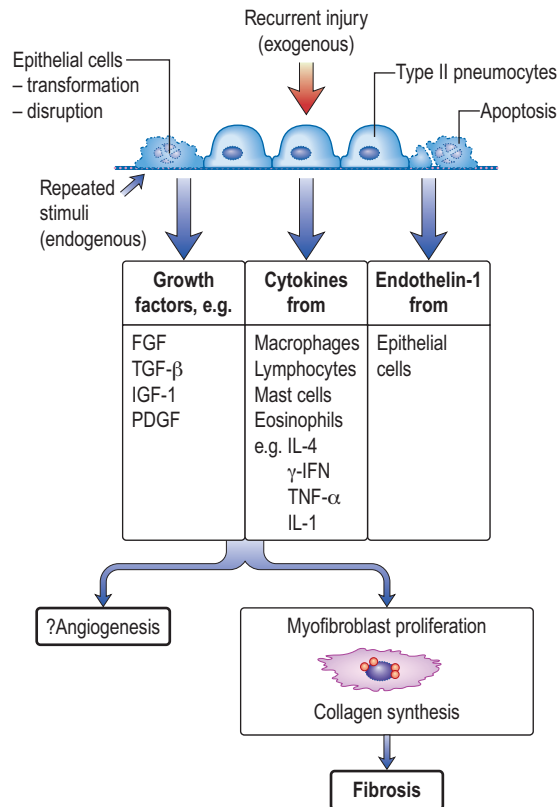

Figure 15.40 Pathogenesis of pulmonary fibrosis (see text).

Figure 15.41 CT scan showing idiopathic pulmonary fibrosis with reticular nodular shadowing and a honeycomb appearance.

maximal in the lower zones) and finally a honeycomb lung.

- **High-resolution CT scan (HRCT)** shows characteristic bilateral changes mainly involving the lower lobes (Fig. 15.41). There may be subpleural reticular abnormalities with minimal or no ground glass changes, honeycombing, i.e. thick-walled cysts 0.5–2 cm in diameter in terminal and respiratory bronchioles, and traction bronchiectasis.
- **Respiratory function tests** show a restrictive ventilatory defect – lung volumes are reduced, the FEV₁ to FVC ratio is normal to high (with both values being reduced),

and carbon monoxide gas transfer is reduced. Peak flow rates may be normal.

- **Blood gases** show arterial hypoxaemia, caused by a combination of alveolar-capillary block and ventilation-perfusion mismatch with normal or low $P_a\text{CO}_2$ owing to hyperventilation.
- **Blood tests.** Anti-nuclear antibodies and rheumatoid factors are present in one-third of patients. The ESR and immunoglobulins are mildly elevated.
- **Bronchoalveolar lavage** shows increased numbers of cells, particularly neutrophils and macrophages.
- **Histological confirmation** is necessary in some patients. Transbronchial lung biopsy is rarely diagnostic, but can exclude other conditions which present similarly, e.g. sarcoidosis or lymphangitis carcinomatosa. Video-assisted thoracoscopic lung biopsy is used to obtain a larger specimen, which will allow a clear histological diagnosis to be made.

Differential diagnosis

The diagnosis of IPF is usually made in a patient presenting with the above signs and characteristic HRCT changes. The differential diagnosis of the chest X-ray appearance includes hypersensitivity pneumonitis, bronchiectasis, chronic left heart failure, sarcoidosis, industrial lung disease and lymphangitis carcinomatosa.

Prognosis and treatment

The median survival time for patients with IPF is approximately 5 years, although mortality is very high in the more acute forms. Treatment with prednisolone (30 mg daily) is usually prescribed for disabling disease although it produces little benefit. Azathioprine or cyclophosphamide is added if there is no response. A number of other treatments have been tried. Pirfenidone, an anti-fibrotic anti-inflammatory drug, has reduced lung function deterioration in two randomized controlled trials. A tyrosine kinase inhibitor, BIBF1120, has shown the same benefit in a phase II study. Supportive treatment includes domiciliary oxygen therapy. In younger patients with severe disease, lung transplantation is offered.

Desquamative interstitial pneumonia (DIP)

This occurs mainly in middle-aged male smokers and is less severe but similar to usual interstitial pneumonia (UIP). Pathologically there are more mononuclear cells than in UIP, due to smoking (pigmented macrophages). The prognosis is good with corticosteroid therapy.

Respiratory bronchiolitis interstitial lung disease (RBILD)

Clinically, RBILD is like DIP. Pathologically, pigmented macrophages are seen in the lumen of respiratory bronchioles. It has a better prognosis than UIP.

Acute interstitial pneumonia (AIP)

There is a very acute onset of pneumonia, often preceded by an upper respiratory tract infection, and progressive respiratory failure. Diffuse alveolar damage (DAD) is seen on lung biopsy. The prognosis is poor.

Nonspecific interstitial pneumonia (NSIP)

The onset is subacute with a fever in 30%. Men and women are equally affected and finger clubbing does not occur.

Biopsy reveals a chronic interstitial pneumonia with mononuclear inflammatory cells and some fibrosis. Prognosis is variable (depending on amount of fibrosis).

Cryptogenic organizing pneumonia (COP)

This condition, previously called bronchiolitis obliterans organizing pneumonia (BOOP), is an organizing pneumonia of unknown aetiology. Typically, patients present with single or recurrent episodes of malaise associated with cough, breathlessness and fever. Pleuritic chest pain is sometimes present but finger clubbing is very rare. Chest X-rays show confluent bilateral parenchymal shadowing. Lung function tests are usually normal but may show a restrictive defect. The white blood count is normal, but the ESR may be raised. The diagnosis is usually made on history and X-ray appearances. Lung biopsy reveals characteristic buds of connective tissue (Masson's bodies) in respiratory bronchioles and in alveolar ducts. Open biopsy has now been replaced by video-assisted thoracoscopic lung biopsy. COP responds rapidly to corticosteroid treatment but can recur episodically, especially in older women.

Lymphoid interstitial pneumonia

This condition is more common in children than in adults and is characterized by infiltration with lymphocytes, plasma cells and immunoblasts. It is thought to be a viral pneumonia and causes diffuse reticulonodular infiltrates on the chest X-ray. Corticosteroid therapy appears to be of benefit, as is zidovudine.

Drugs

Drugs causing diffuse parenchymal lung disease are shown on [page 854](#) and in [Table 15.22](#).

Other types of diffuse lung disease

Langerhans' cell histiocytosis (LCH)

This rare disease (prevalence 1/50 000) is characterized histologically by proliferation of Langerhans' cells, identified by the presence of Birbeck granules on electron microscopy or the CD1a antigen on the surface of the cells. There is a wide variation in clinical presentation, from unifocal bone lesions in older children (which may regress spontaneously), to more disseminated disease in younger children (with a high mortality). Pulmonary LCH occurs almost exclusively in smokers. Chest X-rays (and HRCT) show multiple small cysts (honeycomb lung), fibrosis or widespread nodular shadows. *Treatment* involves stopping smoking, with regression of disease, corticosteroids and immunosuppressive therapy. For advanced progressive disease, lung transplantation is the only option. Five-year and 10-year survivals are 75% and 65%, respectively.

Goodpasture's syndrome

This disease (see also [p. 585](#)) often starts with symptoms of an upper respiratory tract infection followed by cough and intermittent haemoptysis, tiredness and eventually anaemia, although massive bleeding may occur. The chest X-ray shows transient blotchy shadows that are due to intrapulmonary haemorrhage. These features usually precede the development of an acute glomerulonephritis by several weeks or months. The course of the disease is variable: some patients spontaneously improve while others proceed to renal failure.

The disease usually occurs in individuals over 16 years of age. It is due to a type II cytotoxic reaction driven by antibodies directed against the basement membrane of both kidney and lung. It has been proposed that there is a shared antigen. ANCA may be positive. An association with influenza A₂ virus has been reported.

Treatment is with corticosteroids, but in some cases dramatic improvement has been seen with plasmapheresis to remove the autoantibodies.

Table 15.22 Some drug-induced respiratory reactions

Disease	Drugs
Bronchospasm	Penicillins, cephalosporins Sulphonamides Aspirin/NSAIDs Monoclonal antibodies, e.g. infliximab Iodine-containing contrast media β-Adrenoceptor-blocking drugs, (e.g. propranolol) Non-depolarizing muscle relaxants Intravenous thiamine Adenosine
Diffuse parenchymal lung disease and/or fibrosis	Amiodarone Anakinra (IL-1 receptor antagonist) Nitrofurantoin Paraquat Continuous oxygen Cytotoxic agents (many, particularly busulfan, CCNU, bleomycin, methotrexate)
Pulmonary eosinophilia	Antibiotics: Penicillin Tetracycline Sulphonamides, e.g. sulfasalazine NSAIDs Cytotoxic agents
Acute lung injury	(Paraquat – a weedkiller)
Pulmonary hypertension	Fenfluramine, dexfenfluramine, phentermine
SLE-like syndrome including pulmonary infiltrates, effusions and fibrosis	Hydralazine Procainamide Isoniazid Phenytoin ACE inhibitors Monoclonal antibodies
Reactivation of tuberculosis	Immunosuppressant drugs, e.g. steroids Biological agents, e.g. tumour necrosis factor blockers
CCNU, chloroethyl-cyclohexyl-nitrosourea (lomustine); NSAIDs, non-steroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus.	

Diffuse alveolar haemorrhage

This is clinically similar to Goodpasture's syndrome, but anti-basement-membrane antibodies are absent and the kidneys are less frequently involved. Most cases occur in children under 7 years of age. The child develops a chronic cough and anaemia. The chest X-ray shows diffuse shadows that are due to intrapulmonary bleeding, and eventually miliary nodulation. Characteristically, haemosiderin-containing macrophages are found in the sputum. There is an association with sensitivity to cow's milk, and an appropriate diet is usually tried.

The general prognosis is poor but treatment with corticosteroids or azathioprine is usually given.

Lymphangioleiomyomatosis

This is a rare disorder of young women with hamartomatous smooth muscle infiltration of the lungs. Gene mutations in the hamartin-tuberin complex are present; the gene products regulate the activity of rapamycin complex 1. Patients present with dyspnoea, chylous pleural effusions, haemoptysis and pneumothorax. Treatment with hormones/oophorectomy has shown little benefit. Sirolimus (rapamycin) treatment has shown benefit.

Pulmonary alveolar proteinosis

This is a rare disease in which there is accumulation of lipoproteinaceous material within the alveoli. It can be congenital, but most cases are acquired and appear to have an autoimmune basis, with antibodies directed against the cytokine GM-CSF. The disease mostly affects men and presents with progressive exertional dyspnoea and cough. Inspiratory crackles are present in only about 50%. Diagnosis is made by bronchial lavage, which reveals a milky appearance and many large, foamy macrophages but few other inflammatory cells.

Pulmonary infiltration with eosinophilia

The common types and characteristics of these diseases are shown in Table 15.23. They range from very mild, simple, pulmonary eosinophilias to the often fatal hypereosinophilic syndrome.

Simple and prolonged pulmonary eosinophilia

Simple pulmonary eosinophilia is a relatively mild illness with a slight fever and cough and usually lasts for less than 2 weeks. Occasionally, the disease becomes more prolonged, with a high fever lasting for over a month. There is usually an eosinophilia in the blood and this condition is then called prolonged pulmonary eosinophilia. In both conditions

Table 15.23 Common types and characteristics of pulmonary infiltration with eosinophilia

Disease	Symptoms	Blood eosinophils (%)	Multisystem involvement	Duration	Outcome
Simple pulmonary eosinophilia	Mild	10	None	<1 month	Good
Prolonged pulmonary eosinophilia	Mild/moderate	>20	None	>1 month	Good
Asthmatic bronchopulmonary eosinophilia	Moderate/severe	5–20	None	Years	Fair
Tropical pulmonary eosinophilia	Moderate/severe	>20	None	Years	Fair
Hypereosinophilic syndrome	Severe	>20	Always	Months/years	Poor

the chest X-ray shows either localized or diffuse opacities. The simple form is probably due to a transient allergic reaction in the alveoli. Many allergens have been implicated, including *Ascaris lumbricoides*, *Ankylostoma*, *Trichuris*, *Trichinella*, *Taenia* and *Strongyloides*. Drugs such as aspirin, penicillin, nitrofurantoin and sulphonamides have been implicated. Often, no allergen is identified. The disease is self-limiting and no treatment is required, apart from treating the cause. In the more chronic form all unnecessary treatment should be withdrawn and, where appropriate, worms are treated. Corticosteroid therapy is indicated, with resolution of the disease over the ensuing weeks.

Asthmatic bronchopulmonary eosinophilia

This is characterized by the presence of asthma, transient fleeting shadows on the chest X-ray, and blood or sputum eosinophilia. By far the most common cause worldwide is allergy to *A. fumigatus* (see below), although *Candida albicans* and other mycoses may be the allergen in a small number of patients. In many, no allergen can be identified. Whether these cases are intrinsic or driven by an unidentified extrinsic factor is uncertain.

Diseases caused by *Aspergillus fumigatus*

The various types of lung disease caused by *A. fumigatus* are illustrated in Figure 15.42.

The spores of *A. fumigatus* (diameter 5 µm) are readily inhaled and are present in the atmosphere throughout the year, though they are at their highest concentration in the late autumn. They can be grown from the sputum in up to 15% of patients with chronic lung disease in whom they do not produce disease. They are a cause of extrinsic asthma in atopic individuals.

Allergic bronchopulmonary aspergillosis (asthmatic pulmonary eosinophilia)

This rare disease is caused by a hypersensitivity reaction when the bronchi are colonized by *Aspergillus*. It can complicate asthma and cystic fibrosis. Proximal bronchiectasis occurs.

Clinical features. There are episodes of eosinophilic pneumonia throughout the year, particularly in late autumn and winter. The episodes present with a wheeze, cough, fever and malaise. They are associated with expectoration of firm sputum plugs containing the fungal mycelium, which results in the clearing of the pulmonary infiltrates on the chest X-ray. Occasionally large mucus plugs obliterate the bronchial lumen, causing collapse of the lung.

Left untreated, repeated episodes of eosinophilic pneumonia can result in progressive pulmonary fibrosis that usually affects the upper zones and can give rise to a chest X-ray appearance similar to that produced by tuberculosis.

Investigations. The peripheral blood eosinophil count is usually raised, and total levels of IgE are usually extremely high, at >1000 ng/mL (both that specific to *Aspergillus* and nonspecific). Skin-prick testing to protein allergens from *A. fumigatus* gives rise to positive immediate skin tests. Sputum may show eosinophils and mycelia. Precipitating antibodies in the serum are usually, but not always, found in the serum.

Lung function tests show a decrease in lung volumes and gas transfer in more chronic cases, but there is evidence of reversible airflow limitation in all cases.

Figure 15.42 Diseases caused by *Aspergillus fumigatus*. Allergic aspergillosis (initial and later) and three other forms.

Treatment is with prednisolone 30 mg daily, which causes rapid clearing of the pulmonary infiltrates. Frequent episodes of the disease can be prevented by long-term treatment with prednisolone, but doses of 10–15 mg daily are usually required. Antifungal agents (itraconazole, voriconazole) should be used in patients on high doses of steroids; there is evidence that treatment with itraconazole improves pulmonary function. The asthma component responds to inhaled corticosteroids, although these do not influence the occurrence of pulmonary infiltrates. Omalizumab, a humanized monoclonal antibody against IgE, is being trialled.

Aspergilloma and invasive aspergillosis

Aspergilloma is the growth of *A. fumigatus* within previously damaged lung tissue where it forms a ball of mycelium within lung cavities. Typically the chest X-ray shows a round lesion with an air 'halo' above it. Continuing antigenic stimulation gives rise to large quantities of precipitating antibody in the serum. The aspergilloma itself causes little trouble, though occasionally massive haemoptysis may occur, requiring resection of the area of damaged lung containing the

FURTHER READING

Zmeili OS, Soubani AO. Pulmonary aspergillosis – update. *Quarterly Journal of Medicine* 2007; 100:317–334.

aspergilloma. The antifungal agent voriconazole is the drug of choice. Amphotericin is used if patients are intolerant of voriconazole. Invasive aspergillosis is a well-recognized complication of immunosuppression and requires aggressive antifungal therapy; immunosuppression should be reduced if possible.

Tropical pulmonary eosinophilia

This term is reserved for an allergic reaction to microfilaria from *Wuchereria bancrofti*. The condition is seen in the Indian subcontinent and presents with cough and wheeze together with fever, lassitude and weight loss. The typical appearance of the chest X-ray is of bilateral hazy mottling that is often uniformly distributed in both lung fields. Individual shadows may be as large as 5 mm or may become more confluent, giving the appearance of pneumonia.

The disease is characterized by a very high eosinophil count in peripheral blood. The filarial complement fixation test is positive in almost every case, although the microfilaria are seldom found. The treatment of choice is diethylcarbamazine (see p. 154 for details).

The hypereosinophilic syndrome

This disease is characterized by eosinophilic infiltration in various organs, sometimes associated with an eosinophilic arteritis. The heart muscle is particularly involved, but pulmonary involvement in the form of a pleural effusion or interstitial lung disease occurs in about 40% of cases. Typical features are fever, weight loss, recurrent abdominal pain, persistent non-productive cough and congestive cardiac failure. Corticosteroid treatment may be of value in some cases.

Hypersensitivity pneumonitis

In this disease there is a widespread diffuse inflammatory reaction in both the small airways of the lung and the alveoli. It is due to the inhalation of a number of different antigens, the most common being microbial spores contaminating vegetable matter (e.g. straw, hay, mushroom compost). Some examples are illustrated in Table 15.24. By far the most common of these diseases worldwide is farmer's lung, which affects up to 1 in 10 of the farming community in disadvantaged, wet communities around the world. Cigarette smokers have a lower risk of developing the disease due to decreased antibody reaction to the antigen.

Pathogenesis

Histologically there is an initial infiltration of the small airways and alveolar walls with neutrophils followed by T lymphocytes

and macrophages, leading to the development of small non-caseating granulomas. These comprise multinucleated giant cells, occasionally containing the inhaled antigenic material. The allergic response to the inhaled antigens involves both cellular immunity and the deposition of immune complexes causing foci of inflammation through the activation of complement via the classical pathway. Some of the inhaled materials may also lead to inflammation by directly activating the alternative complement pathway. These mechanisms attract and activate alveolar and interstitial macrophages, so that continued antigenic exposure results in the progressive development of pulmonary fibrosis.

Clinical features

Typically fever, malaise, cough and shortness of breath come on several hours after exposure to the causative antigen. Thus, a farmer forking hay in the morning may notice symptoms during the late afternoon and evening with resolution by the following morning. On examination, the patient may have a fever, tachypnoea, and coarse end-inspiratory crackles and wheezes throughout the chest. Cyanosis caused by ventilation-perfusion mismatch may be severe even at rest. Continued exposure leads to a chronic illness characterized by severe weight loss, effort dyspnoea and cough as well as the features of idiopathic pulmonary fibrosis (see p. 848).

Investigations

- **Chest X-ray** shows fluffy nodular shadowing with the subsequent development of streaky shadows, particularly in the upper zones. In very advanced cases, honeycomb lung occurs.
- **High-resolution CT** shows reticular and nodular changes with ground glass opacity, which can be further categorized with multislice CT.
- **Lung function tests** show a restrictive ventilatory defect with a decrease in carbon monoxide gas transfer.
- **Polymorphonuclear leucocyte count** is raised in acute cases. Eosinophilia is not a feature.
- **Precipitating antibodies** are present in the serum. One-quarter of pigeon fanciers have precipitating IgG antibodies against pigeon protein and droppings in their serum, but only a small proportion have lung disease. Precipitating antibodies are evidence of exposure, not disease.
- **Bronchoalveolar lavage** shows increased T lymphocytes and granulocytes.

Table 15.24 Hypersensitivity pneumonitis – some causes

Disease	Situation	Antigens
Farmer's lung	Forking mouldy hay or any other mouldy vegetable material	Thermophilic actinomycetes, e.g. <i>Micropolyspora faeni</i> Fungi, e.g. <i>Aspergillus umbrascus</i>
Bird fancier's lung	Handling pigeons, cleaning lofts or budgerigar cages	Proteins present in the 'bloom' on the feathers and in excreta
Maltworker's lung	Turning germinating barley	<i>Aspergillus clavatus</i>
Humidifier fever	Contaminated humidifying systems in air conditioners or humidifiers in factories (especially in printing works)	Possibly a variety of bacteria or amoeba (e.g. <i>Naegleria gruberi</i>) Thermoactinomyces
Mushroom workers	Turning mushroom compost	Thermophilic actinomycetes
Cheese washer's lung	Mouldy cheese	<i>Penicillium casei</i> <i>Aspergillus clavatus</i>
Winemaker's lung	Mould on grapes	Botrytis

Differential diagnosis

Although hypersensitivity pneumonitis due to inhalation of the spores of *Micropolyspora faeni* is common among farmers, it is probably more common for these individuals to suffer from asthma related to inhalation of antigens from a variety of mites that infest stored grain and other vegetable material. These include *Lepidoglyphus domesticus*, *L. destructor* and *Acarus siro*. Symptoms of asthma resulting from inhalation of these allergens are often mistaken for farmer's lung. Lung function tests will effectively discriminate between the disorders. Pigeon fancier's lung is quite common, but alveolitis from budgerigars, parrots and parakeets is very rare.

Management

Prevention is the aim. This can be achieved by changes in work practice, with the use of silage for animal fodder and the drier storage of hay and grain. Pigeon fancier's lung is more difficult to control since affected individuals remain strongly attached to their hobby. Prednisolone, initially in large doses of 30–60 mg daily, may achieve regression during the early stages of the disease. Established fibrosis will not resolve and in some patients the disease may progress inexorably to respiratory failure in spite of intensive therapy. Farmer's lung is a recognized occupational disease in the UK and sufferers are entitled to compensation, depending upon their degree of disability.

Humidifier fever

Humidifier fever (Table 15.24), one cause of building-related illnesses (p. 936), may present with the typical features of hypersensitivity pneumonitis without any radiographic changes. This disease has occurred in outbreaks in factories in the UK, particularly in printing works. In North America it is more commonly found in office blocks with contaminated air-conditioning systems. Humidifier fever may be effectively prevented by sterilization of the re-circulating water used in large humidifying plants.

Drug and radiation-induced respiratory reactions

Drugs may produce a wide variety of disorders of the respiratory tract (Table 15.22). The mechanisms are varied and include direct toxicity (e.g. bleomycin), immune complex formation with arteritis, hypersensitivity (involving both T cell and IgE mechanisms) and autoimmunity. Tuberculosis reactivation is seen with immunosuppressive drugs.

Pulmonary infiltrates with fibrosis may result from the use of a number of cytotoxic drugs used in the treatment of cancer. The most common cause of these reactions is bleomycin. The pulmonary damage is dose-related, occurring when the total dosage is >450 mg, but will regress in some cases if the drug is stopped. The most sensitive test is a decrease in carbon monoxide gas transfer, and therefore gas transfer should be measured repeatedly during treatment with the drug. The use of corticosteroids may help resolution. Drugs affecting the respiratory system are shown in Table 15.22, together with the types of reaction they produce. Anaphylaxis with bronchospasm can occur with many drugs. The list is not exhaustive; e.g. over 20 different drugs are known to produce a systemic lupus erythematosus-like syndrome, sometimes complicated by pulmonary infiltrates and fibrosis. Paraquat ingestion causes severe pulmonary oedema and death, and pulmonary fibrosis develops in many of the few who survive.

Irradiation of the lung during radiotherapy can cause a radiation pneumonitis. Patients complain of breathlessness and a dry cough. Radiation pneumonitis results in a restrictive lung defect. Corticosteroids should be given in the acute stage.

OCCUPATIONAL LUNG DISEASE

Exposure to dusts, gases, vapours and fumes at work can cause several different types of lung disease:

- Acute bronchitis and even pulmonary oedema from irritants such as sulphur dioxide, chlorine, ammonia or the oxides of nitrogen
- Pulmonary fibrosis due to mineral dust
- Occupational asthma (see Table 15.13) – this is now the commonest industrial lung disease in the developed world
- Hypersensitivity pneumonitis (see Table 15.24)
- Bronchial carcinoma due to industrial agents (e.g. asbestos, polycyclic hydrocarbons, radon in mines).

The degree of fibrosis that follows inhalation of mineral dust varies. While iron (siderosis), barium (baritosis) and tin (stannosis) lead to dramatic dense nodular shadowing on the chest X-ray, their effect on lung function and symptoms is minimal. In contrast, exposure to silica or asbestos leads to extensive fibrosis and disability. Coal dust has an intermediate fibrogenic effect and used to account for 90% of all compensated industrial lung diseases in the UK. The term 'pneumoconiosis' means the accumulation of dust in the lungs and the reaction of the tissue to its presence. The term is not wide enough to encompass all occupational lung disease and is now generally used only in relation to coal dust and its effects on the lung.

Coal-worker's pneumoconiosis

The disease is caused by dust particles approximately 2–5 µm in diameter that are retained in the small airways and alveoli of the lung. The incidence of the disease is related to total dust exposure, which is highest at the coal face, particularly if ventilation and dust suppression are poor. Improved ventilation and working conditions have reduced the risk of this disease.

Two very different syndromes result from the inhalation of coal.

Simple pneumoconiosis

This simply reflects the deposition of coal dust in the lung. It produces fine micronodular shadowing on the chest X-ray and is by far the most common type of pneumoconiosis. It is graded on the chest X-ray appearance according to standard categories set by the International Labour Office (see below). Considerable dispute remains about the effects of simple pneumoconiosis on respiratory function and symptoms. In many cases, the symptoms are due to COPD related to cigarette smoking, but this is not always the case. Changes to UK workers' compensation legislation means that coal miners who develop COPD are compensated for their disability regardless of their chest X-ray appearance.

Categories of simple pneumoconiosis are as follows:

1. Small round opacities definitely present but few in number
2. Small round opacities numerous but normal lung markings still visible

- Small round opacities very numerous and normal lung markings partly or totally obscured.

Simple pneumoconiosis can progress to the development of progressive massive fibrosis (PMF) (see below). PMF virtually never occurs on a background of category 1 simple pneumoconiosis but occurs in about 7% of those with category 2 and in 30% of those with category 3. Miners with category 1 pneumoconiosis are unlikely to receive compensation unless they also have evidence of COPD. Those with more extensive radiographic changes are compensated solely on the basis of their X-ray appearances.

Progressive massive fibrosis

In PMF, patients develop round fibrotic masses several centimetres in diameter, almost invariably in the upper lobes and sometimes having necrotic central cavities. The pathogenesis of PMF is still not understood, though it seems clear that some fibrogenic promoting factor is present in individuals developing the disease, leading to the formation of immune complexes, analogous to the development of large fibrotic nodules in coal miners with rheumatoid arthritis (Caplan's syndrome). Rheumatoid factor and anti-nuclear antibodies are both often present in the serum of patients with PMF, and also in those suffering from asbestosis or silicosis. Pathologically there is apical destruction and disruption of the lung, resulting in emphysema and airway damage. Lung function tests show a mixed restrictive and obstructive ventilatory defect with loss of lung volume, irreversible airflow limitation and reduced gas transfer.

The patient with PMF suffers considerable effort dyspnoea, usually with a cough. The sputum may be black. The disease can progress (or even develop) after exposure to coal dust has ceased and may lead to respiratory failure.

Silicosis

This disease is uncommon though it may still be encountered in stonemasons, sand-blasters, pottery and ceramic workers and foundry workers involved in fettling (removing sand from metal castings made in sand-filled moulds). Silicosis is caused by the inhalation of silica (silicon dioxide). This dust is highly fibrogenic. For example, a coal miner can remain healthy with 30 g of coal dust in his lungs but 3 g of silica is sufficient to kill. Silica seems particularly toxic to alveolar macrophages and readily initiates fibrogenesis (see Fig. 15.40). The chest X-ray appearances and clinical features of silicosis are similar to those of PMF, but distinctive thin streaks of calcification may be seen around the hilar lymph nodes ('eggshell' calcification).

Asbestos

Asbestos is a mixture of silicates of iron, magnesium, nickel, cadmium and aluminium, and has the unique property of occurring naturally as a fibre. It is remarkably resistant to heat, acid and alkali, and has been widely used for roofing, insulation and fireproofing. Asbestos has been mined in southern Africa, Canada, Australia and Eastern Europe. Several different types of asbestos are recognized: about 90% of asbestos is chrysotile, 6% crocidolite and 4% amosite. Chrysotile or white asbestos is the softest asbestos fibre. Each fibre is often as long as 2 cm but only a few microns thick. It is less fibrogenic than crocidolite.

Crocidolite (blue asbestos) is particularly resistant to chemical destruction and exists in straight fibres up to 50 mm in length and 1–2 µm in width. Crocidolite is the type of asbestos most likely to produce asbestosis and

mesothelioma. This may be due to the fact that it is readily trapped in the lung. Its long, thin shape means that it can be inhaled, but subsequent rotation against the long axis of the smaller airways, particularly in turbulent airflow during expiration, causes the fibres to impact. Crocidolite is also particularly resistant to macrophage and neutrophil enzymatic destruction.

Exposure to asbestos occurred particularly in shipbuilding yards and in power stations, but it was used so widely that low levels of exposure were very common. Up to 50% of city dwellers have asbestos bodies (asbestos fibres covered in protein secretions) in their lungs at post mortem. Regulations in the UK prohibit the use of crocidolite and severely restrict the use of chrysotile. Careful dust control measures are enforced, which should eventually abolish the problem. Workers continue to be exposed to blue asbestos in the course of demolition or in the replacement of insulation, and it should be remembered that there is a considerable time lag between exposure and development of disease, particularly mesothelioma (20–40 years).

The risk of primary lung cancer (usually adenocarcinoma) is increased in people exposed to asbestos, even in non-smokers. This risk is about 5–7-fold greater in those who have parenchymal asbestosis and about 1.5-fold in those with pleural plaques without parenchymal fibrosis. A synergistic relationship exists between asbestosis and cigarette smoking with the risk of bronchial carcinoma multiplied about five-fold above the risk attributable to smoking alone.

Diseases caused by asbestos are summarized in Table 15.25. Bilateral diffuse pleural thickening, asbestosis, mesothelioma and asbestos-related carcinoma of the bronchus are all eligible for industrial injuries benefit in the UK.

Asbestosis

Asbestosis is defined as fibrosis of the lungs caused by asbestos dust, which may or may not be associated with fibrosis of the parietal or visceral layers of the pleura. It is a progressive disease characterized by breathlessness and accompanied by finger clubbing and bilateral basal end-inspiratory crackles. Minor degrees of fibrosis that are not seen on chest X-ray are often revealed on high-resolution CT scan. No treatment is known to alter the progress of the disease, though corticosteroids are often prescribed.

Mesothelioma

The number of cases of mesothelioma has increased progressively since the mid-1980s and has now reached 2100 deaths/year in the UK, which has the highest *per capita* death rate from this condition. Rates of mesothelioma in the UK are expected to peak around 2020 at about 2300/year. The most common presentation of mesothelioma is a pleural effusion, typically with persistent chest wall pain, which should raise the index of suspicion even if the initial pleural fluid or biopsy samples are non-diagnostic. Video-assisted thoracoscopic lung biopsy is often needed to obtain sufficient tissue for diagnosis. Some early promise is emerging from clinical trials of chemotherapy, sometimes combined with surgery, but the outlook for most patients remains very limited.

Byssinosis

This disease occurs worldwide but is declining rapidly in areas where the number of people employed in cotton mills is falling. Typically symptoms start on the first day back at work after a break (Monday sickness), with improvement as the week progresses. Tightness in the chest, cough and breathlessness occur within the first hour in dusty areas of

Table 15.25 The effects of asbestos on the lung

	Exposure	Chest X-ray	Lung function	Symptoms	Outcome
Asbestos bodies	Light	Normal	Normal	None	Evidence of asbestos exposure only
Pleural plaques	Light	Pleural thickening (parietal pleura) and calcification (also in diaphragmatic pleura)	Mild restrictive ventilatory defect	Rare, occasional mild effort dyspnoea	No other sequelae
Effusion	First two decades following exposure	Effusion	Restrictive	Pleuritic pain, dyspnoea	Often recurrent
Bilateral diffuse pleural thickening	Light/moderate	Bilateral diffuse thickening (of both parietal and visceral pleura) more than 5 mm thick and extending over more than one-quarter of the chest wall	Restrictive ventilatory defect	Effort dyspnoea	May progress in absence of further exposure
Mesothelioma	Light (interval of 20–40 years from exposure to disease)	Pleural effusion, usually unilateral	Restrictive ventilatory defect	Pleuritic pain, increasing dyspnoea	Median survival 2 years
Asbestosis	Heavy (interval of 5–10 years from exposure to disease)	Diffuse bilateral streaky shadows, honeycomb lung	Severe restrictive ventilatory defect and reduced gas transfer	Progressive dyspnoea	Poor, progression in some cases after exposure
Asbestos-related carcinoma of the bronchus	The features of asbestosis, bilateral diffuse pleural thickening or bilateral pleural plaques plus those of bronchial carcinoma				Fatal

the mill, particularly in the blowing and carding rooms where raw cotton is cleaned and the fibres are straightened.

The exact nature of the disease and its aetiology remain disputed. Pure cotton does not cause the disease, and cotton dust has some effect on airflow limitation in all those exposed. Individuals with asthma are particularly badly affected by exposure to cotton dust. The most likely aetiology is endotoxins from bacteria present in the raw cotton causing constriction of the airways of the lung. There are no changes on the chest X-ray and there is considerable dispute as to whether the progressive airflow limitation seen in some patients with the disease is due to cotton dust or to other factors such as cigarette smoking or co-existent asthma.

Berylliosis

Beryllium-copper alloy has a high tensile strength and is resistant to metal fatigue, high temperature and corrosion. It is used in the aerospace industry, in atomic reactors and in many electrical devices.

When beryllium is inhaled, it can cause a systemic illness with a clinical picture similar to sarcoidosis. Clinically there is progressive dyspnoea with pulmonary fibrosis. However, strict control of levels in the working atmosphere has made this disease a rarity.

LUNG CYSTS

These can be congenital, bronchogenic or the result of a sequestered pulmonary segment. Hydatid disease causes fluid-filled cysts. Lung abscesses are thin-walled cysts, which are particularly found in staphylococcal pneumonia, tuberculous cavities, septic pulmonary infarction, primary bronchogenic carcinoma, cavitating metastatic neoplasm, or

paragonimiasis caused by the lung fluke *Paragonimus westermani*.

TUMOURS OF THE RESPIRATORY TRACT

Malignant tumours

Bronchial carcinoma

- Bronchial carcinoma is the most common malignant tumour worldwide, with around 1.4 million deaths annually.
- It is the third most common cause of death in the UK after ischaemic heart disease and cerebrovascular disease and is now the commonest cause of cancer-related death in both men and women.
- Rates are declining in men but still increasing overall reflecting increasing incidence in women.
- The ratio in men-to-women is now 1.2:1.

Cigarette smoking (including passive smoke exposure) accounts for >90% of lung cancer. There remains a higher incidence of bronchial carcinoma in urban compared with rural areas, even when allowance is made for cigarette smoking. Other aetiological factors include:

- Environmental: radon exposure, asbestos, polycyclic aromatic hydrocarbons and ionizing radiation. Occupational exposure to arsenic, chromium, nickel, petroleum products and oils
- Host factors: pre-existing lung disease such as pulmonary fibrosis; HIV infection; genetic factors.

Legislative control over smoking in public places in many parts of the world has been introduced to reduce ill health related to cigarette smoke.

Pathophysiology

Historically, lung cancers are broadly divided into small cell carcinoma and non-small cell carcinoma based upon the histological appearances of the cells seen within the tumour. This distinction is necessary with respect to the behaviour of the tumour, providing prognostic information and determining best treatment. Non-small cell carcinoma is further divided into a number of cell types (adenocarcinoma, squamous cell carcinoma, large cell carcinoma, large cell neuroendocrine (see Table 15.26).

Clinical features

The presentation and clinical course vary between the different cell types (Table 15.26). Symptoms and signs may vary depending on the extent and site of disease.

Common presenting features can be divided into those caused by direct/local tumour effects, metastatic spread and non-metastatic extrapulmonary features.

Local effects

- **Cough:** this is the most commonly encountered symptom in lung cancer. Because evidence suggests this symptom is neglected by both patients and healthcare professionals, campaigns in the UK have highlighted the 'three week cough' as a symptom that merits a chest X-ray.
- **Breathlessness:** central tumours occlude large airways resulting in lung collapse and breathlessness on exertion. Many patients with lung cancer have co-existent COPD which is also a cause of breathlessness.
- **Haemoptysis:** coughing up fresh or old blood due to tumour bleeding into an airway.
- **Chest pain:** peripheral tumours invade the chest wall or pleura (both well innervated), resulting in sharp pleuritic pain. Large volume mediastinal nodal disease often results in a characteristic dull central chest ache.
- **Wheeze:** monophonic when due to partial obstruction of an airway by tumour.
- **Hoarse voice:** mediastinal nodal or direct tumour invasion of the mediastinum results in compression of the left recurrent laryngeal nerve.

- **Nerve compression:** Pancoast tumours in the apex of the lung invade the brachial plexus causing C8/T1 palsy with small muscle wasting in the hand and weakness as well as pain radiating down the arm. An associated Horner's syndrome due to compression of the sympathetic chain with classic features of miosis, ptosis and anhidrosis also occurs.
- **Recurrent infections:** tumour causing partial obstruction of an airway results in post-obstructive pneumonia.
- **Bronchial carcinoma** can also directly invade the phrenic nerve, causing paralysis of the ipsilateral hemidiaphragm. It can involve the oesophagus, producing progressive dysphagia, and the pericardium, resulting in pericardial effusion and malignant dysrhythmias.
- **Superior vena caval obstruction:** see p. 449.
- **Tracheal tumours** present with progressive dyspnoea and stridor. Flow volume curves show dramatic reductions in inspiratory flow (see Fig. 15.7c).

Metastatic spread

Bronchial carcinoma commonly spreads to mediastinal, cervical and even axillary or intra-abdominal nodes. In addition, the liver, adrenal glands, bones, brain and skin are frequent sites for metastases:

- **Liver:** common symptoms are anorexia, nausea and weight loss. Right upper quadrant pain radiating across the abdomen is associated with liver capsular pain.
- **Bone:** bony pain and pathological fractures as a result of tumour spread occur. If the spine is involved, there is a risk of spinal cord compression, which requires urgent treatment.
- **Adrenal glands:** metastases to the adrenals do not usually result in adrenal insufficiency and are usually asymptomatic.
- **Brain:** metastases present as space-occupying lesions with subsequent mass effect and signs of raised intracranial pressure. Less common presentations include carcinomatous meningitis with cranial nerve defects, headache and confusion.

Lung cysts

Tumours of the respiratory tract

Van Meerbeeck JP et al. Small cell lung cancer. *Lancet* 2011; 378:1741–1755.

Table 15.26 Lung cancer cell types and clinical features

Cell type	Incidence in UK (%)	Features
Squamous cell carcinoma	35	Remains the most common cell type in Europe Arises from epithelial cells, associated with production of keratin Occasionally cavitates with central necrosis Causes obstructing lesions of bronchus with post-obstructive infection Local spread common, metastasizes relatively late
Adenocarcinoma	27–30	Likely to become the most common cell type in the UK in the near future (most common cell type in the USA) Increasing incidence over last 10 years possibly linked to low tar cigarettes Originate from mucus-secreting glandular cells Most common cell type in non-smokers Often causes peripheral lesions on chest X-ray/CT Subtypes include bronchoalveolar cell carcinoma (associated with copious mucus secretion, multifocal disease) Metastases common: pleura, lymph nodes, brain, bones, adrenal glands
Large cell carcinoma	10–15	Often poorly-differentiated Metastasize relatively early
Small cell carcinoma	20	Arise from neuroendocrine cells (APUD cells) Often secrete polypeptide hormones Often arise centrally and metastasize early

Table 15.27 Non-metastatic extrapulmonary manifestations of bronchial carcinoma (percentage of all cases)

Metabolic (universal at some stage)
Loss of weight
Lassitude
Anorexia
Endocrine (10%) (usually small cell carcinoma)
Ectopic adrenocorticotrophin syndrome
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Hypercalcaemia (usually squamous cell carcinoma)
Rarer: hypoglycaemia, thyrotoxicosis, gynaecomastia
Neurological (2–16%)
Encephalopathies – including subacute cerebellar degeneration
Myelopathies – motor neurone disease
Neuropathies – peripheral sensorimotor neuropathy
Muscular disorders – polymyopathy, myasthenic syndrome (Eaton–Lambert syndrome)
Vascular and haematological (rare)
Thrombophlebitis migrans
Non-bacterial thrombotic endocarditis
Microcytic and normocytic anaemia
Disseminated intravascular coagulopathy
Thrombotic thrombocytopenic purpura
Haemolytic anaemia
Skeletal
Clubbing (30%)
Hypertrophic osteoarthropathy (\pm gynaecomastia) (3%)
Cutaneous (rare)
Dermatomyositis
Acanthosis nigricans
Herpes zoster

- **Malignant pleural effusion:** this presents with breathlessness and is commonly associated with pleuritic pain.

Non-metastatic extrapulmonary manifestations of bronchial carcinoma (Table 15.27)

Minor haematological extrapulmonary manifestations of lung cancer such as normocytic anaemia and thrombocytosis are reasonably common. Apart from finger clubbing and HPOA, most other non-metastatic complications are relatively rare. Approximately 10% of small cell tumours produce ectopic hormones giving rise to paraneoplastic syndromes (see Box 9.2).

Investigations

Investigations are necessary:

- to stage the extent of disease
- to make a tissue diagnosis (differentiate small cell from non-small cell lung cancer (NSCLC) as well as to detail the cell type in NSCLC – increasingly relevant with newer targeted biological agents) and
- to assess fitness to undergo treatment.

Staging and diagnosis

Chest X-ray

Plain chest radiographs show obvious evidence of lung cancer or nonspecific appearances (Box 15.19). In some cases, the initial radiograph is normal, either because the lesion is small, or the disease is confined to central structures.

Computed tomography

CT indicates the extent of disease. Imaging should include the liver and adrenal glands which are common sites for metastases. The International Association for the Study of

Lung Cancer (IASLC) has devised the most widely used staging definitions which are based upon CT imaging of tumour size (T), nodal involvement (N) and metastases (M) along with prognostic data. These have been recently updated based upon an extensive review of survival in over 80 000 patients (Table 15.28).

Using CT criteria, lymph nodes that are less than 1 cm in diameter are not classed as being enlarged, yet they can still contain malignant cells. With increasing size, the positive predictive value of CT in detecting malignant nodes increases; however, it cannot be assumed that enlarged nodes are definitely malignant and further staging tests should be performed if there are no distant metastases and the primary tumour is thought to be eligible for curative treatment. These tests would include direct sampling of affected nodes and positron emission tomography to assess for distant spread of cancer.

Positron emission tomography (PET) imaging/CT

This is the investigation of choice for characterizing extent of mediastinal nodal involvement and highlighting distant metastases either not visualized or indeterminate on CT (see p. 797). Most commonly, PET images are combined with CT for best correlation. Negative predictive value is high but a positive node on PET-CT should prompt sampling for confirmation of presence of malignant cells as the positive predictive value is relatively low.

Other imaging modalities

MRI is not useful for the diagnosis of primary lung tumours other than in Pancoast tumours with nerve invasion or when assessing for chest wall involvement prior to surgery.

Fibreoptic bronchoscopy (see also this chapter, Fig. 15.43)

This technique is used to define the bronchial anatomy and to obtain biopsy and cytological specimens. If the carcinoma involves the first 2 cm of either main bronchus, the tumour is inoperable as there would be insufficient resection margins for pneumonectomy. Widening and loss of the sharp angle of the carina indicates the presence of enlarged subcarinal lymph nodes, either malignant or reactive. These can be biopsied 'blind' by passage of a needle through the bronchial wall.

Percutaneous aspiration and biopsy

Peripheral lung lesions cannot be seen by fibreoptic bronchoscopy. Samples are obtained by aspiration or biopsy through the chest wall under CT guidance. The commonest complication is pneumothorax (around 10% patients), especially if the mass is deep in the lung, as opposed to lesions next to the parietal pleura. Mild haemoptysis occurs in <5%. Implantation metastases do not occur.

Endobronchial ultrasound

A fibreoptic scope with ultrasound probe is used in staging of lung cancer, to visualize the majority of mediastinal nodes (not all of which are accessible surgically via mediastinoscopy or mediastinotomy) and then allow fine needle aspiration.

Endoscopic ultrasound via the oesophagus can also be used with the added advantage of enabling sampling of the left adrenal gland, posterior and inferior mediastinal lymph node groups. Figure 15.44 shows the lymph node areas which are commonly involved and sampled in the staging investigations.

Box 15.19 Lung cancer presentations on a chest X-ray

Mass lesion

Lesions visible if greater than 1 cm diameter. Spiculate, cavitating or smooth edged. Often an incidental finding, usually asymptomatic if small. By the time symptoms are present, chest X-ray almost always abnormal

Pleural effusion

Usually unilateral; commonly large, which can cause obscuration of an underlying mass or pleural tumour. Mesothelioma is a differential diagnosis

Mediastinal widening or hilar adenopathy

Lymphadenopathy evident on the plain film, manifested by splayed carina, hilar enlargement or paratracheal shadowing

Slow resolving consolidation

Tumour causes partial obstruction of a bronchus. This results in retention of secretions, bacterial overgrowth and subsequent infection. (Persistent right upper lobe consolidation due to tumour in right upper lobe.)

Collapse

Endoluminal tumour causes complete collapse of a lung and associated mediastinal shift, or collapse of a lobe or segment resulting in volume loss on the affected side with raised hemidiaphragm/deviated trachea

Reticular shadowing

Carcinoma spreads through the lymphatic channels of the lung to give rise to lymphangitis carcinomatosa; in bronchial carcinoma this is usually unilateral and associated with striking dyspnoea. Bilateral lymphangitis should prompt investigation for a primary site other than lung, such as breast, stomach or colon

Normal

A normal film does not rule out an underlying tumour. A minority of tumours are confined to the central airways and mediastinum without obvious change on the plain chest X-ray. Although investigation of isolated haemoptysis with a normal chest X-ray is often negative, a normal chest X-ray should not deter from further investigation, especially in smokers over the age of 40 years

Ultrasound-guided supraclavicular node sampling

In selected cases, where staging suggests N3 nodes to be involved, even where supraclavicular nodes are not palpable, ultrasound fine needle aspiration can be diagnostic.

Video-assisted thoracoscopic surgery

Large effusions with evidence of pleural thickening are amenable to biopsy and drainage via minimally invasive surgery. This technique is particularly useful as pleurodesis to prevent recurrence of effusion can be performed at the same time.

Other investigations

These include a full blood count for the detection of anaemia, and biochemistry for liver involvement, hypercalcaemia and hyponatraemia.

Assessing fitness for treatment

Before radical treatment, an assessment of fitness for treatment should be carried out. This work-up should include full lung function testing with transfer capacity,

Table 15.28 TNM staging system for lung cancer

T – primary tumour	
TX	Primary tumour cannot be assessed, or tumour proven by the presence of malignant cells in sputum or bronchial washings, but not visualized by imaging or bronchoscopy
T0	No evidence of primary tumour
Tis	Carcinoma <i>in situ</i>
T1	Tumour ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e. not in the main bronchus)
T1a	Tumour ≤2 cm in greatest dimension
T1b	Tumour >2 cm but not more than 3 cm in greatest dimension
T2	Tumour >3 cm but not more than 7 cm; or tumour with any of the following features: Involves main bronchus, 2 cm or more distal to the carina Invades visceral pleura Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung
T2a	Tumour >3 cm but not more than 5 cm in greatest dimension
T2b	Tumour >5 cm but not more than 7 cm in greatest dimension
T3	Tumour >7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumours), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumour in the main bronchus <2 cm distal to the carina but without involvement of the carina; or associated atelectasis or obstructive pneumonitis of the entire lung or separate tumour nodule(s) in the same lobe as the primary.
T4	Tumour of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, oesophagus, vertebral body, carina; separate tumour nodule(s) in a different ipsilateral lobe to that of the primary.
N – regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension
N2	Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)
N3	Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)
M – distant metastasis	
M0	No distant metastasis
M1	Distant metastasis
M1a	Separate tumour nodule(s) in a contralateral lobe; tumour with pleural nodules or malignant pleural or pericardial effusion
M1b	Distant metastasis
The resultant stage groupings are:	
Occult carcinoma	TX, N0, M0
Stage 0	TisN0M0
Stage IA	T1a,bN0M0
Stage IB	T2aN0M0
Stage IIA	T2bN0M0; T1a,bN1M0; T2aN1M0
Stage IIB	T2bN1M0; T3N0M0
Stage IIIA	T1a,b, T2a,b, N2M0; T3N1, N2M0; T4N0, N1M0
Stage IIIB	T4N2M0; any T N3M0
Stage IV	Any T any NM1

and if cardiovascular disease is present, cardiopulmonary exercise testing, stress echo or occasionally preoperative angiography.

Treatment (see also p. 471)

Treatment of lung cancer involves several different modalities and should be planned by a multidisciplinary team. Unfortunately, the majority of patients have incurable disease at presentation, or have significant co-morbidities which preclude radical treatment. Table 15.29 shows the mean survival based on tumour stage for NSCLC and SCC: only 25–30% patients are still alive one year after diagnosis and only 6–8% after 5 years.

Surgery

Surgery is performed in early stage non-small cell lung cancer (stage I, II and in selected IIIA) with curative intent. Many patients with stage III disease are treated with chemo-radiation with a view to ‘downstaging’ disease and render it amenable to surgical resection. Where surgical staging of resected lung cancer demonstrates nodal involvement, patients require adjuvant chemotherapy.

Radiation therapy for cure

In selected patients with adequate lung function and early stage NSCLC, high-dose radiotherapy or continuous

Erratum in: *Journal of Thoracic Oncology* 2007; 2(10):985.

Figure 15.44 Lymph node stations commonly involved in lung cancer and sampled during staging investigations.

hyperfractionated accelerated regimens (CHART) provide a good alternative to surgical resection with almost comparable outcomes. It is the treatment of choice if surgery is not possible due to co-morbidities. Radiation pneumonitis (defined as an acute infiltrate precisely confined to the radiation area and occurring within 3 months of radiotherapy) develops in 10–15% of cases. Radiation fibrosis, a fibrotic change occurring within a year or so of radiotherapy and not precisely confined to the radiation area, occurs to some degree in all cases. These complications usually cause no problems.

In patients with significant cardiovascular or respiratory co-morbidities and early stage I disease, stereotactic radiotherapy can be used. In the same patient group radiofrequency ablation is used – an image-guided technique using heat to destroy small peripheral tumours.

Radiation treatment for symptoms

Radiation therapy has a role in palliation of symptoms from lung cancer. Bone and chest wall pain from metastases or direct invasion, haemoptysis, occluded bronchi and superior vena cava obstruction respond favourably to irradiation in the short term. Radiotherapy is also given at the end of chemotherapy to consolidate treatment in small cell lung cancer.

Chemotherapy

This is discussed on page 471. Adjuvant chemotherapy with radiotherapy improves response rate and extends median survival in non-small cell cancer. Newer targeted agents against epidermal growth factor receptors and tyrosine kinases in NSCLC (in particular adenocarcinoma) offer better outcomes in selected patients and can also be used where

Xie Y, Minna D. A lung cancer molecular prognostic test ready for prime time. *Lancet* 2012; 379:785–787.

intravenous chemotherapy offers unacceptable toxicity or as second-line chemotherapy.

Laser therapy, endobronchial irradiation and tracheobronchial stents

These techniques are used in the palliation of inoperable lung cancer in selected patients with tracheobronchial narrowing from intraluminal tumour or extrinsic compression causing disabling breathlessness, intractable cough and complications, including infection, haemoptysis and respiratory failure.

A **neodymium-Yag (Nd-Yag) laser** passed through a fiberoptic bronchoscope can be used to vaporize inoperable fungating intraluminal carcinoma involving short segments of trachea or main bronchus. Benign tumours, strictures and vascular lesions can also be treated effectively with immediate relief of symptoms.

Endobronchial irradiation (brachytherapy) is useful for the treatment of both intraluminal tumour and malignant extrinsic compression. A radioactive source is afterloaded into a catheter placed adjacent to the carcinoma under fiberoptic bronchoscope control. Radiation dose falls rapidly with distance from the source, minimizing damage to adjacent normal tissue. Reduction in endoscopically assessed tumour size occurs in 70–95% of cases.

Tracheobronchial stents made of silicone or as expandable metal springs are available for insertion into strictures caused by tumour or from external compression or when there is weakening and collapse of the tracheobronchial wall.

Palliative care

Patients dying of cancer of the lung need attention to their overall wellbeing (see Ch. 10, p. 485). Much can be done to make the patient's remaining life symptom-free and as active as possible. Furthermore, compared with patients with fatal cancers at other sites, patients with lung cancer tend to remain relatively independent and pain-free, but they die more rapidly once they reach the terminal phase. Both the patient and the relatives require psychological and emotional support, a task that should be shared between the respiratory teams, the primary care team and the nurses, social workers, hospital chaplains and doctors, who make up the palliative care team.

Secondary tumours

Metastases in the lung are very common and usually present as round shadows (1.5–3.0 cm diameter). They are usually detected on chest X-ray in patients already diagnosed as having carcinoma, but can be the first presentation. *Typical sites for the primary tumour include the kidney, prostate, breast, bone, gastrointestinal tract, cervix or ovary.*

Metastases nearly always develop in the parenchyma and are often relatively asymptomatic even when the chest X-ray shows extensive pulmonary metastases. Rarely metastases develop within the bronchi, when they often present with haemoptysis.

Carcinoma, particularly of the stomach, pancreas and breast, can involve mediastinal glands and spread along the lymphatics of both lungs (lymphangitis carcinomatosa), leading to progressive and severe breathlessness. On the chest X-ray, bilateral lymphadenopathy is seen together with streaky basal shadowing fanning out over both lung fields.

Occasionally, a pulmonary metastasis is detected as a *solitary round shadow* on chest X-ray in an asymptomatic patient. The most common primary tumour to do this is a renal cell carcinoma.

The differential diagnosis includes:

- Primary bronchial carcinoma
- Tuberculosis

- Benign tumour of the lung
- Hydatid cyst.

Single pulmonary metastases can be removed surgically but, as CT scans usually show the presence of small metastases undetected on chest X-ray, detailed imaging including PET scanning and assessment is essential before undertaking surgery.

Investigation of solitary pulmonary nodules

With the increased use of CT scanning for other conditions, there has been increasing incidental detection of asymptomatic small sub-centimetre nodules. The majority of these are benign; however, radiological follow-up should be arranged at intervals, determined by the size of the nodule in millimeters and the risk of developing malignancy (i.e. high risk associated with either current or previous smoking history, occupational exposure to carcinogens or family history of lung cancer; low risk if never smoked and no occupational exposure to potential carcinogens or relevant family history).

Screening for lung cancer

A large trial carried out in the USA has demonstrated a 20% mortality benefit from low-dose helical CT screening for lung cancer in high-risk populations of smokers/ex-smokers between the ages of 55–74. A similar trial is underway in Europe. It is likely that CT screening will be employed in the future.

Benign tumours

Pulmonary hamartoma

This is the most common benign tumour of the lung and is usually seen on the X-ray as a very well-defined round lesion 1–2 cm in diameter in the periphery of the lung. Growth is extremely slow, but the tumour can reach several centimetres in diameter. Rarely it arises from a major bronchus and causes obstruction.

Bronchial carcinoid

This rare tumour resembles an intestinal carcinoid tumour and is locally invasive, eventually spreading to mediastinal lymph nodes and finally to distant organs. It is a highly vascular tumour that projects into the lumen of a major bronchus causing recurrent haemoptysis. It grows slowly and eventually blocks the bronchus, leading to lobar collapse. As foregut derivatives, bronchial carcinoids produce ACTH but do not usually produce the 5-hydroxytryptamine that is seen in midgut or hindgut carcinoid tumours. Staging of carcinoid tumours is the same as for NSCLC.

Cylindroma, chondroma and lipoma

These are extremely rare tumours that grow in the bronchus or trachea, causing obstruction.

Tracheal tumours

Benign tumours include squamous papilloma, leiomyoma, haemangiomas and tumours of neurogenic origin.

DISORDERS OF THE CHEST WALL AND PLEURA

Trauma

Trauma to the thoracic wall can cause penetrating wounds and lead to pneumothorax or haemothorax.

National Institute of Health and Clinical Excellence. The diagnosis and treatment of lung cancer (update): <http://www.nice.org.uk/nicemedia/live/13465/54199/54199.pdf>

Rib fractures

Rib fractures are caused by trauma or coughing (particularly in the elderly), and can occur in patients with osteoporosis. Pathological rib fractures are due to metastatic spread (most often from carcinoma of the bronchus, breast, kidney, prostate or thyroid). Ribs can also become involved by a mesothelioma. Fractures may not be readily visible on a PA chest X-ray, so lateral X-rays and oblique views may be necessary.

Pain prevents adequate chest expansion and coughing, and this can lead to pneumonia.

Treatment is with adequate oral analgesia, by local infiltration or an intercostal nerve block.

Two fractures in one rib can lead to a flail segment with paradoxical movement, i.e. part of the chest wall moves inwards during inspiration. This can produce inefficient ventilation and may require intermittent positive-pressure ventilation, especially if several ribs are similarly affected.

Rupture of the trachea or a major bronchus

Rupture of the trachea or a major bronchus can occur during deceleration injuries, leading to pneumothorax, surgical emphysema, pneumomediastinum and haemoptysis. Surgical emphysema is caused by air leaking into the subcutaneous connective tissue; this can also occur after the insertion of an intercostal drainage tube. A pneumomediastinum occurs when air leaks from the lung inside the parietal pleura and extends along the bronchial walls.

Rupture of the oesophagus

Rupture of the oesophagus (p. 244) leads to mediastinitis, usually with mixed bacterial infection. This is a serious complication of external injury, endoscopic procedures, bougienage or necrotic carcinoma, and requires antibacterial chemotherapy.

Lung contusion

This causes widespread fluffy shadows on the chest X-ray owing to intrapulmonary haemorrhage. This may give rise to acute respiratory distress syndrome (see p. 883).

Kyphoscoliosis

Kyphoscoliosis may be congenital, due to disease of the vertebrae such as tuberculosis or osteomalacia, or due to neuromuscular disease such as Friedreich's ataxia or poliomyelitis. The respiratory effects of severe kyphoscoliosis are often more pronounced than might be expected and respiratory failure and death often occur in the 4th or 5th decade. The abnormality should be corrected at an early stage if possible. Positive airway pressure ventilation delivered through a tightly fitting nasal mask is the treatment of choice for respiratory failure (see p. 895).

Ankylosing spondylitis

Limitation of chest wall movement is often well compensated by diaphragmatic movement, and so the respiratory effects of this disease are relatively mild (see also p. 527). It is occasionally associated with upper lobe fibrosis.

Pectus excavatum and carinatum

Pectus excavatum causes few problems other than embarrassment about the deep vertical furrow in the chest, which can be corrected surgically. The heart is seen to lie well to the left on the chest X-ray. Pectus carinatum (pigeon chest) is often the result of rickets but is rarely seen in the West. No treatment is required.

Pleurisy

Pleurisy is pain arising from any disease of the pleura. The localized inflammation produces sharp localized pain, which is worse on deep inspiration, coughing and occasionally on twisting and bending movements. Common causes are pneumonia, pulmonary infarct and carcinoma. Rarer causes include rheumatoid arthritis and systemic lupus erythematosus.

Epidemic myalgia (Bornholm disease) is due to infection by Coxsackie B virus. This illness is common in young adults in the late summer and autumn and is characterized by an upper respiratory tract illness followed by pleuritic pain in the chest and upper abdomen with tender muscles. The chest X-ray remains normal and the illness clears within a week.

Mesothelioma

This (see also p. 855) is usually associated with asbestos exposure. It is described with other pleural diseases caused by asbestosis in Table 15.25.

Pleural effusion

A pleural effusion is an excessive accumulation of fluid in the pleural space. It can be detected on X-ray when ≥ 300 mL of fluid is present and clinically, when 500 mL or more is present. The chest X-ray appearances (Fig. 15.45) range from the obliteration of the costophrenic angle to dense homogeneous shadows occupying part or all of the hemithorax. Fluid below the lung (a subpulmonary effusion) can simulate a raised hemidiaphragm. Fluid in the fissures may resemble an intrapulmonary mass. The physical signs are shown in Table 15.2 (p. 857).

Diagnosis

This is by pleural aspiration (see p. 805), usually done with ultrasound guidance. The fluid that accumulates may be a transudate or an exudate (Box 15.20).

Transudates

Effusions that are transudates can be bilateral, but are often larger on the right side. The protein content is <30 g/L, the lactic dehydrogenase is <200 IU/L and the fluid to serum LDH ratio is <0.6 . Causes include:

- Heart failure
- Hypoproteinaemia (e.g. nephrotic syndrome)
- Constrictive pericarditis
- Hypothyroidism
- Ovarian tumours producing right-sided pleural effusion – Meigs' syndrome.

Exudates

The protein content of exudates is >30 g/L and the lactic dehydrogenase is >200 IU/L. Causes include:

Box 15.20 Light's criteria to diagnose an exudative effusion

- Pleural fluid protein: serum protein >0.5
- Pleural fluid LDH: serum LDH >0.6
- Pleural fluid LDH $> \frac{2}{3}$ upper limit of normal for serum (105–333 IU/L)

Adapted from Light RW, Macgregor MI, Luchsinger PC et al. Pleural effusions: the diagnostic separation of transudates and exudates. Annals of Internal Medicine 1972;77(4):507–13.

a

b

Figure 15.45 Radiographs showing (a) small and (b) large pleural effusions.

- Bacterial pneumonia (common)
- Carcinoma of the bronchus and pulmonary infarction – fluid may be blood-stained (common)
- Tuberculosis
- Autoimmune rheumatic diseases
- Post-myocardial infarction syndrome (rare)
- Acute pancreatitis (high amylase content) (rare)
- Mesothelioma (rare)
- Sarcoidosis (very rare)
- Yellow-nail syndrome (effusion due to lymphoedema) (very rare)
- Familial Mediterranean fever (rare).

Pleural biopsy (see p. 806) may be necessary if the diagnosis has not been established by simple aspiration.

Treatment is of the underlying condition unless the fluid is purulent (empyema) in which case drainage is mandatory.

Management of malignant pleural effusions

Malignant pleural effusions that reaccumulate and are symptomatic can be aspirated to dryness followed by the instillation of a sclerosing agent such as tetracycline or talc. Effusions should be drained slowly since rapid shift of the mediastinum causes severe pain and occasionally shock. This treatment produces only temporary relief.

Chylothorax

This is due to the accumulation of lymph in the pleural space, usually resulting from leakage from the thoracic duct following trauma or infiltration by carcinoma.

Empyema

This is the presence of pus in the pleural space and can be a complication of pneumonia (see p. 837).

Pneumothorax

‘Pneumothorax’ means air in the pleural space. It may be spontaneous or occur as a result of trauma to the chest. Spontaneous pneumothorax is commonest in young males, the male-to-female ratio being 6:1. It is caused by the rupture

of a pleural bleb, usually apical, and is thought to be due to congenital defects in the connective tissue of the alveolar walls. Both lungs are affected with equal frequency. Often these patients are tall and thin. In patients over 40 years of age, the usual cause is underlying COPD. Rarer causes include bronchial asthma, carcinoma, a lung abscess breaking down and leading to bronchopleural fistula, and severe pulmonary fibrosis with cyst formation.

Pneumothorax may be localized if the visceral pleura has previously become adherent to the parietal pleura, or generalized if there are no pleural adhesions. Normally the pressure in the pleural space is negative but this is lost once a communication is made with atmospheric pressure; the elastic recoil pressure of the lung then causes it to partially deflate. If the communication between the airways and the pleural space remains open, a bronchopleural fistula results. Once the communication between the lung and the pleural space is closed, air will be reabsorbed at a rate of 1.25% of the total radiographic volume of the hemithorax per day. Thus, a 50% collapse of the lung will take about 40 days to reabsorb completely once the air leak is closed.

It has been postulated that a valvular mechanism may develop through which air can be sucked into the pleural space during inspiration but not expelled during expiration. The intrapleural pressure remains positive throughout breathing, the lung deflates further, the mediastinum shifts, and venous return to the heart decreases, with increasing respiratory and cardiac embarrassment. This is called tension pneumothorax and is very rare except in patients on positive pressure ventilation.

The usual presenting features are sudden onset of unilateral pleuritic pain or progressively increasing breathlessness. If the pneumothorax enlarges, the patient becomes more breathless and may develop pallor and tachycardia. There may be few physical signs if the pneumothorax is small.

The characteristic features and management are shown in Figure 15.46. The main aim is to get the patient back to active life as soon as possible. The procedure for simple aspiration is shown in Practical Box 15.4.

Recurrence. A third of patients will have a recurrence. Chemical pleurodesis with talc is used for patients with

Figure 15.46 Pneumothorax: an algorithm for management. VATS, video-assisted thoracoscopic surgery.

Practical Box 15.4

Simple aspiration of pneumothorax

1. Explain the nature of the procedure and obtain consent.
2. Infiltrate 2% lidocaine down to the pleura in the second intercostal space in the mid-clavicular line.
3. Push a 3–4 cm 16 French gauge cannula through the pleura.
4. Connect the cannula to a three-way tap and 50 mL syringe.
5. Aspirate up to 2.5 L of air. Stop if resistance to suction is felt or the patient coughs excessively.
6. Repeat chest X-ray (in expiration) in the X-ray department.

contraindication for surgery. Bleb resection and pleurodesis are achieved using a video-assisted thoracoscopic (VATS) approach or by open thoracotomy.

DISORDERS OF THE DIAPHRAGM

Diaphragmatic fatigue

The diaphragm can become fatigued if the force of contraction during inspiration exceeds 40% of the force it can

develop in a maximal static effort. When this occurs acutely, in patients with exacerbations of COPD or cystic fibrosis or in quadriplegics, positive-pressure ventilation is required. Further rehabilitation requires exercises to increase the strength and endurance of the diaphragm by breathing against a resistance for 30 minutes a day.

Unilateral diaphragmatic paralysis

This is common and symptomless. The affected diaphragm is usually elevated and moves paradoxically on inspiration. It can be diagnosed when a sniff causes the paralysed diaphragm to rise, and the unaffected diaphragm to descend. Causes include:

- Surgery
- Carcinoma of the bronchus with involvement of the phrenic nerve
- Neurological, including poliomyelitis, herpes zoster
- Trauma to cervical spine, birth injury, subclavian vein puncture
- Infection: tuberculosis, syphilis, pneumonia.

Bilateral diaphragmatic weakness or paralysis

This causes breathlessness in the supine position and is a cause of sleep apnoea leading to daytime headaches and

FURTHER READING

McCool ED, Tzelepis GE. Dysfunction of the diaphragm. *N Engl J Med* 2012; 366:932–942.

somnolence. Tidal volume is decreased and respiratory rate increased. Vital capacity is substantially reduced when lying down, and sniffing causes a paradoxical inward movement of the abdominal wall best seen in the supine position. Causes include viral infections, multiple sclerosis, motor neurone disease, poliomyelitis, Guillain-Barré syndrome, quadriplegia after trauma, and rare muscle diseases. Treatment is either diaphragmatic pacing or night-time assisted ventilation.

Complete eventration of the diaphragm

This is a congenital condition (invariably left-sided) in which muscle is replaced by fibrous tissue. It presents as marked elevation of the left hemidiaphragm, sometimes associated with gastrointestinal symptoms. Partial eventration, usually on the right, causes a hump (often anteriorly) on the diaphragmatic shadow on X-ray.

Diaphragmatic hernias

These are most commonly through the oesophageal hiatus, but occasionally occur anteriorly, through the foramen of Morgagni, posterolaterally through the foramen of Bochdalek, or at any site following traumatic tears.

Hiccups

Hiccups are due to involuntary diaphragmatic contractions with closure of the glottis and are extremely common. Occasionally patients present with persistent hiccups. This can be as a result of diaphragmatic irritation (e.g. subphrenic abscess) or a metabolic cause (e.g. uraemia). Treatment for persistent hiccups is with gabapentin 300 mg or pregabalin 50 mg three times daily. The underlying cause should be treated, if known.

MEDIASTINAL LESIONS

The mediastinum is defined as the region between the pleural sacs. It is additionally divided as shown in Figure 15.47. Tumours affecting the mediastinum are rare. Masses are detected very accurately on CT, as well as on MR scan (Fig. 15.48).

Retrosternal or intrathoracic thyroid

The most common mediastinal tumour is a retrosternal or intrathoracic thyroid, which is nearly always an extension of the thyroid present in the neck. Enlargement of the thyroid by a colloid goitre, malignant disease or rarely, in thyrotoxicosis, can cause displacement of the trachea and oesophagus to the opposite side. Symptoms of compression develop insidiously before producing the cardinal feature of dyspnoea. Flow-volume loops are useful to assess the physiological impact. Very occasionally an intrathoracic thyroid may cause dysphagia or hoarseness and vocal cord paralysis due to stretching of the recurrent laryngeal nerve. The treatment is surgical removal.

Thymic tumours (thymomas)

The thymus is large in childhood and occupies the superior and anterior mediastinum. It involutes with age but may be enlarged by cysts, which are rarely symptomatic, or by tumours, which may cause myasthenia gravis or compress the trachea or, rarely, the oesophagus. Surgery is the treatment of choice. Approximately half of the patients presenting with a thymic tumour have myasthenia gravis. Good's syndrome, a combined defect in humoral and cellular immunity, is seen in 10% of thymomas.

Figure 15.47 Subdivisions of the mediastinum and mass lesions.

Figure 15.48 CT scan of a dermoid cyst in the mediastinum.

Pleuropericardial cysts

These cysts, which may be up to 10 cm in diameter, are filled with clear fluid. 70% of them are situated anteriorly in the cardiophrenic angle on the right side. Infection is rare and malignant change does not occur. The diagnosis is usually made by needle aspiration. No treatment is required, but these patients should be followed up as an increase in cyst size suggests an alternative pathology; surgical excision is then advisable.

INTRODUCTION

Critical care medicine (or 'intensive care medicine') is concerned predominantly with the management of patients with acute life-threatening conditions ('the critically ill') in specialized units. As well as emergency cases, such units admit high-risk patients electively after major surgery (Table 16.1). Intensive care medicine also encompasses the resuscitation and transport of those who become acutely ill, or are injured in the community. Management of seriously ill patients throughout the hospital (e.g. in coronary care units, acute admissions wards, postoperative recovery areas or emergency units), including critically ill patients who have been discharged to the ward ('outreach care'), is also undertaken. Teamwork and a multidisciplinary approach are central to the provision of intensive care and are most effective when directed and coordinated by committed specialists.

Intensive care units (ICUs) are usually reserved for patients with established or potential organ failure and provide facilities for the diagnosis, prevention and treatment of multiple organ dysfunction. They are fully equipped with monitoring and technical facilities, including an adjacent laboratory (or 'near patient testing' devices) for the rapid determination of blood gases and simple biochemical data such as serum potassium, blood glucose and blood lactate levels. Patients receive continuous expert nursing care and the constant attention of appropriately trained medical staff. High dependency units (HDUs) offer a level of care intermediate between that available on the general ward and that provided in an ICU. They provide monitoring and support for patients with acute (or acute-on-chronic) single organ failure and for those who are at risk of developing organ failure. These units are a more comfortable environment for less severely ill patients who are often conscious and alert. They can also provide a 'step-down' facility for patients being discharged from intensive care.

The provision of staff and the level of technical support must match the needs of the individual patient and resources are used more efficiently when they are combined in a single critical care facility rather than being divided between physically and managerially separate units.

In the UK, only around 3.4% of hospital beds are designated for intensive care (3.5 ICU beds per 100 000 population), whereas in many other developed economies, the proportion is much higher.

GENERAL ASPECTS OF MANAGING THE CRITICALLY ILL

Recognition and diagnosis of critical illness

Early recognition and immediate resuscitation are fundamental to the successful management of the critically ill. In order to facilitate identification of 'at risk' patients on the ward and early referral to the critical care emergency or outreach team a number of early warning systems have been devised (e.g. the Modified Early Warning Score, MEWS; see Box 16.1). These are based primarily on bedside recognition of deteriorating physiological variables and can be used to supplement clinical intuition. A MEWS score of ≥ 5 is associated with an increased risk of death and warrants immediate admission to ICU. Another example of a system used to trigger referral to a Medical Emergency Team (MET) is also shown in Box 16.1 (see also 'Management of shock and sepsis' and 'Clinical assessment of respiratory failure', below).

In some of the most seriously ill patients, the precise underlying diagnosis is initially unclear but in all cases, the *immediate objective* is to preserve life and prevent, reverse or minimize damage to vital organs such as the lungs, brain, kidneys and liver. This involves a rapid assessment of the physiological derangement followed by prompt institution of

FURTHER READING

Fullerton JN, Perkins GD. Who to admit to intensive care? *Clin Med* 2011; 11:601–604.

measures to support cardiovascular and respiratory function in order to restore perfusion of vital organs, improve delivery of oxygen to the tissues and encourage the removal of carbon dioxide and other waste products of metabolism (following the ABC approach: Airway, Breathing, Circulation, see

Fig. 16.25, below). The patient's condition and response to treatment should be closely monitored throughout. The underlying diagnosis may only become clear as the results of investigations become available, a more detailed history is obtained and a more thorough physical examination is performed. In practice resuscitation, assessment and diagnosis usually proceed in parallel.

Critically ill patients require multidisciplinary care with:

- Intensive skilled nursing care (usually 1:1 or 1:2 nurse/patient ratio in the UK).
- Specialized physiotherapy including mobilization and rehabilitation.
- Management of pain and distress with judicious administration of analgesics and sedatives (see p. 893).
- Constant reassurance and support (critically ill patients easily become disorientated and delirium is common).
- H₂-receptor antagonists or proton pump inhibitors in selected cases to prevent stress-induced ulceration.
- Compression stockings (full-length and graduated), pneumatic compression devices and subcutaneous low-molecular-weight heparin to prevent venous thrombosis.
- Care of the mouth, prevention of constipation and of pressure sores.
- Nutritional support (see p. 222). Protein energy malnutrition is common in critically ill patients and is associated with muscle wasting, weakness, delayed mobilization, difficulty weaning from ventilation, immune compromise and impaired wound healing. There is also an association between malnutrition and increased mortality. It is therefore recommended that nutritional support should be instituted as soon as is practicable in those unable to meet their nutritional needs orally, ideally within 1–2 days of the acute episode. Enteral

Table 16.1 Some common indications for admission to intensive care

Surgical emergencies

Acute intra-abdominal catastrophe
Perforated viscus, especially with faecal soiling of peritoneum (often complicated by sepsis/septic shock)
Ruptured/leaking abdominal aortic aneurysm
Trauma (often complicated by hypovolaemic and later sepsis/septic shock)
Multiple injuries
Massive blood loss
Severe head injury

Medical emergencies

Respiratory failure
Exacerbation of chronic obstructive pulmonary disease (COPD)
Acute severe asthma
Severe pneumonia (often complicated by sepsis/septic shock)
Meningococcal infection
Status epilepticus
Severe diabetic ketoacidosis
Coma

Elective surgical

Extensive/prolonged procedure (e.g. oesophagogastrectomy)
Cardiothoracic surgery
Major head and neck surgery
Co-existing cardiovascular or respiratory disease

Obstetric emergencies

Severe pre-eclampsia/eclampsia
Haemorrhage
Amniotic fluid embolism

Box 16.1 Early warning systems for referral of 'at risk' patients to the critical care team

Modified Early Warning Score (MEWS)

Score	3	2	1	0	1	2	3
Systolic blood pressure (mmHg)	<70	71–80	81–100	101–199		200	
Heart rate (b.p.m.)	<40		41–50	51–100	101–110	111–129	130
Respiratory rate (b.p.m.)		<9		9–14	15–20	21–29	30
Temperature (°C)	<35	34–35		35–38.4		38.5	
AVPU score				Alert	Reacting to voice	Reacting to pain	Unresponsive

Medical emergency team-calling criteria

Airway If threatened

Breathing All respiratory arrests

Respiratory rate <5 breaths/min

Respiratory rate >36 breaths/min

Circulation All cardiac arrests

Pulse rate <40 beats/min

Pulse rate >140 beats/min

Systolic blood pressure <90 mmHg

Neurology Sudden fall in level of consciousness (fall in Glasgow Coma Scale of >2 points)
Repeated or prolonged seizures

Other Any patient who does not fit the criteria above, but about whom you are seriously worried

Introduction

General aspects of managing the critically ill

Applied cardiorespiratory physiology

nutrition, which is less expensive, preserves gut mucosal integrity, is more physiological and is associated with fewer complications, is preferred. Recently, the value of early feeding has been questioned, apart from giving small amounts to ensure gut viability. Parenteral nutrition is sometimes indicated at a later stage for those unable to tolerate or absorb enteral nutrition and should be initiated without delay, at least within 3 days. Persistent attempts at enteral nutrition in those with gastrointestinal intolerance leads to underfeeding and malnutrition.

- Critically ill patients commonly require intravenous insulin infusions, often in high doses, to combat hyperglycaemia and insulin resistance (see p. 1006). Although the use of intensive insulin therapy to achieve 'tight glycaemic control' (blood glucose level between 4.4 and 6.1 mmol/L) was shown to improve outcome (at least when combined with aggressive nutritional support), more recent studies have failed to confirm this finding and have indicated that this approach is associated with an unacceptably high incidence of hypoglycaemia, and possibly an increase in mortality. Current recommendations suggest that blood glucose levels should be maintained at <8–10 mmol/L.

Discharge of patients from intensive care should normally be planned in advance and should ideally take place during normal working hours. Planned discharge often involves a period in a 'step-down' intermediate care area. Premature or unplanned discharge, especially during the night, has been associated with higher hospital mortality rates. A summary including 'points to review' should be included in the clinical notes and there should be a detailed handover to the receiving team (medical and nursing). The intensive care team should continue to review the patient, who might deteriorate following discharge, on the ward and should be available at all times for advice on further management (e.g. tracheostomy care, nutritional support). In this way, deterioration and readmission to intensive care (which is associated with a particularly poor outcome) or even cardiorespiratory arrest might be avoided.

This chapter concentrates on cardiovascular and respiratory problems. Many patients also have failure of other organs such as the kidney and liver; treatment of these is dealt with in more detail in the relevant chapters.

APPLIED CARDIORESPIRATORY PHYSIOLOGY

Oxygen delivery and consumption

Oxygen delivery (DO_2) (Fig. 16.1) is defined as the total amount of oxygen delivered to the tissues per unit time. It is dependent on the volume of blood flowing through the microcirculation per minute (i.e. the total cardiac output, \dot{Q}_t) and the amount of oxygen contained in that blood (i.e. the arterial oxygen content, C_aO_2). Oxygen is transported both in combination with haemoglobin and dissolved in plasma. The amount combined with haemoglobin is determined by the oxygen capacity of haemoglobin (usually taken as 1.34 mL of oxygen per gram of haemoglobin) and its percentage saturation with oxygen (SO_2), while the volume dissolved in plasma depends on the partial pressure of oxygen (PO_2). Except when hyperbaric oxygen is administered, the amount of dissolved oxygen in plasma is insignificant.

Clinically, however, the utility of this global concept of oxygen delivery is limited because it fails to account for

Figure 16.1 Tissue oxygen delivery and consumption in a normal 70 kg person breathing air. Oxygen delivery (DO_2) = cardiac output \times (haemoglobin concentration \times oxygen saturation (S_aO_2) \times 1.34). In normal adults, oxygen delivery is roughly 1000 mL/min, of which 250 mL is taken up by tissues. Mixed venous blood is thus 75% saturated with oxygen. C_vO_2 , mixed venous oxygen content; S_vO_2 , mixed venous oxygen saturation; C_aO_2 , arterial oxygen content.

changes in the relative flow to individual organs and the distribution of flow through the microcirculation (i.e. the efficiency with which oxygen delivery is matched to the metabolic requirements of individual tissues or cells). Furthermore, some organs (such as the heart) have high oxygen requirements relative to their blood flow and will receive insufficient oxygen, even if the overall oxygen delivery is apparently adequate. Lastly, microcirculatory flow is influenced by blood viscosity.

Oxygenation of the blood

Oxyhaemoglobin dissociation curve

The saturation of haemoglobin with oxygen is determined by the partial pressure of oxygen (PO_2) in the blood, the relationship between the two being described by the oxyhaemoglobin dissociation curve (Fig. 16.2). The sigmoid shape of this curve is significant for a number of reasons:

- Modest falls in the partial pressure of oxygen in the arterial blood (P_aO_2) may be tolerated (since oxygen content is relatively unaffected) provided that the percentage saturation remains above 92%.
- Increasing the P_aO_2 to above normal has only a minimal effect on oxygen content unless hyperbaric oxygen is administered (when the amount of oxygen in solution in plasma becomes significant).
- Once on the steep 'slippery slope' of the curve (percentage saturation below about 90%), a small decrease in P_aO_2 can cause large falls in oxygen content, whereas increasing P_aO_2 only slightly, e.g. by administering 28% oxygen to a patient with chronic obstructive pulmonary disease (COPD), can lead to a useful increase in oxygen saturation and content.

The P_aO_2 is in turn influenced by the alveolar oxygen tension (P_AO_2), the efficiency of pulmonary gas exchange, and the partial pressure of oxygen in mixed venous blood P_vO_2 .

Alveolar oxygen tension (P_AO_2)

The partial pressures of inspired gases are shown in Figure 16.3. By the time the inspired gases reach the alveoli they are fully saturated with water vapour at body temperature (37°C), which has a partial pressure of 6.3 kPa (47 mmHg) and contain CO_2 at a partial pressure of approximately

Figure 16.2 The oxyhaemoglobin dissociation curve. a, arterial point; v, venous point; x, arteriovenous oxygen content difference. HbO_2 (%) is the percentage saturation of haemoglobin with oxygen. The curve will move to the right in the presence of acidosis (metabolic or respiratory), pyrexia or an increased red cell 2,3-DPG concentration. For a given arteriovenous oxygen content difference, the mixed venous PO_2 will then be higher. Furthermore, if the mixed venous PO_2 is unchanged, the arteriovenous oxygen content difference increases and more oxygen is off-loaded to the tissues (see p. 374). P_{50} (the PO_2 at which haemoglobin is half saturated with O_2) is a useful index of these shifts – the higher the P_{50} (i.e. shift to the right), the lower the affinity of haemoglobin for O_2 .

Figure 16.3 The composition of inspired and alveolar gas (partial pressures in kPa).

5.3 kPa (40 mmHg); the $P_{\text{A}\text{O}_2}$ is thereby reduced to approximately 13.4 kPa (100 mmHg).

The clinician can influence $P_{\text{A}\text{O}_2}$ by administering oxygen or by increasing the barometric pressure.

Pulmonary gas exchange

In *normal* subjects there is a small alveolar-arterial oxygen difference ($P_{\text{A-a}\text{O}_2}$). This is due to:

- a small (0.133 kPa, 1 mmHg) pressure gradient across the alveolar membrane
- a small amount of blood (2% of total cardiac output) bypassing the lungs via the bronchial and thebesian veins
- a small degree of ventilation/perfusion mismatch.

Figure 16.4 The carbon dioxide dissociation curve. Note that in the physiological range the curve is essentially linear.

Pathologically, there are three possible causes of an increased $P_{\text{A-a}\text{O}_2}$ difference:

- **Diffusion defect.** This is not a major cause of hypoxaemia even in conditions such as lung fibrosis, in which the alveolar-capillary membrane is considerably thickened. Carbon dioxide is also not affected, as it is more soluble than oxygen.
- **Right-to-left shunts.** In certain congenital cardiac lesions or when a segment of lung is completely collapsed, a proportion of venous blood passes to the left side of the heart without taking part in gas exchange, causing arterial hypoxaemia. This hypoxaemia cannot be corrected by administering oxygen to increase the $P_{\text{A}\text{O}_2}$, because blood leaving normal alveoli is already fully saturated; further increases in PO_2 will not, therefore, significantly affect its oxygen content. On the other hand, because of the shape of the carbon dioxide dissociation curve (Fig. 16.4), the high PCO_2 of the shunted blood can be compensated for by over-ventilating patent alveoli, thus lowering the CO_2 content of the effluent blood. Indeed, many patients with acute right-to-left shunts hyperventilate in response to the hypoxia and/or to stimulation of mechanoreceptors in the lung, so that their $P_{\text{a}\text{CO}_2}$ is normal or low.
- **Ventilation/perfusion mismatch** (see p. 796). Diseases of the lung parenchyma (e.g. pulmonary oedema, acute lung injury) result in \dot{V}/\dot{Q} mismatch, producing an increase in alveolar deadspace and hypoxaemia. The increased deadspace can be compensated for by increasing overall ventilation. In contrast to the hypoxia resulting from a true right-to-left shunt, that due to areas of low \dot{V}/\dot{Q} can be partially corrected by administering oxygen and thereby increasing the $P_{\text{A}\text{O}_2}$ even in poorly ventilated areas of lung.

Mixed venous oxygen tension $P_{\text{v}\text{O}_2}$ and saturation ($\text{S}_{\text{v}\text{O}_2}$)

The $P_{\text{v}\text{O}_2}$ is the partial pressure of oxygen in pulmonary arterial blood that has been thoroughly mixed during its passage through the right heart. Assuming $P_{\text{A}\text{O}_2}$ remains constant, $P_{\text{v}\text{O}_2}$ and $\text{S}_{\text{v}\text{O}_2}$ will fall if more oxygen has to be extracted from each unit volume of blood arriving at the tissues. A low $P_{\text{v}\text{O}_2}$ therefore indicates either that oxygen delivery has fallen or that tissue oxygen requirements have increased without a compensatory rise in cardiac output. If $P_{\text{v}\text{O}_2}$ falls, the effect of a given degree of pulmonary shunting on arterial oxygenation will be exacerbated. Thus, worsening arterial hypoxaemia does not necessarily indicate a deterioration in pulmonary function but might instead reflect a fall in cardiac output and/or a rise in oxygen consumption.

Figure 16.5 The determinants of cardiac output.

Conversely, a rise in P_{vO_2} and S_{vO_2} may reflect impaired tissue oxygen extraction (due to microcirculatory dysfunction) and/or reduced oxygen utilization (e.g. due to mitochondrial dysfunction) as seen in severe sepsis (see below).

Monitoring the oxygen saturation in central venous (S_{vO_2}), rather than pulmonary artery blood is less invasive and has been shown to be a valuable guide to the resuscitation of critically ill patients (see p. 891).

Cardiac output

Cardiac output is the product of heart rate and stroke volume, and is affected by changes in either of these (see Fig. 16.5).

Heart rate

When heart rate increases, the duration of systole remains essentially unchanged, whereas diastole, and thus the time available for ventricular filling, becomes progressively shorter, and the stroke volume eventually falls. In the normal heart this occurs at rates greater than about 160 beats per minute, but in those with cardiac pathology, especially when this restricts ventricular filling (e.g. mitral stenosis), stroke volume may fall at much lower heart rates. Furthermore, tachycardias cause a marked increase in myocardial oxygen consumption (\dot{V}_{mO_2}) and this may precipitate ischaemia in areas of the myocardium with restricted coronary perfusion. When the heart rate falls, a point is reached at which the increase in stroke volume is insufficient to compensate for bradycardia and again cardiac output falls.

Alterations in heart rate are often caused by disturbances of rhythm (e.g. atrial fibrillation, complete heart block) in which ventricular filling is not augmented by atrial contraction, exacerbating the fall in stroke volume.

Stroke volume

The volume of blood ejected by the ventricle in a single contraction is the difference between the ventricular end-diastolic volume (VEDV) and end-systolic volume (VESV) (i.e. stroke volume = VEDV – VESV). The ejection fraction describes the stroke volume as a percentage of VEDV (i.e. ejection fraction = (VEDV – VESV)/VEDV × 100%) and is an indicator of myocardial performance.

Three interdependent factors determine the stroke volume (see p. 671).

Preload

This is defined as the tension of the myocardial fibres at the end of diastole, just before the onset of ventricular contraction, and is therefore related to the degree of stretch of the fibres. As the end-diastolic volume of the ventricle increases, tension in the myocardial fibres is increased and stroke volume rises (Fig. 16.6). Myocardial oxygen consumption (\dot{V}_{mO_2}) increases only slightly with an increase in preload (produced, for example, by a 'fluid challenge', see below) and this is therefore the most efficient way of improving cardiac output.

Figure 16.6 The Frank–Starling relationship: as preload is increased, stroke volume rises. If the ventricle is overstretched, stroke volume will fall (x). In myocardial failure, the curve is depressed and flattened. Increasing contractility, e.g. due to sympathetic stimulation, shifts the curve upwards and to the left (z).

Figure 16.7 The effect of changes in afterload on the ventricular function curve. At any given preload, decreasing afterload increases the stroke volume.

Myocardial contractility

This refers to the ability of the heart to perform work, independent of changes in preload and afterload. The state of myocardial contractility determines the response of the ventricles to changes in preload and afterload. Contractility is often reduced in critically ill patients, as a result of either pre-existing myocardial damage (e.g. ischaemic heart disease), or the acute disease process itself (e.g. sepsis). Changes in myocardial contractility alter the slope and position of the Starling curve; worsening ventricular performance is manifested as a depressed, flattened curve (Fig. 16.6 and Fig. 14.5). Inotropic drugs can be used to increase myocardial contractility (see below).

Afterload

This is defined as the myocardial wall tension developed during systolic ejection. In the case of the left ventricle, the resistance imposed by the aortic valve, the peripheral vascular resistance and the elasticity of the major blood vessels are the major determinants of afterload. Ventricular wall tension will also be increased by ventricular dilatation, an increase in intraventricular pressure or a reduction in ventricular wall thickness.

Decreasing the afterload (exercise, sepsis, vasodilator agents) can increase the stroke volume achieved at a given preload (Fig. 16.7), while reducing \dot{V}_{mO_2} . The reduction in wall tension also leads to an increase in coronary blood flow, thereby improving the myocardial oxygen supply/demand ratio. Excessive reductions in afterload will cause hypotension.

Increasing the afterload (increased sympathetic activity, vasoconstrictor agents), on the other hand, can cause a fall in stroke volume and is a potent cause of increased \dot{V}_{mO_2} . Right ventricular afterload is normally negligible because the resistance of the pulmonary circulation is very low but is increased in pulmonary hypertension.

Monitoring critically ill patients

As well as allowing immediate recognition of changes in the patient's condition, monitoring can also be used to establish or confirm a diagnosis, to gauge the severity of the condition, to follow the evolution of the illness, to guide interventions and to assess the response to treatment. Invasive monitoring is generally indicated in the more seriously ill patients and in those who fail to respond to initial treatment. These techniques are, however, associated with a significant risk of complications, as well as additional costs and patient discomfort and should therefore only be used when the potential benefits outweigh the dangers. Likewise, invasive devices should be removed as soon as possible.

Assessment of tissue perfusion

- **Pale, cold skin**, delayed capillary refill and the absence of visible veins in the hands and feet indicate poor perfusion. Although peripheral skin temperature measurements can help clinical evaluation, the earliest compensatory response to hypovolaemia or a low cardiac output, and the last to resolve after resuscitation is vasoconstriction in the splanchnic region.
- **Metabolic acidosis with raised lactate concentration** suggests that tissue perfusion is sufficiently compromised to cause cellular hypoxia and anaerobic glycolysis. Persistent, severe lactic acidosis is associated with a very poor prognosis. In many critically ill patients, especially those with sepsis, however, lactic acidosis can also be caused by metabolic disorders unrelated to tissue hypoxia and can be exacerbated by reduced clearance owing to hepatic or renal dysfunction as well as the administration of adrenaline (epinephrine).
- **Urinary flow** is a sensitive indicator of renal perfusion and haemodynamic performance.

Blood pressure

Alterations in blood pressure are often interpreted as reflecting changes in cardiac output. However, if there is vasoconstriction with a high peripheral resistance, the blood pressure may be normal, even when the cardiac output is reduced. Conversely, the vasodilated patient may be hypotensive, despite a very high cardiac output.

Hypotension jeopardizes perfusion of vital organs. The adequacy of blood pressure in an individual patient must always be assessed in relation to the premorbid value. Blood pressure is traditionally measured using a sphygmomanometer but if rapid alterations are anticipated, continuous monitoring using an intra-arterial cannula is indicated (Practical Box 16.1; Fig. 16.8).

Central venous pressure (CVP)

This provides a fairly simple, but approximate method of gauging the adequacy of a patient's circulating volume and the contractile state of the myocardium. The absolute value of the CVP is not as useful as its response to a fluid challenge (the infusion of 100–200 mL of fluid over a few minutes)

Practical Box 16.1

Radial artery cannulation

Technique

1. The procedure is explained to the patient and, if possible, consent obtained.
2. The arm is supported, with the wrist extended, by an assistant. (Gloves should be worn.)
3. The skin should be cleaned with chlorhexidine.
4. The radial artery is palpated where it arches over the head of the radius.
5. In conscious patients, local anaesthetic is injected to raise a wheal over the artery, taking care not to puncture the vessel or obscure its pulsation.
6. A small skin incision is made over the proposed puncture site.
7. A small parallel-sided cannula (20 gauge for adults, 22 gauge for children) is used in order to allow blood flow to continue past the cannula.
8. The cannula is inserted over the point of maximal pulsation and advanced in line with the direction of the vessel at an angle of approximately 30°.
9. 'Flashback' of blood into the cannula indicates that the radial artery has been punctured.
10. To ensure that the shoulder of the cannula enters the vessel, the needle and cannula are lowered and advanced a few millimetres into the vessel.
11. The cannula is threaded off the needle into the vessel and the needle withdrawn.
12. The cannula is connected to a non-compliant manometer line filled with saline. This is then connected via a transducer and continuous flush device to a monitor, which records the arterial pressure.

Complications

- **Thrombosis**
- **Loss of arterial pulsation**
- **Distal ischaemia, e.g. digital necrosis (rare)**
- **Infection**
- **Accidental injection of drugs – can produce vascular occlusion**
- **Disconnection – rapid blood loss.**

Figure 16.8 Percutaneous cannulation of the radial artery.

(Fig. 16.9). The hypovolaemic patient will initially respond to transfusion with little or no change in CVP, together with some improvement in cardiovascular function (falling heart rate, rising blood pressure, increased peripheral temperature and urine output). As the normovolaemic state is approached, the CVP usually rises slightly and reaches a plateau, while

Figure 16.9 The effects on the central venous pressure (CVP) of a rapid administration of a 'fluid challenge' to patients with a CVP within the normal range. (From Sykes MK. Venous pressure as a clinical indication of adequacy of transfusion. *Annals of Royal College of Surgeons of England* 1963; 33:185–197.)

Figure 16.10 Cannulation of the right internal jugular vein.

other cardiovascular values begin to stabilize. At this stage, volume replacement should be slowed, or even stopped, in order to avoid overtransfusion (indicated by an abrupt and sustained rise in CVP, often accompanied by some deterioration in the patient's condition). In cardiac failure, the venous pressure is usually high; the patient will not improve in response to volume replacement, which will cause a further, sometimes dramatic, rise in CVP.

Central venous catheters are usually inserted via a percutaneous puncture of the subclavian or internal jugular vein using a guidewire technique (Practical Box 16.2; Figs 16.10, 16.11). The guidewire techniques can also be used in conjunction with a vein dilator for inserting multilumen catheters, double lumen cannulae for haemofiltration or pulmonary artery catheter introducers. The routine use of ultrasound to guide central venous cannulation reduces complication rates.

The CVP should be read intermittently using a manometer system or continuously using a transducer and bedside monitor. It is essential that the pressure recorded always be

Figure 16.11 Seldinger technique – insertion of a catheter over guidewire. (1) Puncture vessel; (2) advance guidewire; (3) remove needle; (4) dilate vessel; (5) advance catheter over guidewire; (6) remove guidewire; (7) catheter in situ.

Practical Box 16.2

Internal jugular vein cannulation

Technique

1. The procedure is explained to the patient and, if possible, consent obtained.
2. The patient is placed head-down to distend the central veins (this facilitates cannulation and minimizes the risk of air embolism but may exacerbate respiratory distress and is dangerous in those with raised intracranial pressure).
3. The skin is cleaned with an antiseptic solution such as chlorhexidine. Sterile precautions are taken throughout the procedure.
4. Local anaesthetic (1% plain lidocaine) is injected intradermally to raise a weal at the apex of a triangle formed by the two heads of sternomastoid with the clavicle at its base.
5. A small incision is made through the weal.
6. The cannula or needle is inserted through the incision and directed laterally downwards and backwards in the direction of the nipple until the vein is punctured just beneath the skin and deep to the lateral head of sternomastoid.

Ultrasound-guided puncture is recommended to reduce the incidence of complications.

7. Check that venous blood is easily aspirated.
8. The cannula is threaded off the needle into the vein or the guidewire is passed through the needle (see Fig. 16.11).
9. The CVP manometer line is connected to a manometer/transducer.
10. A chest X-ray should be taken to verify that the tip of the catheter is in the superior vena cava and to exclude pneumothorax.

Possible complications

- Haemorrhage
- Accidental arterial puncture (carotid or subclavian)
- Pneumothorax
- Damage to thoracic duct on left
- Air embolism
- Thrombosis
- Catheter-related sepsis.

FURTHER READING

Ortega R, Song M, Hansen CJ et al. Ultrasound-guided internal jugular vein cannulation. Videos in Medicine. *N Engl J Med* 2010; 362:e57.

related to the level of the right atrium. Various landmarks are advocated (e.g. sternal notch with the patient supine, sternal angle or mid-axilla when the patient is at 45°), but which is chosen is largely immaterial provided it is used consistently in an individual patient. Pressure measurements should be obtained at end-expiration.

The following are common pitfalls in interpreting central venous pressure readings:

- **Blocked catheter.** This results in a sustained high reading, with a damped or absent waveform, which often does not correlate with clinical assessment.
- **Transducer wrongly positioned.** Failure to level the system is a common cause of erroneous readings.
- **Catheter tip in right ventricle.** If the catheter is advanced too far, an unexpectedly high pressure with pronounced oscillations is recorded. This is easily recognized when the waveform is displayed.

Left atrial pressure

In uncomplicated cases, careful interpretation of the CVP provides a reasonable guide to the filling pressures of both sides of the heart. In many critically ill patients, however, there is a disparity in function between the two ventricles. Most commonly, left ventricular performance is worse, so that the left ventricular function curve is displaced downward and to the right (Fig. 16.12). High right ventricular filling pressures, with normal or low left atrial pressures, are less common but occur with right ventricular dysfunction and in cases where the pulmonary vascular resistance (i.e. right ventricular afterload) is raised, such as in acute respiratory failure and pulmonary embolism.

Pulmonary artery pressure

A 'balloon flotation catheter' enables reliable catheterization of the pulmonary artery. These 'Swan-Ganz' catheters can be inserted centrally (Fig. 16.10) or through the femoral vein, or via a vein in the antecubital fossa. Passage of the catheter

Figure 16.12 Left ventricular (LV) and right ventricular (RV) function curves in a patient with left ventricular dysfunction. Since the stroke volume of the two ventricles must be the same (except perhaps for a few beats during a period of circulatory adjustment), left atrial pressure (LAP) must be higher than right atrial pressure (RAP). Moreover, an increase in stroke volume (x) produced by expanding the circulatory volume may be associated with a small rise in RAP (y) but a marked increase in LAP (z).

Practical Box 16.3

Passage of a pulmonary artery balloon flotation catheter through the chambers of the heart into the 'wedged' position

Consent should be obtained if possible from the patient after explanation of the procedure.

Note: (a), (b), (c), (d) refer to Figure 16.13.

1. A balloon flotation catheter is inserted through a large vein (see text).
2. Once in the thorax, respiratory oscillations are seen. The catheter should be advanced further towards the lower superior vena cava/right atrium **(a)**, where pressure oscillations become more pronounced. The balloon should then be inflated and the catheter advanced.
3. When the catheter is in the right ventricle **(b)**, there is no dicrotic notch and the diastolic pressure is close to zero. The patient should be returned to the horizontal, or slightly head-up, position before advancing the catheter further.
4. When the catheter reaches the pulmonary artery **(c)** a dicrotic notch appears and there is elevation of the diastolic pressure. The catheter should be advanced further with the balloon inflated.
5. Reappearance of a venous waveform indicates that the catheter is 'wedged'. The balloon is deflated to obtain the pulmonary artery pressure. The balloon is inflated intermittently to obtain the pulmonary artery occlusion (also known as pulmonary artery, or capillary, 'wedge') pressure **(d)**.

from the major veins, through the chambers of the heart, into the pulmonary artery and into the wedged position is monitored and guided by the pressure waveforms recorded from the distal lumen (Practical Box 16.3; Fig. 16.13). A chest X-ray should always be obtained to check the final position of the catheter. In difficult cases, screening with an image intensifier may be required.

Once in place, the balloon is deflated and the pulmonary artery mean, systolic and end-diastolic pressures (PAEDP) can be recorded. The pulmonary artery occlusion pressure (PAOP, previously referred to as the pulmonary artery or capillary 'wedge' pressure) is measured by reinflating the balloon, thereby propelling the catheter distally until it impacts in a medium-sized pulmonary artery. In this position there is a continuous column of fluid between the distal lumen of the catheter and the left atrium, so that PAOP is usually a reasonable reflection of left atrial pressure.

The technique is generally safe – the majority of complications such as 'knotting', valve trauma and pulmonary artery rupture (which can be fatal) are related to user inexperience. Pulmonary artery catheters should preferably be removed within 72 h, since the incidence of complications, especially infection, then increases progressively.

Cardiac output

Cardiac output can be continuously monitored using a modified pulmonary artery catheter which transmits low heat energy into the surrounding blood and constructs a 'thermodilution curve'. These catheters also optically measure and continuously display S_vO_2 .

In general, pulmonary artery catheters enable the clinician to optimize cardiac output and oxygen delivery, while minimizing the risk of volume overload. They can also be used to guide the rational use of inotropes and vasoactive agents and are particularly helpful in patients with pulmonary hypertension. There is, however, a considerable body of evidence to suggest that the unselective use of this monitoring device in the absence of evidence-based haemodynamic goals does

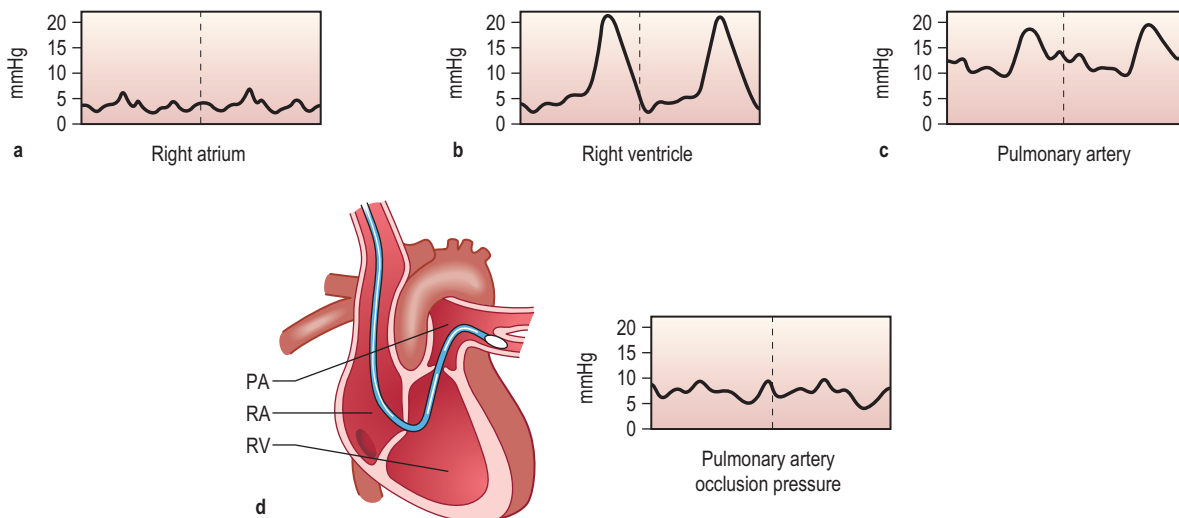

Figure 16.13 Passage of pulmonary artery balloon flotation catheter through the chambers of the heart into the 'wedged' position to measure the pulmonary artery occlusion pressure. (See [Practical Box 16.3](#).)

not lead to improved outcomes and less invasive techniques are increasingly preferred.

Less invasive techniques for assessing cardiac function and guiding volume replacement

Arterial pressure variation as a guide to hypovolaemia

Systolic arterial pressure decreases during the inspiratory phase of intermittent positive pressure ventilation (p. 894). The magnitude of this cyclical variability has been shown to correlate more closely with hypovolaemia than other monitored variables, including CVP. Systolic pressure (or pulse pressure) variation during mechanical ventilation can therefore be used as a simple and reliable guide to the adequacy of the circulatory volume. The response to fluid loading can also easily be predicted by observing the changes in pulse pressure during passive leg raising.

Oesophageal Doppler

Stroke volume, cardiac output and myocardial function can be assessed non-invasively using Doppler ultrasonography. A probe is passed into the oesophagus to continuously monitor velocity waveforms from the descending aorta (Fig. 16.14). Although reasonable estimates of stroke volume, and hence cardiac output can be obtained, the technique is best used for trend analysis rather than for making absolute measurements. Oesophageal Doppler probes can be inserted quickly and easily and are particularly valuable for perioperative optimization of the circulating volume and cardiac performance in the unconscious patient. They are contraindicated in patients with oropharyngeal/oesophageal pathology.

Pulse contour analysis

Lithium dilution/pulse contour analysis does not require pulmonary artery catheterization or instrumentation of the oesophagus and is suitable for use in conscious patients. A bolus of lithium chloride is administered via a central venous catheter and the change in arterial plasma lithium concentration is detected by a lithium-sensitive electrode. This sensor can be connected to an existing arterial cannula via a three-way tap. A small battery-powered peristaltic pump is used to create a constant blood flow through the sensor and over the electrode tip. The cardiac output determined in this way

Figure 16.14 Doppler ultrasonography. Velocity waveform traces are obtained using oesophageal Doppler ultrasonography. (Reproduced from Singer et al (1991) with permission © 1991 The Williams & Wilkins Co., Baltimore.)

can be used to calibrate an arterial pressure waveform ('pulse contour') analysis programme that will continuously monitor changes in cardiac output. Devices that use uncalibrated pulse contour analysis to estimate cardiac output are also available. As with pulse pressure variation, stroke volume variation using these devices can accurately predict fluid replacements.

Echocardiography

Echocardiography is being used increasingly often to provide immediate diagnostic information about cardiac structure and function (myocardial contractility, ventricular filling) in the critically ill patient. Transoesophageal echocardiography (TOE) is preferred because of its superior image clarity (Fig. 16.15).

If there is disagreement between clinical signs and a monitored variable, it should be assumed that the monitor is incorrect until all sources of potential error have been checked

Figure 16.15 Aortic dissection (transoesophageal echocardiography, TOE). **(a)** Mid-oesophageal, long axis view showing Type A aortic dissection. **(b)** Short axis view of descending aorta showing intimal flap with false and true lumen. Table 16.2 Arterial blood gas and acid–base values (normal ranges)		
H ⁺	35–45 nmol/L	pH 7.35–7.45
PO ₂ (breathing room air)	10.6–13.3 kPa	(80–100 mmHg)
PCO ₂	4.8–6.1 kPa	(36–46 mmHg)
Base deficit	±2.5	
Plasma HCO ₃ [−]	22–26 mmol/L	
O ₂ saturation	95–100%	

and eliminated. Changes and trends in monitored variables are more informative than a single reading.

Disturbances of acid–base balance

The physiology of acid–base control is discussed on [page 660](#). Acid–base disturbances can be described in relation to the diagram illustrated in [Figure 13.13, p. 663](#) (which shows $P_a\text{CO}_2$ plotted against arterial [H⁺]).

Both acidosis and alkalosis can occur, each of which are either metabolic (primarily affecting the bicarbonate component of the system) or respiratory (primarily affecting $P_a\text{CO}_2$). Compensatory changes may also be apparent. In clinical practice, arterial [H⁺] values outside the range 18–126 nmol/L (pH 6.9–7.7) are rarely encountered.

Blood gas and acid–base values (normal ranges) are shown in [Table 16.2](#). (For blood gas analysis, see [p. 891](#).)

Respiratory acidosis. This is caused by retention of carbon dioxide. The $P_a\text{CO}_2$ and [H⁺] rise. A chronically raised $P_a\text{CO}_2$ is compensated by renal retention of bicarbonate, and the [H⁺] returns towards normal. A constant arterial bicarbonate concentration is then usually established within 2–5 days. This represents a primary respiratory acidosis with a compensatory metabolic alkalosis (see [p. 666](#)). Common causes of respiratory acidosis include ventilatory failure and COPD (type II respiratory failure where there is a high $P_a\text{CO}_2$ and a low $P_a\text{O}_2$, see [p. 814](#)).

Respiratory alkalosis. In this case, the reverse occurs and there is a fall in $P_a\text{CO}_2$ and [H⁺], often with a small reduction in bicarbonate concentration. If hypocarbia persists, some degree of renal compensation may occur, producing a metabolic acidosis, although in practice this is unusual. A respiratory alkalosis may be produced, intentionally or unintentionally, when patients are mechanically ventilated; it may also be seen with hypoxaemic (type I) respiratory failure (see [Ch. 15, p. 817](#)), spontaneous hyperventilation and in those living at high altitudes.

Metabolic acidosis ([p. 664](#)). This may be due to excessive acid production, most commonly lactate and H⁺ (lactic acidosis) as a consequence of anaerobic metabolism during an episode of shock or following cardiac arrest. A metabolic acidosis may also develop in chronic renal failure or in diabetic ketoacidosis. It can also follow the loss of bicarbonate from the gut or from the kidney in renal tubular acidosis. Respiratory compensation for a metabolic acidosis is usually slightly delayed because the blood–brain barrier initially prevents the respiratory centre from sensing the increased blood [H⁺]. Following this short delay, however, the patient hyperventilates and ‘blows off’ carbon dioxide to produce a compensatory respiratory alkalosis. There is a limit to this respiratory compensation, since in practice values for $P_a\text{CO}_2$ less than about 1.4 kPa (11 mmHg) are rarely achieved. Spontaneous respiratory compensation cannot occur if the patient’s ventilation is controlled or if the respiratory centre is depressed, for example by drugs or head injury.

Metabolic alkalosis. This can be caused by loss of acid, for example from the stomach with nasogastric suction, or in high intestinal obstruction, or excessive administration of absorbable alkali. Overzealous treatment with intravenous sodium bicarbonate is sometimes implicated. Respiratory compensation for a metabolic alkalosis is often slight, and it is rare to encounter a $P_a\text{CO}_2$ above 6.5 kPa (50 mmHg), even with severe alkalosis.

SHOCK, SEPSIS AND ACUTE DISTURBANCES OF HAEMODYNAMIC FUNCTION

Shock is the term used to describe acute circulatory failure with inadequate or inappropriately distributed tissue perfusion resulting in generalized cellular hypoxia and/or an inability of the cells to utilize oxygen.

Causes of shock

Abnormalities of tissue perfusion can result from:

- failure of the heart to act as an effective pump
- mechanical impediments to forward flow
- loss of circulatory volume
- abnormalities of the peripheral circulation.

The causes of shock are shown in [Table 16.3](#). Often shock can result from a combination of these factors (e.g. in sepsis, distributive shock is frequently complicated by hypovolaemia and myocardial depression).

Pathophysiology

The sympatho-adrenal response to shock (Fig. 16.16)

Hypotension stimulates the baroreceptors, and to a lesser extent the chemoreceptors, causing increased sympathetic nervous activity with ‘spill-over’ of noradrenaline (norepinephrine) into the circulation. Later this is augmented by the release of catecholamines (predominantly, adrenaline (epinephrine)) from the adrenal medulla. The resulting vasoconstriction, together with increased myocardial contractility and heart rate, help to restore blood pressure and cardiac output.

Reduction in perfusion of the renal cortex stimulates the juxtaglomerular apparatus to release renin. This converts angiotensinogen to angiotensin I, which in turn is converted in the lungs and by the vascular endothelium to the potent

vasoconstrictor angiotensin II. Angiotensin II also stimulates secretion of aldosterone by the adrenal cortex, causing sodium and water retention (p. 566). This helps to restore the circulating volume (see p. 639).

Neuroendocrine response

- There is *release of pituitary hormones* such as adrenocorticotrophic hormone (ACTH), vasopressin (antidiuretic hormone, ADH) and endogenous opioid peptides. (In septic shock there may be a relative deficiency of vasopressin.)
- There is *release of cortisol*, which causes fluid retention and antagonizes insulin.
- There is *release of glucagon*, which raises the blood sugar level.

Although absolute adrenocortical insufficiency (e.g. due to bilateral adrenal haemorrhage or necrosis) is rare, there is evidence that patients with septic shock have a blunted response to exogenous ACTH (so-called 'relative' or 'occult' adrenocortical insufficiency) and that this could be associated

with an impaired pressor response to noradrenaline (norepinephrine) and a worse prognosis. The diagnosis, causes and clinical significance of this phenomenon remain unclear.

Release of pro- and anti-inflammatory mediators

Severe infection (often with bacteraemia or endotoxaemia), the presence of large areas of damaged tissue (e.g. following trauma or extensive surgery), hypoxia or prolonged/repeated episodes of hypoperfusion can trigger an exaggerated inflammatory response with systemic activation of leucocytes and release of a variety of potentially damaging 'mediators' (see also Ch. 3). Although beneficial when targeted against local areas of infection or necrotic tissue, dissemination of this 'innate immune' response can produce shock and widespread tissue damage. Characteristically the initial episode of overwhelming inflammation is followed by a period of immune suppression, which in some cases may be profound and during which the patient is at increased risk of developing secondary infections. It also seems that pro- and anti-inflammatory elements of the host response may co-exist.

Microorganisms and their toxic products

(Fig. 16.17)

In sepsis/septic shock the innate immune response and inflammatory cascade are triggered by the recognition of pathogen-associated molecular patterns (PAMPs), including cell wall components (e.g. endotoxin) and/or exotoxins (antigenic proteins produced by bacteria such as staphylococci, streptococci and *Pseudomonas*).

Endotoxin is a lipopolysaccharide (LPS) derived from the cell wall of Gram-negative bacteria and is a potent trigger of the inflammatory response. The lipid A portion of LPS can be bound by a protein normally present in human serum known as lipopolysaccharide binding protein (LBP). The LBP/LPS complex attaches to the cell surface marker CD14 and,

Hypovolaemic	Obstructive
Exogenous losses (e.g. haemorrhage, burns)	Obstruction to outflow (e.g. pulmonary embolus)
Endogenous losses	Restricted cardiac filling (e.g. cardiac tamponade, tension pneumothorax)
Cardiogenic	Distributive
(e.g. ischaemic myocardial injury)	(e.g. sepsis, anaphylaxis)
	Vascular dilatation
	Sequestration
	Arteriovenous shunting
	Maldistribution of flow
	Myocardial depression

Figure 16.16 The sympatho-adrenal response to shock showing the effect of increased catecholamines on the left of the diagram and the release of angiotensin and aldosterone on the right. Both mechanisms help to maintain the cardiac output and blood pressure in shock.

Figure 16.17 Induction of the innate immune response by the lipopolysaccharide–lipopolysaccharide-binding protein (LPS–LBP) complex. This simplified figure illustrates the intracellular events initiated by Gram-negative and Gram-positive bacteria, which eventually lead to bacterial killing. LPS, lipopolysaccharide; LBP, lipopolysaccharide binding protein; LTA, lipoteichoic acid; NFκB, nuclear factor kappa B; IκB, inhibitory factor kappa B; PEPG, peptidoglycan-N; TLR, toll-like receptors; MSR, macrophage scavenger receptor; MyD88, myeloid differentiation factor 88; TIR, toll-interleukin 1 receptor adaptor protein; MD2 is a secreted protein involved in binding lipopolysaccharide with TLR4; TIRAP/Mal, an adaptor protein for TLR2 and TLR4.

combined with a secreted protein (MD2), this complex then binds to a member of the toll-like receptor family (TLR4), which transduces the activation signal into the cell. These receptors act through a critical adaptor molecule, myeloid differentiation factor 88 (MyD88), to regulate the activity of NFκB pathways. Intracellular pattern recognition receptors such as nucleotide-binding oligomerization domain (NOD) 1 may also be involved. Another mechanism in this complex area involves TREM-1 (triggering receptor expressed in myeloid cells, see p. 54), which triggers secretion of pro-inflammatory cytokines.

Specific kinases then phosphorylate inhibitory kappa B (IκB), releasing the nuclear transcription factor NFκB, which passes into the nucleus where it binds to DNA and promotes the synthesis of a wide variety of inflammatory mediators. Gram-positive bacteria have cell wall components which are similar in structure to LPS (e.g. lipoteichoic acid), and can also trigger a systemic inflammatory response, probably through similar (TLR2) but not identical pathways (Fig. 16.17). Following traumatic or surgical tissue injury, inflammatory pathways may be triggered by damage-associated molecular patterns (DAMPs) such as DNA fragments.

Activation of complement cascade

Fragments of C3 act as opsonins and co-stimulatory molecules that assist lymphocytes with the adaptive immune response, while small peptides derived from C3, C4 and C5 cause leucocyte chemotaxis, release of cytokines and increased vascular permeability (see p. 51).

Cytokines

Pro-inflammatory cytokines (see also p. 49) such as the interleukins (ILs) and tumour necrosis factor (TNF) are also mediators of the systemic inflammatory response. TNF release initiates many of the responses to endotoxin, for example, and acts synergistically with IL-1, in part through induction of cyclo-oxygenase, platelet-activating factor (PAF) and nitric oxide synthase (see below). Subsequently, other cytokines including IL-6 and IL-8 appear in the circulation. IL-6 is the major stimulant for hepatic synthesis of acute phase proteins and is involved in the induction of fever, anaemia and cachexia, while IL-8 is a chemoattractant. The cytokine network is extremely complex, with many endogenous self-regulating mechanisms. For example, naturally occurring soluble TNF receptors are shed from cell surfaces during the

inflammatory response, binding to TNF and thereby reducing its biological activity. An endogenous inhibitory protein that binds competitively to the IL-1 receptor has also been identified.

In addition to pro-inflammatory mediators such as TNF, anti-inflammatory cytokines, e.g. IL-10, are released. When excessive, this anti-inflammatory response is associated with an inappropriate immune hyporesponsiveness.

Products of arachidonic acid metabolism

Arachidonic acid, derived from the breakdown of membrane phospholipid, is metabolized to form prostaglandins and leukotrienes, which are key inflammatory mediators (see Fig. 15.30) and p. 826).

Heat shock proteins (HSPs)

HSPs are synthesized after exposure to various harmful stimuli such as heat, cytokines, hypoxia, endotoxin, various chemicals and oxygen free radicals. They appear to be protective in sepsis, probably because they recognize and form complexes with denatured proteins, thus inducing correct protein folding and, where necessary, proteolytic degradation. They also protect normal, functional proteins against degradation and inhibit apoptosis. HSPs are therefore often referred to as 'molecular chaperones'.

Adhesion molecules

Adhesion of activated leucocytes to the vessel wall and their subsequent extravascular migration is a key component of the sequence of events leading to endothelial injury, tissue damage and organ dysfunction (see also p. 23). This process is mediated by inducible intercellular adhesion molecules (ICAMs) found on the surface of leucocytes and endothelial cells. Expression of these molecules can be induced by endotoxin and pro-inflammatory cytokines. Several families of molecules are involved in promoting leucocyte-endothelial interaction. The selectins are 'capture' molecules and initiate the process of leucocyte rolling on vascular endothelium, while members of the immunoglobulin superfamily (ICAM-1 and vascular cell adhesion molecule-1) are involved in the formation of a more secure bond which leads to leucocyte migration into the tissues (see Fig. 3.13).

Endothelium-derived vasoactive mediators

Endothelial cells synthesize a number of mediators which contribute to the regulation of blood vessel tone and the fluidity of the blood; these include nitric oxide, prostacyclin and endothelin (a potent vasoconstrictor). Nitric oxide (NO) is synthesized from the terminal guanidino-nitrogen atoms of the amino acid L-arginine under the influence of nitric oxide synthase (NOS). NO inhibits platelet aggregation and adhesion and produces vasodilatation by activating guanylate cyclase in the underlying vascular smooth muscle to form cyclic guanosine monophosphate (cGMP) from guanosine triphosphate (GTP) (Fig. 16.18). There are several distinct NOS enzymes.

- **Constitutive or endothelial NOS** (cNOS or eNOS) present in endothelial cells is responsible for the basal release of NO and is involved in the physiological regulation of vascular tone, blood pressure and tissue perfusion.
- **Neuronal NOS** (nNOS). The role of nerves containing nNOS is uncertain but they probably provide neurogenic vasodilator tone. In the central nervous system nNOS may be a regulator of local cerebral blood flow as well as fulfilling a number of other physiological functions,

Figure 16.18 Synthesis and biochemical action of nitric oxide. cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate.

such as the acute modulation of neuronal firing behaviour.

- **Inducible NOS** (iNOS) is induced in vascular endothelial smooth muscle cells and monocytes within 4–18 h of stimulation with endotoxin and certain cytokines, such as TNF. The resulting prolonged increase in NO formation is believed to be a cause of the sustained vasodilatation, hypotension and reduced reactivity to adrenergic agonists ('vasoplegia') that characterizes septic shock. This mechanism is also involved in severe prolonged haemorrhage/traumatic shock. The NO generated by macrophages contributes to their role as highly effective killers of intracellular and extracellular pathogens, in part as a consequence of its ability to bind to cytochrome oxidase and inhibit electron transport, but also via the production of the highly reactive radical peroxynitrite.

Redox imbalance

In health, the balance between reducing and oxidizing conditions (redox) is controlled by antioxidants which either prevent radical formation (e.g. transferrin and lactoferrin which bind iron, a catalyst for radical formation) or remove/inactivate reactive oxygen and nitrogen species (e.g. enzymes such as superoxide dismutases, vitamins C and E and sulphhydryl group donors such as glutathione). There are also mechanisms to remove and repair oxidatively damaged molecules and in particular to preserve DNA integrity. In severe systemic inflammation the uncontrolled production of oxygen-derived free radicals and reactive nitrogen species, e.g. superoxide ($O_2^{\bullet-}$), hydroxyl radicals (OH^{\bullet}), hydrogen peroxide (H_2O_2) and peroxynitrite ($ONOO^-$), particularly by activated polymorphonuclear leucocytes, can overwhelm these defensive mechanisms and cause:

- lipid and protein peroxidation
- damage to cell membranes
- increased capillary permeability
- impaired mitochondrial respiration
- DNA strand breakage
- apoptosis (see p. 32) (which may contribute to the organ damage and immune hyporesponsiveness associated with sepsis).

Influence of genetic variation

Individuals vary considerably in their susceptibility to infection, as well as their ability to recover from apparently similar infections, illnesses or traumatic insults. There is evidence to

Figure 16.19 Still side-stream dark field (SDF) image of the microcirculation in (a) a normal subject and (b) septic shock.

suggest that interindividual variations in susceptibility to, and outcome from, sepsis can be partly explained by genetic variation.

Haemodynamic and microcirculatory changes

The dominant haemodynamic feature of severe sepsis/septic shock is peripheral vascular failure with:

- vasodilatation
- maldistribution of regional blood flow
- abnormalities in the microcirculation (Fig. 16.19):
 - 'stop-flow' capillaries (flow is intermittent)
 - 'no-flow' capillaries (capillaries are obstructed)
 - failure of capillary recruitment
 - increased capillary permeability with interstitial oedema.

Although these *vascular and microvascular abnormalities* may partly account for the reduced oxygen extraction often seen in septic shock, there is also a *primary defect of cellular oxygen utilization* caused by mitochondrial dysfunction (see above). Initially, before hypovolaemia supervenes, or when therapeutic replacement of the circulating volume has been adequate, *cardiac output is usually high and peripheral resistance is low*. These changes may be associated with impaired oxygen consumption, a reduced arteriovenous oxygen content difference, an increased S_aO_2 and a lactic acidosis (so-called '*tissue dysoxia*'). Vasodilatation and increased vascular permeability also occur in anaphylactic shock.

In the initial stages of other forms of shock, and sometimes when hypovolaemia and myocardial depression supervene in sepsis and anaphylaxis, cardiac output is low and increased sympathetic activity causes vasoconstriction. This helps to maintain the systemic blood pressure.

Activation of the coagulation system

The inflammatory response to shock, tissue injury and infection is frequently associated with systemic activation of the clotting cascade, leading to platelet aggregation, widespread microvascular thrombosis and inadequate tissue perfusion.

Initially the production of PGI_2 by the capillary endothelium is impaired. Cell damage (e.g. to the vascular endothelium) leads to exposure to tissue factor (p. 416), which triggers coagulation. In severe cases these changes are compounded by elevated levels of plasminogen activation inhibitor type 1, which impairs fibrinolysis, as well as by deficiencies in physiological inhibitors of coagulation (including antithrombin, proteins C and S and tissue factor-pathway inhibitor). Anti-thrombin and protein C have a number of anti-inflammatory properties, whereas thrombin is pro-inflammatory.

Plasminogen is converted to plasmin, which breaks down thrombus, liberating fibrin/fibrinogen degradation products

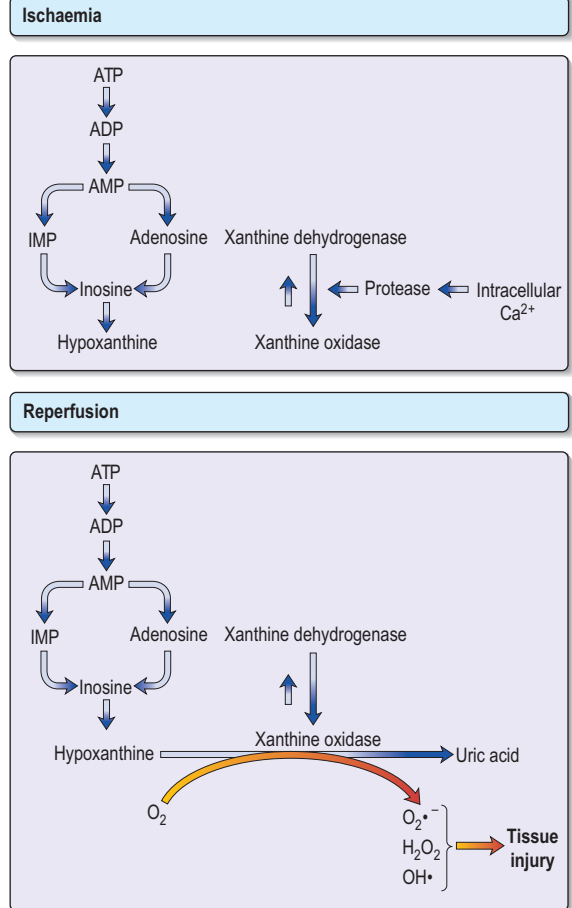

Figure 16.20 Generation of reactive oxygen species following ischaemia and reperfusion. ATP, ADP, AMP, adenosyl tri-, di- and monophosphate, respectively. IMP, inositol monophosphate.

(FDPs). In some cases there is increased fibrinolysis. Circulating levels of FDPs are therefore increased, the thrombin time, PTT and PT are prolonged and platelet and fibrinogen levels fall. Activation of the coagulation cascade can be confirmed by demonstrating increased plasma levels of D-dimers. The development of *disseminated intravascular coagulation (DIC)* often heralds the onset of multiple organ failure. Because clotting factors and platelets are consumed in DIC, they are unavailable for haemostasis elsewhere and a coagulation defect results – hence the alternative name for DIC is '*consumption coagulopathy*'. DIC presents with microvascular bleeding or generalized 'oozing' of blood, e.g. from surgical or traumatic wounds and skin puncture sites. In some cases, a microangiopathic haemolytic anaemia develops. DIC is relatively uncommon but is particularly associated with septic shock, especially when due to meningococcal infection (see p. 127). Management of the *underlying cause* is most urgent. Supportive treatment may include infusions of fresh frozen plasma, platelets, cryoprecipitate when fibrinogen levels are low and occasionally factor VIII concentrates.

Reperfusion injury

Restoration of flow to previously hypoxic tissues can exacerbate cell damage through the generation of large quantities of reactive oxygen species and activation of polymorphonuclear leucocytes (see above) (Fig. 16.20). The gut mucosa seems to be especially vulnerable to this 'ischaemia-reperfusion injury'.

Metabolic response to trauma, major surgery and severe infection

This is initiated and controlled by the neuroendocrine system and various cytokines (e.g. IL-6) acting in concert, and is characterized initially by an increase in energy expenditure ('hypermetabolism') (see also p. 201). Gluconeogenesis is stimulated by increased glucagon and catecholamine levels, while hepatic mobilization of glucose from glycogen is increased. Catecholamines inhibit insulin release and reduce peripheral glucose uptake. Combined with elevated circulating levels of other insulin antagonists such as cortisol, and downregulation of insulin receptors, these changes mean that the majority of patients are hyperglycaemic ('insulin resistance'). Later hypoglycaemia may be precipitated by depletion of hepatic glycogen stores and inhibition of gluconeogenesis. Free fatty acid synthesis is also increased, leading to hypertriglyceridaemia.

Protein breakdown is initiated to provide energy from amino acids, and hepatic protein synthesis is preferentially augmented to produce the 'acute phase reactants'. The amino acid glutamine (which is indispensable in this situation) is mobilized from muscle for use as a metabolic fuel in rapidly dividing cells such as leucocytes and enterocytes. Glutamine is also required for hepatic production of the free radical scavenger glutathione. When severe and prolonged, this catabolic response can lead to considerable weight loss. Protein breakdown is associated with wasting and weakness of skeletal and respiratory muscle, prolonging the need for mechanical ventilation and delaying mobilization. Tissue repair, wound healing and immune function also are compromised.

Clinical features of shock and sepsis

Although many clinical features are common to all types of shock, there are certain aspects in which they differ (Box 16.2).

Hypovolaemic shock

- **Inadequate tissue perfusion:**
 - a. Skin: cold, pale, slate-grey, slow capillary refill, 'clammy'
 - b. Kidneys: oliguria, anuria
 - c. Brain: drowsiness, confusion and irritability.
 - **Increased sympathetic tone:**
 - a. Tachycardia, narrowed pulse pressure, 'weak' or 'thready' pulse
 - b. Sweating
 - c. Blood pressure: may be maintained initially (despite up to a 25% reduction in circulating volume if the patient is young and fit), but later hypotension supervenes.
 - **Metabolic acidosis:** compensatory tachypnoea.
- Extreme hypovolaemia may be associated with bradycardia.

Additional clinical features may occur in the following types of shock.

Cardiogenic shock (see p. 722)

Signs of myocardial failure, e.g. raised jugular venous pressure (JVP), pulsus alternans, 'gallop' rhythm, basal crackles, pulmonary oedema.

Obstructive shock

- Elevated JVP
- Pulsus paradoxus and muffled heart sounds in cardiac tamponade
- Signs of pulmonary embolism (see p. 764).

Box 16.2 Haemodynamic changes in shock

Hypovolaemic shock

Low central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP)
Low cardiac output
Increased systemic vascular resistance

Cardiogenic shock

Signs of myocardial failure
Increased systemic vascular resistance
CVP and PAOP high (except when hypovolaemic)

Cardiac tamponade

Parallel increases in CVP and PAOP
Low cardiac output
Increased systemic vascular resistance

Pulmonary embolism

Low cardiac output
High CVP, high pulmonary artery pressure but low PAOP
Increased systemic vascular resistance

Anaphylaxis

Low systemic vascular resistance
Low CVP and PAOP
High cardiac output

Septic shock

Low systemic vascular resistance
Low CVP and PAOP
Cardiac output usually high
Myocardial depression – low ejection fraction
Stroke volume maintained by ventricular dilatation
Cardiac output maintained or increased by tachycardia

Anaphylactic shock (see p. 69)

- Signs of profound vasodilatation:
 - a. Warm peripheries
 - b. Low blood pressure
 - c. Tachycardia
- Erythema, urticaria, angio-oedema, pallor, cyanosis
- Bronchospasm, rhinitis
- Oedema of the face, pharynx and larynx
- Pulmonary oedema
- Hypovolaemia due to vascular leak
- Nausea, vomiting, abdominal cramps, diarrhoea.

Ideally, 10 mL of clotted blood should be taken within 45–60 minutes after the reaction for confirmation of the diagnosis, e.g. by measurement of mast cell tryptase. Serum should be separated and stored at –20°C. Follow-up of these patients is essential.

Sepsis, severe sepsis and septic shock

- Pyrexia and rigors, or hypothermia (unusual)
- Nausea, vomiting
- Vasodilatation, warm peripheries
- Bounding pulse
- Rapid capillary refill
- Hypotension (septic shock)
- Occasionally signs of cutaneous vasoconstriction
- Other signs:
 - a. Jaundice
 - b. Coma, stupor
 - c. Bleeding due to coagulopathy (e.g. from vascular puncture sites, GI tract and surgical wounds)
 - d. Rash and meningism
 - e. Hyper-, and in more severe cases hypoglycaemia.

Box 16.3 Terminology used in systemic inflammation and sepsis

Infection

Invasion of normally sterile host tissue by microorganisms

Bacteraemia

Viable bacteria in blood

Systemic inflammatory response syndrome (SIRS)

The systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following:

- Temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$
- Heart rate >90 beats/min
- Respiratory rate >20 breaths/min or $P_{\text{a}}\text{CO}_2 <4.3$ kPa
- White cell count $>12 \times 10^9/\text{L}$, $<4 \times 10^9/\text{L}$ or $>10\%$ immature forms.

Sepsis

SIRS resulting from documented infection.

Severe sepsis

Sepsis associated with organ dysfunction, hypoperfusion or hypotension. Hypoperfusion and perfusion abnormalities include, but are not limited to, lactic acidosis, oliguria or an acute alteration in mental state.

Septic shock

Severe sepsis with hypotension (systolic BP <90 mmHg or a reduction of >40 mmHg from baseline) in the absence of other causes for hypotension and despite adequate fluid resuscitation.

(Patients receiving inotropic or vasopressor agents may not be hypotensive when perfusion abnormalities are documented.)

Refractory shock

Shock unresponsive to conventional therapy (intravenous fluids and inotropic/vasoactive agents) within 1 h.

Compensatory anti-inflammatory response syndrome (CARS)

Release of anti-inflammatory mediators which downregulate the inflammatory response. If excessive, may lead to inappropriate immune hyporesponsiveness.

The diagnosis of sepsis is easily missed, particularly in the elderly when the classical signs may not be present. Mild confusion, tachycardia and tachypnoea may be the only clues, sometimes associated with unexplained hypotension, a reduction in urine output, a rising plasma creatinine and glucose intolerance.

The clinical signs of sepsis (triggered by PAMPS) are not always associated with bacteraemia and can occur with non-infectious processes such as pancreatitis, cardiopulmonary bypass or severe trauma (triggered by DAMPS). The term 'systemic inflammatory response syndrome' (SIRS) describes the disseminated inflammation that can complicate this diverse range of disorders (Box 16.3). Patterns of systemic inflammatory response are shown in Figure 16.21, which illustrates the pro-inflammatory response (SIRS) and the counter-regulatory anti-inflammatory response syndrome (CARS).

Sepsis and multiple organ failure (MOF) (also known as multiple organ dysfunction syndrome, MODS)

Sepsis is being diagnosed with increasing frequency and is now the commonest cause of death in non-coronary adult intensive care units. The estimated incidence of severe

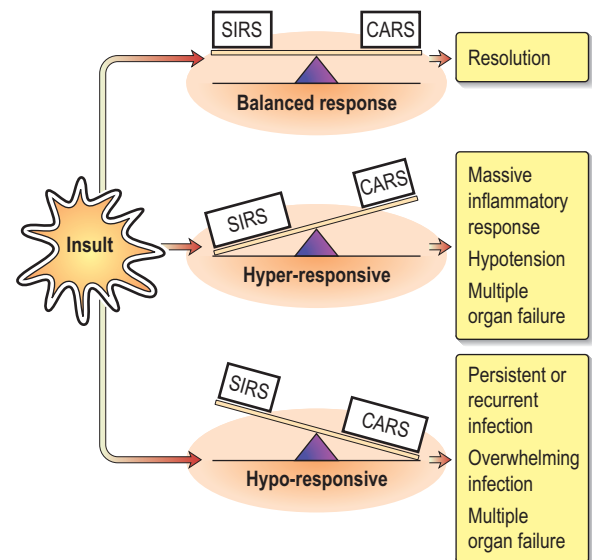

Figure 16.21 Patterns of systemic inflammatory response. CARS, compensatory anti-inflammatory response syndrome; SIRS, systemic inflammatory response syndrome. (From Hinds CJ, Watson JD. *Intensive Care: A Concise Textbook*, 3rd edn. Edinburgh: Saunders; 2008, with permission.)

Figure 16.22 Bilateral pneumococcal pneumonia. Community acquired pneumonia is the commonest cause of sepsis requiring admission to intensive care. (From Hinds CJ, Watson JD. *Intensive Care: A Concise Textbook*, 3rd edn. Edinburgh: Saunders; 2008. Courtesy of Dr SPG Padley.)

sepsis has varied from 77 to 300 cases per 100 000 of the population. Mortality rates are high (between 20% and 60%) and are closely related to the severity of illness and the number of organs that fail. Those who die are overwhelmed by persistent or recurrent sepsis, with fever, intractable hypotension and failure of several organs (Fig. 16.22).

Sequential failure of vital organs occurs progressively over weeks, although the pattern of organ dysfunction is variable. In most cases the lungs are the first to be affected (acute lung injury, ALI; acute respiratory distress syndrome, ARDS; see below) in association with cardiovascular instability and deteriorating renal function. Damage to the mucosal lining of the gastrointestinal tract, as a result of reduced splanchnic flow followed by reperfusion, allows bacteria within the gut lumen, or their cell wall components, to gain access to the circulation. The liver defences, which are often compromised by poor perfusion, are overwhelmed and the lungs and other organs

are exposed to bacterial toxins and inflammatory mediators released by liver macrophages. Some have therefore called the gut the 'motor of multiple organ failure'. Secondary pulmonary infection, complicating ALI/ARDS, also frequently acts as a further stimulus to the inflammatory response. Later, kidney injury and liver dysfunction develop (see p. 884). Gastrointestinal failure, with an inability to tolerate enteral feeding and paralytic ileus, is common. Ischaemic colitis, acalculous cholecystitis, pancreatitis and gastrointestinal haemorrhage may also occur. Features of central nervous system dysfunction include impaired consciousness and disorientation, progressing to coma. Characteristically, these patients initially have a hyperdynamic circulation with vasodilatation and a high cardiac output, associated with an increased metabolic rate. Eventually, however, cardiovascular collapse supervenes. It is now often possible to support such patients for weeks or months; many now die following a decision to withdraw or not to escalate treatment (see p. 897).

ACUTE LUNG INJURY/ACUTE RESPIRATORY DISTRESS SYNDROME

Definition and causes (Table 16.4)

Acute lung injury (ALI) and the more severe acute respiratory distress syndrome (ARDS) are diagnosed in an appropriate clinical setting with one or more recognized risk factors. ALI/ARDS can be defined as follows:

- Respiratory distress
- Stiff lungs (reduced pulmonary compliance resulting in high inflation pressures)
- Chest radiograph: new bilateral, diffuse, patchy or homogeneous pulmonary infiltrates
- Cardiac: no apparent cardiogenic cause of pulmonary oedema (pulmonary artery occlusion pressure <18 mmHg if measured or no clinical evidence of left atrial hypertension)
- Gas exchange abnormalities: ALI – arterial oxygen tension/fractional inspired oxygen (P_aO_2/F_iO_2) ratio <40 kPa (<300 mmHg); ARDS – P_aO_2/F_iO_2 <26.6 kPa (<200 mmHg) (in both cases, despite normal arterial carbon dioxide tension and regardless of positive end-expiratory pressure). *The criterion for arterial oxygen*

tension/fractional inspired oxygen is arbitrary and the value of differentiating ALI from ARDS has been questioned.

ALI/ARDS can occur as a nonspecific reaction of the lungs to a wide variety of direct pulmonary and indirect non-pulmonary insults. By far the commonest predisposing factor is sepsis, and 20–40% of patients with severe sepsis will develop ALI/ARDS (Table 16.4).

Pathogenesis and pathophysiology of ALI/ARDS

Acute lung injury can be viewed as an early manifestation of a generalized inflammatory response with endothelial dysfunction and is therefore frequently associated with the development of multiple organ dysfunction syndrome (MODS) (see p. 882).

Non-cardiogenic pulmonary oedema

This is the cardinal feature of ALI and is the first and clinically most evident sign of a generalized increase in vascular permeability caused by the microcirculatory changes and release of inflammatory mediators described previously (see p. 877), with activated neutrophils playing a particularly key role. The pulmonary epithelium is also damaged in the early stages, reducing surfactant production and lowering the threshold for alveolar flooding.

Pulmonary hypertension

Pulmonary hypertension sometimes complicated by right ventricular failure (p. 762) is a common feature of ALI/ARDS. Initially, mechanical obstruction of the pulmonary circulation may occur as a result of vascular compression by interstitial oedema, while local activation of the coagulation cascade leads to thrombosis and obstruction in the pulmonary microvasculature. Later, pulmonary vasoconstriction may develop in response to increased autonomic nervous activity and circulating substances such as catecholamines, serotonin, thromboxane and complement. Those vessels supplying alveoli with low oxygen tensions constrict (the 'hypoxic vasoconstrictor response'), diverting pulmonary blood flow to better oxygenated areas of lung, thus limiting the degree of shunt.

Haemorrhagic intra-alveolar exudate

This exudate is rich in platelets, fibrin, fibrinogen and clotting factors and may inactivate surfactant and stimulate inflammation, as well as promoting hyaline membrane formation and the migration of fibroblasts into the air spaces.

Resolution, fibrosis and repair

Within days of the onset of lung injury, formation of a new epithelial lining is underway and activated fibroblasts accumulate in the interstitial spaces. Subsequently, interstitial fibrosis progresses, with loss of elastic tissue and obliteration of the lung vasculature, together with lung destruction and emphysema. In those who recover, the lungs are substantially remodelled.

Physiological changes

Shunt and deadspace increase, compliance falls, and there is evidence of airflow limitation. Although the lungs in ALI and ARDS are diffusely injured, the pulmonary lesions, when identified as densities on a CT scan, are predominantly located in dependent regions (Fig. 16.23). This is partly explained by the effects of gravity on the distribution of extravascular lung water and areas of lung collapse. Pleural effusions are common.

Table 16.4 Disorders associated with acute respiratory distress syndrome

Direct lung injury	Indirect lung injury
Common causes	
Pneumonia	Sepsis
Aspiration of gastric contents	Severe trauma with shock and multiple transfusions
Less common causes	
Pulmonary contusion	Cardiopulmonary bypass
Blast injury	Drug overdose (heroin, barbiturates)
Fat embolism	Acute pancreatitis
Near-drowning	Transfusion-associated lung injury
Inhalational injury (smoke or corrosive gases)	Eclampsia
Reperfusion lung injury after lung transplantation or pulmonary embolectomy	High altitude
Amniotic fluid embolism	

Figure 16.23 Acute respiratory distress syndrome.

(a) Lung computed tomography scan showing ground-glass opacification in non-dependent regions with atelectasis and consolidation in dependent regions. There are small pleural effusions.

(b) Same patient as shown in (a) using soft-tissue window settings to demonstrate small bilateral effusions layering in the dependent region of both hemithoraces. Figure 16.24 Chest radiograph appearances in acute respiratory distress syndrome. Bilateral diffuse alveolar shadowing with air bronchograms and no cardiac enlargement.

Clinical presentation of ALI/ARDS

The first sign of the development of ALI/ARDS is often an unexplained tachypnoea, followed by increasing hypoxaemia, with central cyanosis, and breathlessness. Fine crackles are heard throughout both lung fields. Later, the chest X-ray shows bilateral diffuse shadowing, interstitial at first, but subsequently with an alveolar pattern and air bronchograms (Fig. 16.24). The differential diagnosis includes cardiac failure and lung fibrosis.

Management of ALI/ARDS

This is based on treatment of the underlying condition (e.g. eradication of sepsis), supportive measures and avoidance of complications such as ventilator-associated pneumonia.

Mechanical ventilation

Strategies designed to minimize ventilator-associated lung injury and encourage lung healing should be used (see p. 895).

Pulmonary oedema limitation. Pulmonary oedema formation should be limited by minimizing left ventricular filling pressure with fluid restriction, the use of diuretics and, if these measures fail, preventing fluid overload by haemofiltration. The aim should be to achieve a consistently negative

fluid balance. Cardiovascular support and the reduction of oxygen requirements are also necessary.

Prone position. When the patient is changed from the supine to the prone position, lung densities in the dependent region are redistributed and shunt fraction is reduced. More uniform alveolar ventilation, caudal movement of the diaphragm, redistribution of perfusion and recruitment of collapsed alveoli all contribute to the improvement in gas exchange. Body position changes can be achieved with minimal complications despite the presence of multiple indwelling vascular lines. Repeated position changes between prone and supine allow reductions in airway pressures and the inspired oxygen fraction. The response to prone positioning is, however, variable and it seems that this strategy does not improve overall outcome (and perhaps therefore should be reserved for those with severe refractory hypoxaemia).

Inhaled nitric oxide. This vasodilator, when inhaled, may improve \dot{V}/\dot{Q} matching by increasing perfusion of ventilated lung units, as well as reducing pulmonary hypertension. It has been shown to improve oxygenation in so-called 'responders' with ALI/ARDS but has not been shown to increase survival. Its administration requires specialized monitoring equipment, as products of its combination with oxygen include toxic nitrogen dioxide.

Aerosolized prostacyclin. This appears to have similar effects to inhaled NO and is easier to monitor and deliver. As with inhaled NO, the response to aerosolized prostacyclin is, however, variable and although it has been shown to improve oxygenation its effect on outcome has yet to be established.

Aerosolized surfactant. Surfactant replacement therapy reduces morbidity and mortality in neonatal respiratory distress syndrome and is beneficial in animal models of ALI/ARDS. In adults with ARDS, however, the value of surfactant administration remains uncertain.

Steroids. Administration of steroids to patients with persistent ALI/ARDS does not appear to improve outcome.

Prognosis

Mortality from ALI/ARDS has fallen over the last decade, from around 60% to between 30% and 40%, perhaps as a consequence of improved general care, the increasing use of management protocols, and attention to infection control and nutrition, as well as the introduction of novel treatments and lung-protective strategies for respiratory support. Prognosis is, however, still very dependent on aetiology. When ARDS occurs in association with intra-abdominal sepsis, mortality rates remain very high, whereas much lower mortality rates are to be expected in those with 'primary' ARDS (pneumonia, aspiration, lung contusion). Mortality rises with increasing age and failure of other organs. Most of those dying with ARDS do so as a result of MODS and haemodynamic instability rather than impaired gas exchange.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) is a common and serious complication of critical illness which adversely affects the prognosis. A modification of the RIFLE classification has been proposed and covers the spectrum of severity and consequences of acute kidney injury (see Ch. 12; Box 12.5).

The importance of preventing renal injury by rapid and effective resuscitation, as well as the avoidance of nephrotoxic drugs (especially NSAIDs), and control of infection cannot be overemphasized. Shock and sepsis are the most

common causes of AKI in the critically ill, but diagnosis of the cause of renal dysfunction is necessary to exclude reversible pathology, especially obstruction (see Ch. 12).

Oliguria is usually the first indication of renal impairment and immediate attempts should be made to optimize cardiovascular function, particularly by expanding the circulating volume and restoring blood pressure. Restoration of the urine output is a good indicator of successful resuscitation. Evidence now suggests that dopamine is not an effective means of preventing or reversing renal impairment and this agent should not be used for renal protection in sepsis (p. 888). If these measures fail to reverse oliguria, administration of diuretics such as furosemide by bolus or infusion, or less often mannitol (for example in rhabdomyolysis) may be indicated (see Ch. 12). If oliguria persists, it is necessary to reduce fluid intake and review drug doses.

Intermittent haemodialysis has a number of theoretical disadvantages in the critically ill. In particular, it is frequently complicated by hypotension and it may be difficult to remove sufficient volumes of fluid. Nevertheless, provided that strict guidelines are used to improve tolerance and metabolic control, almost all patients with acute kidney injury can be managed successfully with daily haemodialysis. The use of continuous veno-venous haemofiltration, often with dialysis (CVVHD), is however generally preferred in the critically ill (see Ch. 12) and is indicated for fluid overload, electrolyte disturbances (especially hyperkalaemia), severe acidosis and, less often uraemia. The intensity of renal replacement therapy does not seem to influence outcome. Peritoneal dialysis is unsatisfactory in critically ill patients and is contraindicated in those who have undergone intra-abdominal surgery.

If the underlying problems resolve, renal function almost invariably recovers a few days to several weeks later.

MANAGEMENT OF SHOCK AND SEPSIS (Fig. 16.25)

Delays in making the diagnosis and in initiating treatment (especially antibiotics), as well as inadequate resuscitation, are associated with increased morbidity and mortality and should be avoided.

A patent airway must be maintained and oxygen must be given. If necessary, an oropharyngeal airway or an endotracheal tube is inserted. The latter has the advantage of preventing aspiration of gastric contents. Very rarely, emergency tracheostomy is indicated (see below). Some patients may require immediate mechanical ventilation.

The underlying cause of shock should be corrected, e.g. haemorrhage should be controlled or infection eradicated. In patients with septic shock, every effort must be made to identify the source of infection and isolate the causative organism. As well as a thorough history and clinical examination, X-rays, ultrasonography or CT scanning may be required to locate the origin of the infection. Appropriate samples (urine, sputum, cerebrospinal fluid, pus drained from abscesses) should be sent to the laboratory for microscopy, culture and sensitivities. Several blood cultures should be performed and empirical, broad-spectrum antibiotic therapy (p. 85) should be commenced *within the first hour* of recognition of sepsis. If an organism is isolated later, therapy can be adjusted appropriately. The choice of antibiotic depends on the likely source of infection, previous antibiotic therapy and known local resistance patterns, as well as on whether infection was acquired in hospital or in the community. Abscesses must be drained and infected indwelling catheters removed.

Whatever the aetiology of the haemodynamic abnormality, tissue blood flow must be restored by achieving and maintaining an adequate cardiac output, as well as ensuring that arterial blood pressure is sufficient to maintain perfusion of vital organs. Published guidelines for adult patients suffering severe sepsis or septic shock advocate targeting an MAP >65 mmHg, CVP 8–12 mmHg (>12 mmHg if mechanically ventilated), urine output >0.5 mL/kg per hour and an $S_{v}O_2 \geq 70\%$ (or $S_{v}O_2 \geq 65\%$) as the initial goals of resuscitation. Administration of fluids can also be targeted at abolishing arterial pressure variation and/or optimizing stroke volume.

Preload and volume replacement

Optimizing preload is the most efficient way of increasing cardiac output. Volume replacement is obviously essential in hypovolaemic shock but is also required in anaphylactic and septic shock because of vasodilatation, sequestration of blood and loss of circulating volume because of vascular leak.

In obstructive shock, high filling pressures may be required to maintain an adequate stroke volume. Even in cardiogenic shock, careful volume expansion may, on occasions, lead to a useful increase in cardiac output. On the other hand, patients with severe cardiac failure, in whom ventricular filling pressures are markedly elevated, often benefit from measures to reduce preload (and afterload) – such as the administration of vasodilators and diuretics (see below). Adequate perioperative volume replacement also reduces morbidity and mortality in high-risk surgical patients.

The circulating volume must be replaced quickly (in minutes not hours) to reduce tissue damage and prevent acute kidney injury. Fluid is administered via wide-bore intravenous cannulae to allow large volumes to be given quickly, and the effect is continuously monitored.

You must prevent volume overload, which leads to cardiac dilatation, a reduction in stroke volume, and a rise in left atrial pressure with a risk of pulmonary oedema. Pulmonary oedema is more likely in seriously ill patients because of a low colloid osmotic pressure (usually due to a low serum albumin) and disruption of the alveolar–capillary membrane (e.g. in acute lung injury).

Choice of fluid for volume replacement

Blood

This is conventionally given for haemorrhagic shock as soon as it is available. In extreme emergencies, group-specific crossmatch can be performed in minutes (see p. 408). When available and not contraindicated, blood salvage should be employed for those with severe on-going bleeding.

Although red cell transfusion will augment oxygen-carrying capacity, and hence global oxygen delivery, tissue oxygenation is also dependent on microcirculatory flow. This is influenced by the viscosity of the blood and hence the packed cell volume (PCV). Conventionally, a PCV of 30–35% has been considered to provide the optimal balance between oxygen-carrying capacity and tissue flow, although it is well recognized that previously fit people with haemorrhagic shock can tolerate extremely low Hb concentrations, provided their circulating volume and cardiac output are maintained. Transfusion of old stored red cells, which become spherical rather than biconcave and poorly deformable, with increased adhesiveness, can compromise microvascular flow and worsen tissue hypoxia. Whole blood has now been largely replaced by red cell concentrates (see p. 412).

Massive blood transfusion can be defined as a volume of >8–10 units of red cells transfused within a 24-hour period,

and massive haemorrhage as a loss of 50% of blood volume within 3 hours or a rate of blood loss exceeding 150 mL/min.

Complications of blood transfusion are discussed on page 408.

Special problems arise as a result of massive transfusion:

- **Temperature changes.** Bank blood is stored at 4°C; transfusion may result in hypothermia, peripheral vasoconstriction (which slows the rate of the infusion) and arrhythmias. If possible, blood should be warmed during massive transfusion and in those at risk of hypothermia (e.g. during prolonged major surgery with open body cavity).

- **Coagulopathy.** Stored blood has virtually no effective platelets or clotting factors. Massive transfusions that often include large volumes of colloid/crystalloid can therefore be associated with a coagulopathy. This often needs to be treated by replacing clotting factors with fresh frozen plasma and administering platelet concentrates. Occasionally cryoprecipitate is required. There is some evidence that a higher ratio of FFP to blood transfused is associated with improved survival, especially in the military trauma setting. Recombinant factor VIIa may occasionally be indicated in those with uncontrollable bleeding, although the safety of this product has been questioned. Prothrombin complex concentrates have some advantages compared with

FFP, in that they do not need to be crossmatched or thawed.

- **Hypocalcaemia.** Citrate in stored blood binds calcium ions. During rapid transfusion total body ionized calcium levels may be reduced, causing myocardial depression and exacerbating coagulation defects. This is uncommon in practice but can be corrected by administering 10 mL of 10% calcium chloride intravenously. Routine treatment with calcium is not recommended.
- **Increased oxygen affinity.** In stored blood, the red cell 2,3-disphosphoglycerate (2,3-DPG) content is reduced, so that the oxyhaemoglobin dissociation curve is shifted to the left. The oxygen affinity of haemoglobin is therefore increased and oxygen unloading is impaired. Red cell levels of 2,3-DPG are substantially restored within 12 h of transfusion.
- **Hyperkalaemia.** Plasma potassium levels rise progressively as blood is stored. However, hyperkalaemia is rarely a problem as rewarming of the blood increases red cell metabolism – the sodium pump becomes active and potassium levels fall.
- **Microembolism.** Microaggregates in stored blood may be filtered out by the pulmonary capillaries. This process is thought by some to contribute to ALI.

Concern about the supply, cost and safety of blood, including the risk of disease transmission and immune suppression, has encouraged a more conservative approach to transfusion. There is some evidence to suggest that in normovolaemic critically ill patients a restrictive strategy of red cell transfusion (Hb maintained at >70 g/L) is at least as effective, and may be safer than a liberal transfusion strategy (Hb maintained at 100–120 g/L). However, in some groups of patients (e.g. the elderly and those with significant cardiac or respiratory disease and patients who are actively bleeding) it is preferable to maintain Hb closer to the higher level. The use of leucodepleted blood is considered to be safer in terms of disease transmission and immune suppression.

Crystalloids and colloids

The choice of intravenous fluid for resuscitation and the relative merits of crystalloids or colloids has long been controversial. Crystalloid solutions such as Hartmann's solution are cheap, convenient to use and free of side-effects.

It has been generally accepted that volumes of crystalloid several times that of colloid are required to achieve an equivalent haemodynamic response and that colloidal solutions produce a greater and more sustained increase in circulating volume, with associated improvements in cardiovascular function and oxygen transport. This traditional view has been challenged, however, and a large, prospective, randomized, controlled trial has demonstrated that in a heterogeneous group of critically ill patients the use of either physiological saline or 4% albumin for fluid resuscitation resulted in similar outcomes.

Polygelatin solutions have an average molecular weight of 35 000, which is iso-osmotic with plasma. They are cheap and do not interfere with crossmatching. Large volumes can be administered, as clinically significant coagulation defects are unusual and renal function is not impaired. However, because they readily cross the glomerular basement membrane, their half-life in the circulation is only approximately 4 h and they can promote an osmotic diuresis. These solutions are useful during the acute phase of resuscitation, especially when volume losses are continuing. Allergic reactions can, however, occur.

Hydroxyethyl starches (HES). Numerous preparations are now available, characterized by their concentrations (3%, 6%, 10%) and low, medium or high molecular weight. The half-life of high and medium molecular weight solutions is between 12 and 24 h, while that of the low-molecular-weight solutions is 4–6 h. Elimination of HES occurs primarily via the kidneys following hydrolysis by amylase. HES are stored in the reticuloendothelial system, apparently without causing functional impairment, but skin deposits have been associated with persistent pruritus. HES, especially the higher-molecular-weight fractions, have anticoagulant properties and many therefore recommend limiting the volume administered. HES have been implicated in the development of acute kidney injury.

Human albumin solution (HAS) is a natural colloid which has been used for volume replacement in shock and burns, and for the treatment of hypoproteinaemia. HAS is not generally recommended for routine volume replacement, because supplies are limited and other cheaper solutions are equally effective. Some use HAS to expand the circulating volume in patients who are hypoalbuminaemic. There is some suggestion that the administration of HAS may improve outcome from sepsis.

Myocardial contractility and inotropic agents

Myocardial contractility can be impaired by many factors such as hypoxaemia and hypocalcaemia, as well as by some drugs (e.g. beta-blockers, antiarrhythmics and sedatives).

Severe lactic acidosis conventionally is said to depress myocardial contractility and limit the response to vasopressor agents. Attempted correction of acidosis with intravenous sodium bicarbonate, however, generates additional carbon dioxide which diffuses across cell membranes, producing or exacerbating intracellular acidosis. Other disadvantages of bicarbonate therapy include sodium overload and a left shift of the oxyhaemoglobin dissociation curve. Ionized calcium levels may be reduced and, combined with the fall in intracellular pH, this may impair myocardial performance. Treatment of lactic acidosis should therefore concentrate on correcting the cause. Bicarbonate should only be administered to correct *extreme persistent metabolic acidosis* (see Chapter 13).

If the signs of shock persist despite adequate volume replacement, and perfusion of vital organs is jeopardized, pressor agents should be administered to improve cardiac output and blood pressure. Vasopressor therapy may also be required to maintain perfusion in those with life-threatening hypotension, even when volume replacement is incomplete. All inotropes increase myocardial oxygen consumption, particularly if a tachycardia develops, and this can lead to an imbalance between myocardial oxygen supply and demand, with the development or extension of ischaemic areas. Inotropes should therefore be used with especial caution, particularly in cardiogenic shock following myocardial infarction and in those known to have ischaemic heart disease.

Many of the most seriously ill patients become increasingly resistant to the effects of pressor agents, an observation attributed to 'downregulation' of adrenergic receptors and NO-induced 'vasoplegia' (p. 879).

All inotropic agents should be administered via a large central vein, and their effects continually monitored (Table 16.5).

Adrenaline (epinephrine)

Adrenaline stimulates both α - and β -adrenergic receptors, but at low doses, β effects seem to predominate. Heart

Table 16.5 Receptor actions of sympathomimetic and dopaminergic agents

rate and cardiac index increase, while peripheral resistance is reduced. If there is an associated increase in perfusion pressure, urine output may improve. Adrenaline at higher doses can cause excessive (α -mediated) vasoconstriction, with reductions in splanchnic flow, and cardiac output may fall. Prolonged high-dose administration can cause peripheral gangrene and lactic acidosis. The minimum effective dose of adrenaline should therefore be used for as short a time as possible.

Noradrenaline (norepinephrine)

This is predominantly an α -adrenergic agonist. It is particularly useful in those with hypotension associated with a low systemic vascular resistance, e.g. in septic shock. There is a risk of producing excessive vasoconstriction with impaired organ perfusion and increased afterload. Noradrenaline administration should normally therefore be guided by comprehensive haemodynamic monitoring, including invasive or non-invasive determination of cardiac output (see p. 875) and calculation of systemic vascular resistance.

Dopamine

Dopamine is a natural precursor of adrenaline (epinephrine) which acts on β receptors and α receptors, as well as dopaminergic DA₁ and DA₂ receptors.

In **low doses** (e.g. 1–3 $\mu\text{g/kg}$ per min), dopaminergic vasodilatory receptors in the renal, mesenteric, cerebral and coronary circulations are activated. DA₁ receptors are located on postsynaptic membranes and mediate vasodilatation, while DA₂ receptors are presynaptic and potentiate these vasodilatory effects by preventing the release of adrenaline (epinephrine). Renal and hepatic flow increase and urine

output is improved. The significance of the renal vasodilator effect of dopamine has, however, been questioned and it has been suggested that the increased urine output is largely attributable to the rise in cardiac output and blood pressure, combined with a decrease in aldosterone and inhibition of tubular sodium reabsorption mediated via DA₁ stimulation.

In **moderate doses** (e.g. 3–10 $\mu\text{g/kg}$ per min), dopamine increases heart rate, myocardial contractility and cardiac output. In some patients the dose of dopamine is limited by β -receptor effects such as tachycardia and arrhythmias.

In **higher doses** (e.g. >10 $\mu\text{g/kg}$ per min) the increased noradrenaline (norepinephrine) produced is associated with vasoconstriction. This increases afterload and raises ventricular filling pressures.

Dopexamine

Dopexamine is an analogue of dopamine which activates β_2 receptors as well as DA₁ and DA₂ receptors. Dopexamine is a weak positive inotrope, but is a powerful splanchnic vasodilator, reducing afterload and improving blood flow to vital organs, including the kidneys. Dopexamine has been used as an adjunct to the perioperative management of high-risk surgical patients (see below).

Dobutamine

Dobutamine is closely related to dopamine and has predominantly β_1 activity. Dobutamine has no specific effect on the renal vasculature but urine output often increases as cardiac output and blood pressure improve. It reduces systemic vascular resistance, as well as improving cardiac performance, thereby decreasing afterload and ventricular filling pressures. Dobutamine is therefore useful in patients with cardiogenic

shock and cardiac failure. In septic shock, dobutamine can be used to increase cardiac output and oxygen delivery.

Phosphodiesterase inhibitors (e.g. milrinone, enoximone)

These agents have both inotropic and vasodilator properties. Because the phosphodiesterase type III inhibitors bypass the β -adrenergic receptor they do not cause tachycardia and are less arrhythmogenic than β agonists. They are useful in patients with receptor 'downregulation', those receiving beta-blockers, for weaning patients from cardiopulmonary bypass and for patients with cardiac failure. In vasodilated septic patients, however, they can precipitate or worsen hypotension.

Vasopressin

Patients with septic shock have inappropriately low circulating levels of vasopressin. Low-dose vasopressin can increase blood pressure and systemic vascular resistance in patients with vasodilatory septic shock and a high cardiac output unresponsive to other vasopressors ('vasoplegia'). A 2008 randomized controlled trial suggests that low-dose vasopressin added to conventional vasopressors may have some value in less severe septic shock.

Levosimendan

Levosimendan is a myofilament calcium sensitizer and novel inotrope. Unlike other inotropes, levosimendan does not exert its action through increases in intracellular Ca^{2+} and as a result does not impair diastolic relaxation of the heart. Levosimendan binds to troponin C with high affinity but only during systole when the intracellular calcium concentration is high. Levosimendan has phosphodiesterase inhibitor actions but these are not thought to be clinically significant. Significantly, a long-acting metabolite of levosimendan has similar calcium sensitizing actions, maintaining the inotropic effect of levosimendan once an infusion is stopped. Adverse cardiovascular effects of levosimendan include tachycardia and hypotension; as a consequence the addition of a vasopressor may be required.

Guidelines for use of inotropic and vasopressor agents

Some still consider dopamine in low to moderate doses to be the first-line agent for restoring blood pressure, although evidence suggests that dopamine is associated with a greater number of adverse events (especially arrhythmias) than norepinephrine. Certainly high-dose dopamine is best avoided. Dobutamine is particularly indicated in patients in whom the vasoconstriction caused by dopamine could be dangerous (i.e. patients with cardiac disease and septic patients with fluid overload or myocardial failure). The combination of dobutamine and noradrenaline (norepinephrine) is popular for the management of patients who are *shocked with a low systemic vascular resistance* (e.g. septic shock). Dobutamine is given to achieve an optimal cardiac output, while noradrenaline (norepinephrine) is used to restore an adequate blood pressure by reducing vasodilatation. In *vasodilated septic patients* with a high cardiac output, noradrenaline (norepinephrine) can be used alone. At time of writing, there is evidence to suggest that adrenaline (epinephrine) may be equally safe and effective as a dobutamine/noradrenaline combination. Because of its potency, adrenaline is particularly useful in patients with *refractory hypotension*. The role of levosimendan in the management of shock has yet to be established.

Box 16.4 Patients at risk of developing perioperative multiorgan failure

- The elderly
- Patients with co-morbidity, especially limited cardiorespiratory reserve
- Patients with trauma to two body cavities requiring multiple blood transfusions
- Patients undergoing surgery involving extensive tissue dissection, e.g. oesophagectomy, pancreatectomy, aortic aneurysm surgery
- Patients undergoing emergency surgery for intra-abdominal or intrathoracic catastrophic states, e.g. faecal peritonitis, oesophageal perforation.

Modified from Shoemaker WC, Appel PL, Kram HB et al. Prospective trial of supranormal values of survivors as therapeutic goals in high-risk surgical patients. Chest 1988; 94:1176–1186.

Targeting haemodynamics and oxygen transport

Although resuscitation has conventionally aimed at achieving normal haemodynamics, survival of many critically ill patients is associated with raised values for cardiac output, DO_2 and VO_2 . However, elevation of DO_2 and VO_2 to these 'supranormal' levels following admission to intensive care produces no benefit and may be harmful. By contrast, *early* goal-directed therapy to resuscitate patients in the emergency room, aimed at maintaining a central venous oxygen saturation of more than 70%, significantly improves outcome in patients with severe sepsis or septic shock, as does therapy targeted at lactate clearance.

High-risk surgical patients (Box 16.4)

These patients benefit from intensive perioperative monitoring and circulatory support, in particular maintenance of an adequate circulating volume, and postoperative admission to a critical care area. Volume replacement and administration of inotropes or vasopressors should be guided by monitoring of stroke volume/cardiac output, usually using an oesophageal Doppler or pulse contour analysis. The value of the routine use of inodilators such as dopexamine remains unclear.

Vasodilator therapy

In selected cases, afterload reduction is used to increase stroke volume and decrease myocardial oxygen requirements by reducing the systolic ventricular wall tension. Vasodilatation (see p. 720) also decreases heart size and the diastolic ventricular wall tension so that coronary blood flow is improved. The relative magnitude of the falls in preload and afterload depends on the pre-existing haemodynamic disturbance, concurrent volume replacement and the agent selected (see below). Vasodilators also improve microcirculatory flow.

Vasodilator therapy can be particularly helpful in patients with cardiac failure in whom the ventricular function curve is flat (Fig. 16.6) so that falls in preload have only a limited effect on stroke volume. This form of treatment, combined in selected cases with inotropic support, is therefore useful in cardiogenic shock and in the management of patients with cardiogenic pulmonary oedema or mitral regurgitation.

Nitrate vasodilators are usually used. Nitrates, because of their ability to improve the myocardial oxygen supply/demand ratio, also help to control angina and limit ischaemic myocardial injury.

Sodium nitroprusside (SNP) dilates arterioles and venous capacitance vessels, as well as the pulmonary vasculature by donating nitric oxide. SNP therefore reduces the afterload and preload of both ventricles and can improve cardiac output and the myocardial oxygen supply/demand ratio. The effects of SNP are rapid in onset and spontaneously reversible within a few minutes of discontinuing the infusion. A large overdose of SNP can cause cyanide poisoning, with intracellular hypoxia caused by inhibition of cytochrome oxidase, the terminal enzyme of the respiratory chain. This is manifested as a metabolic acidosis and a fall in the arteriovenous oxygen content difference.

Nitroglycerine (NTG). At low doses, NTG is predominantly a venodilator, but as the dose is increased, it also causes arterial dilatation, thereby decreasing both preload and afterload. Nitrates are particularly useful in the treatment of cardiac failure with pulmonary oedema and are usually used in combination with intravenous furosemide. NTG reduces pulmonary vascular resistance, an effect that can be exploited in patients with a low cardiac output secondary to pulmonary hypertension.

Mechanical support of the myocardium

Intra-aortic balloon counterpulsation (IABCP) is the technique used most widely for mechanical support of the failing myocardium. It is discussed on [page 696](#).

Adjunctive treatment

Initial attempts to combat the high mortality associated with sepsis concentrated on cardiovascular and respiratory support in the hope that survival could be prolonged until surgery, antibiotics and the patient's own defences had eradicated the infection and injured tissues were repaired. Despite some success, mortality rates remained unacceptably high. So far, attempts to improve outcome by modulating the inflammatory response (including high-dose steroids) or neutralizing endotoxin ([Table 16.6](#)) have proved disappointing and in some cases may even have been harmful.

The administration of relatively low, 'stress' doses of hydrocortisone to patients with refractory vasopressor-resistant septic shock may assist shock reversal and perhaps improve outcome. Careful control of the blood sugar level to between 8 and 10 mmol/L is also recommended.

The aim of current sepsis guidelines is to combine these, and other evidence-based interventions, with early effective resuscitation (aimed especially at achieving an adequate circulating volume, combined with the rational use of inotropes and/or vasoactive agents to maintain blood pressure, cardiac output and oxygen transport) in order to create 'bundles of care' delivered within specific time limits (see <http://www.survivingsepsis.org>).

RESPIRATORY FAILURE (see Ch. 15)

Types and causes

The respiratory system consists of a gas-exchanging organ (the lungs) and a ventilatory pump (respiratory muscles/thorax), either or both of which can fail and precipitate respiratory failure. Respiratory failure occurs when pulmonary gas exchange is sufficiently impaired to cause hypoxaemia with or without hypercarbia. In practical terms, respiratory failure is present when the P_aO_2 is <8 kPa (60 mmHg) or the P_aCO_2 is >7 kPa (55 mmHg). It can be divided into:

- Type I respiratory failure, in which the P_aO_2 is low and the P_aCO_2 is normal or low
- Type II respiratory failure, in which the P_aO_2 is low and the P_aCO_2 is high.

Type I or 'acute hypoxaemic' respiratory failure occurs with diseases that damage lung tissue. Hypoxaemia is due to right-to-left shunts or \dot{V}/\dot{Q} mismatch. Common causes include cardiogenic pulmonary oedema, pneumonia, acute lung injury and lung fibrosis.

Type II or 'ventilatory failure' occurs when alveolar ventilation is insufficient to excrete the volume of carbon dioxide being produced by tissue metabolism. Inadequate alveolar ventilation is due to reduced ventilatory effort, inability to overcome an increased resistance to ventilation, failure to compensate for an increase in deadspace and/or carbon dioxide production, or a combination of these factors. The most common cause is chronic obstructive pulmonary disease (COPD). Other causes include chest-wall deformities, respiratory muscle weakness (e.g. Guillain-Barré syndrome) and depression of the respiratory centre (e.g. overdose).

Deterioration in the mechanical properties of the lungs and/or chest wall increases the work of breathing and the oxygen consumption/carbon dioxide production of the respiratory muscles. The concept that respiratory muscle fatigue (either acute or chronic) is a major factor in the pathogenesis of respiratory failure is controversial.

Clinical assessment of respiratory failure

A clinical assessment of respiratory distress should be made on the following criteria (those marked with an asterisk* may be indicative of respiratory muscle fatigue):

- the use of accessory muscles of respiration
- intercostal recession
- tachypnoea*
- tachycardia
- sweating
- pulsus paradoxus (rarely present)
- inability to speak, unwillingness to lie flat
- agitation, restlessness, diminished conscious level
- asynchronous respiration (a discrepancy in the timing of movement of the abdominal and thoracic compartments)*
- paradoxical respiration (abdominal and thoracic compartments move in opposite directions)*
- respiratory alternans (breath-to-breath alteration in the relative contribution of intercostal/accessory muscles and the diaphragm)*.

Blood gas analysis should be performed to guide oxygen therapy and to provide an objective assessment of the severity of the respiratory failure. The *most sensitive clinical*

indicator of increasing respiratory difficulty is a rising respiratory rate. *Measurement of tidal volume* is a less sensitive indicator.

Vital capacity is often a better guide to deterioration and is particularly useful in patients with respiratory inadequacy that is due to neuromuscular problems such as the Guillain-Barré syndrome or myasthenia gravis, in which the vital capacity decreases as weakness increases.

Monitoring of respiratory failure

Pulse oximetry

Lightweight oximeters can be applied to an ear lobe or finger. They measure the changing amount of light transmitted through the pulsating arterial blood and provide a continuous, non-invasive assessment of arterial oxygen saturation (S_pO_2). These devices are reliable, easy to use and do not require calibration, although remember that pulse oximetry is not a sensitive guide to *changes* in oxygenation. An S_pO_2 within normal limits in a patient receiving supplemental oxygen does not exclude the possibility of hypoventilation with carbon dioxide retention. Readings are occasionally inaccurate in those with poor peripheral perfusion.

Blood gas analysis

Normal values of blood gas analysis are shown in Table 16.2.

Errors can result from malfunctioning of the analyser or incorrect sampling of arterial blood. Disposable pre-heparinized syringes are available for blood gas analysis.

- The sample should be analysed immediately. Alternatively, the syringe should be immersed in iced water (the end having first been sealed with a cap) to prevent the continuing metabolism of white cells causing a reduction in PO_2 and a rise in PCO_2 .
- Air almost inevitably enters the sample. The gas tensions within these air bubbles will equilibrate with those in the blood, thereby lowering the PCO_2 and usually raising the PO_2 of the sample. However, provided the bubbles are ejected immediately by inverting the syringe and expelling the air that rises to the top of the sample, their effect is insignificant.

Interpretation of the results of blood gas analysis can be considered in two separate parts:

- Disturbances of acid-base balance (see pp. 638, 876)
- Alterations in oxygenation.

Correct interpretation requires a knowledge of the clinical history, the age of the patient, the inspired oxygen concentration and any other relevant treatment (e.g. the ventilator

settings for those on mechanical ventilation or the administration of sodium bicarbonate). The oxygen content of the arterial blood is determined by the percentage saturation of haemoglobin with oxygen. The relationship between the latter and the P_aO_2 is determined by the oxyhaemoglobin dissociation curve (Fig. 16.2).

Capnography

Continuous breath-by-breath analysis of expired carbon dioxide concentration can be used to:

- confirm tracheal intubation
- continuously monitor end-tidal PCO_2 , which approximates to P_aCO_2 in normal subjects. Continuous capnography is now recommended for all mechanically ventilated patients to detect acute airway problems, e.g. tracheal tube/tracheostomy blocked/dislodged (also essential when transporting critically ill patients)
- detect apparatus malfunction
- detect acute alterations in cardiorespiratory function.

Management of respiratory failure

Standard management of patients with respiratory failure includes:

- administration of supplemental oxygen through a patent airway
- treatment for distal airways obstruction
- measures to limit pulmonary oedema
- control of secretions
- treatment of pulmonary infection.

The load on the respiratory muscles should be reduced by improving lung mechanics. Correction of abnormalities which may lead to respiratory muscle weakness, such as hypophosphataemia and malnutrition, is also necessary.

Oxygen therapy

Methods of oxygen administration

Oxygen is initially given via a facemask. In the majority of patients (except those with COPD and chronically elevated P_aCO_2) the concentration of oxygen given is not vital and oxygen can therefore be given by a 'variable performance' device such as a simple facemask or nasal cannulae (Fig. 16.26).

With these devices, the inspired oxygen concentration varies from about 35% to 55%, with oxygen flow rates of between 6 and 10 L/min. Nasal cannulae are often preferred because they are less claustrophobic and do not interfere with feeding or speaking, but they can cause ulceration of

Figure 16.26 Methods of administering supplemental oxygen to the unintubated patient. (a) Simple facemask. (b) Nasal cannulae. (c) Mask with reservoir bag and non-rebreathing valve.

the nasal or pharyngeal mucosa. Higher concentrations of oxygen can be administered by using a mask with a reservoir bag attached (Fig. 16.26c). Figure 16.26 should be compared with the fixed-performance mask shown in Figure 15.25, with which the oxygen concentration can be controlled. This latter type of mask is used in patients with COPD and chronic type II failure; the hazards of reducing hypoxic drive can be over-emphasized and are less dangerous when the patient is in a critical care unit – *remember*, severe hypoxaemia is more dangerous than hypercapnia.

Oxygen toxicity

Experimentally, mammalian lungs have been shown to be damaged by continuous exposure to high concentrations of oxygen, but oxygen toxicity in humans is less well proven. Nevertheless, it is reasonable to assume that high concentrations of oxygen might damage the lungs, and so the lowest inspired oxygen concentration compatible with adequate arterial oxygenation should be used. Dangerous hypoxia should never be tolerated through a fear of pulmonary oxygen toxicity. There has been concern that in some circumstances (e.g. following myocardial infarction) routine administration of supplemental oxygen may be harmful, perhaps because of associated vasoconstriction.

Respiratory support

If, despite the above measures, the patient continues to deteriorate or fails to improve, the institution of some form of respiratory support is necessary (Table 16.7). Non-invasive ventilation via a mask or hood (see p. 895) can be used, particularly in respiratory failure due to COPD, but in critically ill patients invasive ventilation through an endotracheal tube or tracheostomy is more usual.

Intermittent positive pressure ventilation (IPPV) is achieved by intermittently inflating the lungs with a positive pressure delivered by a mechanical ventilator. Over the last few decades there have been a number of refinements and modifications to the manner in which positive pressure is applied to the airway and in the interplay between the patient's respiratory efforts and mechanical assistance (p. 894).

Controlled mechanical ventilation (CMV), with the abolition of spontaneous breathing, rapidly leads to atrophy of

respiratory muscles so that assisted modes that are triggered by the patient's inspiratory efforts (see below) are preferred.

The rational use of mechanical ventilation depends on a clear understanding of its potential beneficial effects, as well as the dangers.

Beneficial effects of mechanical ventilation

- **Relief from exhaustion.** Mechanical ventilation reduces the work of breathing, 'rests' the respiratory muscles and relieves the extreme exhaustion present in patients with respiratory failure. In some cases, if ventilation is not instituted, this exhaustion may culminate in respiratory arrest.
- **Effects on oxygenation.** Application of positive pressure can prevent or reverse atelectasis. In those with severe pulmonary parenchymal disease, the lungs may be very stiff and the work of breathing is therefore greatly increased. Under these circumstances, the institution of respiratory support significantly reduces total body oxygen consumption; consequently P_iO_2 and thus P_aO_2 may improve. Because ventilated patients are connected to a leak-free circuit, it is possible to administer high concentrations of oxygen (up to 100%) accurately and to apply a positive end-expiratory pressure (PEEP). In selected cases, the latter may reduce shunting and increase P_aO_2 (see below).
- **Improved carbon dioxide elimination.** By increasing the volume of ventilation, the P_aCO_2 can be controlled.

Indications for mechanical ventilation

- **Acute respiratory failure**, with signs of severe respiratory distress (e.g. respiratory rate >40/min, inability to speak, patient exhausted) persisting despite maximal therapy. Confusion, restlessness, agitation, a decreased conscious level, a rising P_aCO_2 (>8 kPa) and extreme hypoxaemia (<8 kPa), despite oxygen therapy, are further indications.
- **Acute ventilatory failure** due, for example, to myasthenia gravis or Guillain-Barré syndrome. Mechanical ventilation should usually be instituted when

Table 16.7 Techniques for respiratory support

CPPV, continuous positive-pressure ventilation; ECMO, extracorporeal membrane oxygenation; ECCO ₂ -R, extracorporeal CO ₂ removal; PEEP, positive end-expiratory pressure.	

the vital capacity has fallen to 10 mL/kg or less. This will avoid complications such as atelectasis and infection as well as preventing respiratory arrest. The tidal volume and respiratory rate are relatively insensitive indicators of respiratory failure in the above conditions and change late in the course of the disease. A high $P_a\text{CO}_2$ (particularly if rising) is an indication for urgent mechanical ventilation.

By no means all patients with respiratory failure and/or a reduced vital capacity require ventilation; clinical assessment of each individual case is essential. The patient's general condition, degree of exhaustion, level of consciousness and ability to protect their airway are often more useful than blood gas values.

Other indications include:

- Postoperative ventilation in high-risk patients
- Head injury: to avoid hypoxia and hypercarbia, which increase cerebral blood flow and intracranial pressure
- Trauma: chest injury and lung contusion
- Severe left ventricular failure with pulmonary oedema
- Coma with breathing difficulties, e.g. following drug overdose.

Institution of invasive respiratory support

This requires tracheal intubation. If the patient is conscious, the procedure must be fully explained and consent obtained before anaesthesia is induced. The complications of tracheal intubation are given in Table 16.8.

Intubating patients in severe respiratory failure is a hazardous undertaking and should only be performed by experienced staff. In extreme emergencies, it may be preferable to ventilate the patient by hand using an oropharyngeal airway and a facemask with added oxygen until experienced help arrives. An alternative is insertion of a laryngeal mask airway.

The patient is usually hypoxic and hypercarbic, with increased sympathetic activity; the stimulus of laryngoscopy and intubation can precipitate dangerous arrhythmias, bradycardia and even cardiac arrest. Except in an extreme emergency, therefore, the ECG and oxygen saturation should be monitored, and the patient preoxygenated with 100% oxygen before intubation. Resuscitation drugs should be immediately available. If time allows, the circulating volume should be optimized and, if necessary, inotropes commenced before attempting intubation. In some cases, it is appropriate to establish intra-arterial and central venous pressure monitoring before instituting mechanical ventilation, although many patients will not tolerate the supine or head-down position. In some deeply comatose patients, no sedation is required, but in the majority of patients, a short-acting intravenous anaesthetic agent, usually with an opiate followed by muscle relaxation will be necessary. When available, capnography must be used to confirm tracheal intubation.

Sedation, analgesia and muscle relaxation

Most critically ill patients will require analgesia and many will receive sedatives. The combination of an opiate with a benzodiazepine or propofol is often used to facilitate mechanical ventilation and to obtund the physiological response to stress. Heavy sedation is indicated in those with severe respiratory failure, especially since 'lung protective' ventilatory strategies (see p. 895) are inherently uncomfortable. A few may require neuromuscular blockade, indeed evidence suggests that early administration of atracurium improves outcomes for mechanically ventilated patients with severe ARDS. It is now recognized, however, that minimizing sedation levels using 'sedation scores' and 'daily awakening', or even the avoidance of sedatives altogether, often in combination with spontaneous breathing modes of respiratory

Table 16.8 Complications of endotracheal intubation

Complication	Comments
Immediate	
Trauma to the upper airway Tube in oesophagus	Lips, teeth, gums, trachea Gives rise to hypoxia and abdominal distension Detected by capnography Requires immediate removal, bag-mask ventilation with oxygen and re-insertion of the tracheal tube
Tube in one or other (usually the right) main bronchus	Avoid by checking both lungs are being inflated, i.e. both sides of the chest move and air entry is heard bilaterally on auscultation Obtain chest X-ray to check position of tube and to exclude lung collapse
Early	
Migration of the tube out of the trachea Leaks around the tube Obstruction of tube because of kinking or secretions	Dangerous complications The patient becomes distressed, cyanosed and has poor chest expansion The following should be performed immediately: Manual inflation with 100% oxygen Tracheal suction Check position of tube Deflate cuff Check tube for 'kinks' or blockage with secretions or blood (common) If no improvement, remove tube, ventilate with facemask and then insert new endotracheal tube
Late	
Sinusitis Mucosal oedema and ulceration Laryngeal injury Tracheal narrowing and fibrosis Tracheomalacia

support (see p. 895) is associated with reductions in the duration of mechanical ventilation and more rapid discharge from the ICU and hospital. It is also now recognized that benzodiazepines predispose to the development of delirium (which is an independent predictor of increased mortality and length of hospital stay) in critically ill patients. The use of dexmedetomidine (an α_2 agonist) rather than a benzodiazepine has been shown to be associated with less delirium and reduced time on the ventilator.

Tracheostomy

Tracheostomy may be required for the long-term control of excessive bronchial secretions, particularly in those with a reduced conscious level, and/or to maintain an airway and protect the lungs in those with impaired pharyngeal and laryngeal reflexes. Tracheostomy is also performed when intubation is likely to be prolonged, for patient comfort, to reduce sedation requirements and to facilitate weaning from mechanical ventilation.

Tracheostomy can be performed in the ICU or in an operating theatre. A percutaneous dilatational approach, which is quick and can be performed at the bedside, is a suitable technique for most critically ill patients (and can be used in an emergency). The alternative surgical approach, opening the trachea vertically through the second, third and fourth tracheal rings via a transverse skin incision, involves transferring the patient to an operating theatre.

A life-threatening obstruction of the upper respiratory tract that cannot be bypassed with an endotracheal tube can be relieved by a *cricothyroidotomy*, which is safer, quicker and easier to perform than a formal tracheostomy.

Tracheostomy has a small but significant mortality rate. Complications of tracheostomy are shown in Table 16.9.

Complications associated with mechanical ventilation

Airway complications. There may be complications associated with tracheal intubation or tracheostomy (see above) (Tables 16.8, 16.9).

Disconnection, failure of gas or power supply, mechanical faults. These are unusual but dangerous. A method of manual ventilation, a facemask and oxygen must always be available by the bedside.

Cardiovascular complications. The application of positive pressure to the lungs and thoracic wall impedes venous return and distends alveoli, thereby 'stretching' the pulmonary capillaries and causing a rise in pulmonary vascular resistance. Both these mechanisms can produce a fall in cardiac output.

Respiratory complications. Mechanical ventilation can be complicated by a deterioration in gas exchange because of \dot{V}/\dot{Q} mismatch, fluid retention and collapse of peripheral alveoli. Traditionally, the latter was prevented by using high tidal volumes (10–12 mL/kg) but high inflation pressures, with overdistension of compliant alveoli, perhaps exacerbated by the repeated opening and closure of distal airways, can disrupt the alveolar–capillary membrane. There is an increase in microvascular permeability and release of inflammatory mediators leading to '*ventilator-associated lung injury*'. Extreme overdistension of the lungs during mechanical ventilation with high tidal volumes and PEEP can rupture alveoli and cause air to dissect centrally along the perivascular sheaths. This '*barotrauma*' may be complicated by pneumomediastinum, subcutaneous emphysema, pneumoperitoneum, pneumothorax, and intra-abdominal air. The risk of pneumothorax is increased in those with destructive lung disease (e.g. necrotizing pneumonia, emphysema), asthma or fractured ribs.

A *tension pneumothorax* can be rapidly fatal in ventilated patients. Suggestive signs include the development or worsening of hypoxia, hypercarbia, respiratory distress, an unexplained increase in airway pressure, as well as hypotension and tachycardia, sometimes accompanied by a rising CVP. Examination may reveal unequal chest expansion, mediastinal shift away from the side of the pneumothorax (deviated trachea, displaced apex beat) and a hyperresonant hemithorax. Although breath sounds are often diminished over the pneumothorax, this sign can be misleading in ventilated patients. If there is time, the diagnosis can be confirmed by chest X-ray prior to definitive treatment with chest tube drainage.

Ventilator-associated pneumonia. Hospital-acquired pneumonia occurs in as many as one-third of patients receiving mechanical ventilation and this is associated with a significant increase in mortality. It can be difficult to diagnose. The measurement of serum procalcitonin, a specific marker of severe bacterial infections, can be helpful. Various organisms can be isolated, such as aerobic Gram-negative bacilli, e.g. *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *E. coli*, *Acinetobacter* spp. and *Staphylococcus aureus*, including MRSA. Leakage of infected oropharyngeal secretions past the tracheal tube cuff is thought to be largely responsible. Bacterial colonization of the oropharynx may be promoted by regurgitation of colonized gastric fluid and the risk of ventilator-associated pneumonia can be reduced by nursing patients in the semi-recumbent, rather than the supine, position and by oropharyngeal decontamination.

Table 16.9 Complications of tracheostomy (As for tracheal intubation, see Table 16.8), plus:

Early

Death
Pneumothorax
Haemorrhage
Hypoxia
Hypotension
Cardiac arrhythmias
Tube misplaced in pretracheal subcutaneous tissues
Subcutaneous emphysema

Intermediate

Mucosal ulceration
Erosion of tracheal cartilages (can cause tracheo-oesophageal fistula)
Erosion of innominate artery (occasionally leads to fatal haemorrhage)
Stomal infection
Pneumonia

Late

Failure of stoma to heal
Tracheal granuloma
Tracheal stenosis at level of stoma, cuff or tube tip
Collapse of tracheal rings at level of stoma
Cosmetic

Techniques for respiratory support (Table 16.7)**Controlled mechanical ventilation (CMV)**

This technique is used in patients in whom respiratory efforts are absent or have been abolished.

Ventilation involves one of two types:

- **Volume controlled ventilation.** The tidal volume and respiratory rate are preset on the ventilator. The airway pressure varies according to both the ventilator setting and the patient's lung mechanics (airways resistance and compliance).

- **Pressure controlled ventilation.** Both the inspiratory pressure and the respiratory rate are preset but the tidal volume varies according to the patient's lung mechanics.

Positive end-expiratory pressure (PEEP)

A positive airway pressure can be maintained at a chosen level throughout expiration by attaching a threshold resistor valve to the expiratory limb of the circuit. PEEP re-expands underventilated lung units, and redistributes lung water from the alveoli to the perivascular interstitial space, thereby reducing shunt and increasing P_{aO_2} . The inevitable rise in mean intrathoracic pressure associated with the application of PEEP may, however, further impede venous return, increase pulmonary vascular resistance and reduce cardiac output. The fall in cardiac output can be ameliorated by expanding the circulating volume, although in some cases inotropic or vasopressor support is required. Thus, although arterial oxygenation is often improved by the application of PEEP, a simultaneous fall in cardiac output can lead to a reduction in total oxygen delivery.

Traditionally, the application of PEEP was only considered if it proved difficult to achieve adequate oxygenation of arterial blood despite raising the inspired oxygen concentration above 50%. Many now use low levels of PEEP (5–7 cmH₂O) in the majority of mechanically ventilated patients in order to maintain lung volume, as well as for those with basal atelectasis and in selected cases with airways obstruction.

Continuous positive airway pressure (CPAP)

The application of CPAP achieves for the spontaneously breathing patient what PEEP does for the ventilated patient. Oxygen and air are delivered under pressure via an endotracheal tube, a tracheostomy, a tightly fitting facemask or a hood (Fig 16.27). Not only can CPAP improve oxygenation, but the lungs become more compliant, and the work of breathing is reduced.

Pressure support ventilation (PSV)

Spontaneous breaths are augmented by a preset level of positive pressure (usually between 5 and 20 cmH₂O) triggered by the patient's spontaneous respiratory effort and applied for a given fraction of inspiratory time or until inspiratory flow falls below a certain level. Tidal volume is determined by the set pressure, the patient's effort and pulmonary

mechanics. The level of pressure support can be reduced progressively as the patient improves.

Intermittent mandatory ventilation (IMV)

This technique allows the patient to breathe spontaneously between the 'mandatory' tidal volumes delivered by the ventilator. These mandatory breaths are timed to coincide with the patient's own inspiratory effort (synchronized IMV or SIMV). SIMV can be used with or without CPAP, and spontaneous breaths may be assisted with pressure support ventilation.

'Lung-protective' ventilation

This is designed to avoid exacerbating or perpetuating lung injury by avoiding overdistension of alveoli, minimizing airway pressures and preventing the repeated opening and closure of distal airways. Alveolar volume is maintained with PEEP, and sometimes by prolonging the inspiratory phase, while tidal volumes are limited to 6–8 mL/kg ideal bodyweight. Peak airway pressures should not exceed 35–40 cmH₂O. An alternative is to deliver a constant preset inspiratory pressure for a prescribed time in order to generate a low tidal volume at reduced airway pressures ('pressure-limited' mechanical ventilation). Respiratory rate can be increased to improve CO₂ removal and avoid severe acidosis (pH <7.2), but hypercarbia is frequent and should be accepted ('permissive hypercarbia'). Both techniques can be used with SIMV. Ventilation with low tidal volumes has been shown to improve outcome in patients with acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS) (see p. 884). Lung protective ventilation should now be used in almost all patients undergoing mechanical ventilation.

High frequency oscillation (HFO)

With HFO, there is no bulk flow of gas; rather gas oscillates to and fro at rates of 60–3000 cycles/min with a V_T of 1–3 mL/kg. Both inspiration and expiration are actively controlled with a sine wave pump. The mechanism of gas exchange is not fully understood but lung volume is well maintained and oxygenation may be improved. There is some evidence to suggest that HFO is a safe and effective intervention for patients with severe ARDS.

Extracorporeal gas exchange (ECGE)

In patients with severe refractory respiratory failure pumped veno-venous bypass through a membrane lung (extracorporeal membrane oxygenation, ECMO or extracorporeal carbon dioxide removal, ECCO₂-R) has been used to reduce ventilation requirements, thereby minimizing further ventilation-induced lung damage and encouraging resolution of the lung injury. A recent (2010) randomized controlled trial suggested that ECMO might improve outcome in adult patients with severe respiratory failure. There is also some indication that the technique is particularly valuable in young patients with acute respiratory distress syndrome caused by influenza.

Non-invasive ventilation (NIV)

NIV is suitable for patients who are conscious, cooperative and able to protect their airway; they must also be able to expectorate effectively. Positive pressure is applied to the airways using a tight-fitting full-face/nasal mask or a hood. The most popular ventilators for this purpose are those that deliver bilevel positive airway pressure (BiPAP), which are simple to use, cheap and flexible. With the latter technique,

Figure 16.27 Use of a continuous positive airway pressure (CPAP) hood.

Box 16.5 Some indications for the use of non-invasive ventilation (NIV)

- Acute exacerbation of COPD (pH <7.35)
- Cardiogenic pulmonary oedema
- Chest wall deformity/neuromuscular disease (hypercapnic respiratory failure)
- Obstructive sleep apnoea
- Severe pneumonia (see Box 15.7)
- Asthma (occasionally)
- Weaning patients from invasive ventilation

Contraindications include facial or upper airway surgery, reduced conscious level, inability to protect the airway.

Modified from BTS guidelines after 1997, <http://www.britishthoracic society.co.uk>.

inspiratory and expiratory pressure levels and times are set independently and unrestricted spontaneous respiration is possible throughout the respiratory cycle. BiPAP can also be patient triggered. There is a reduced risk of ventilator-associated pneumonia and improved patient comfort, with preservation of airway defence mechanisms, speech and swallowing (which allows better nutrition). Spontaneous coughing and expectoration are not hampered, allowing effective physiotherapy, and sedation is usually unnecessary. Institution of non-invasive respiratory support can rest the respiratory muscles, reduce respiratory acidosis and breathlessness, improve clearance of secretions and re-expand collapsed lung segments. The intubation rate, length of ICU and hospital stay and, in some categories of patient, mortality, may all be reduced. NIV is particularly useful in acute hypercapnic respiratory failure associated with COPD, provided the patient is not profoundly hypoxic. NIV may also be useful as a means of avoiding tracheal intubation in immunocompromised patients with acute respiratory failure. Evidence suggests that early NIV after extubation of hypercapnic patients with respiratory disorders can reduce the risk of subsequent respiratory failure and mortality. Box 16.5 shows some indications for the use of NIV when standard medical treatment has failed. Remember, NIV should not be used as a substitute for invasive ventilation when the latter is clearly more appropriate.

Weaning

Weakness and wasting of respiratory muscles is an inevitable consequence of the catabolic response to critical illness and is often exacerbated by the reduction in respiratory work during mechanical ventilation ('disuse atrophy'). Often abnormalities of gas exchange and lung mechanics persist. Not surprisingly, therefore, many patients experience difficulty in resuming spontaneous ventilation. In a significant proportion of patients who have undergone a prolonged period of respiratory support the situation is further complicated by the development of a neuropathy, a myopathy or both.

Neuromuscular weakness complicating critical illness

Polyneuromyopathies have most often been described in association with persistent sepsis and multiple organ failure (see below). Critical illness polyneuropathy is characterized by a primary axonal neuropathy involving both motor and, to a lesser extent, sensory nerves. Clinically, the initial manifestation is often difficulty in weaning the patient from respiratory support. There is muscle wasting, the limbs are weak and flaccid, and deep tendon reflexes are reduced or absent.

Cranial nerves are relatively spared. Nerve conduction studies confirm axonal damage. The cerebrospinal fluid (CSF) protein concentration is normal or minimally elevated. These findings differentiate critical illness neuropathy from Guillain-Barré syndrome, in which nerve conduction studies nearly always show evidence of demyelination and CSF protein is usually high.

The cause of critical illness polyneuropathy is not known and there is no specific treatment. Weaning from respiratory support and rehabilitation are likely to be prolonged. With resolution of the underlying critical illness, recovery can be expected after 1–6 months but muscle weakness and fatigue frequently persist.

Myopathies can also occur, often in association with a neuropathy. A severe quadriplegic myopathy has been particularly associated with the administration of steroids and muscle relaxants to mechanically ventilated patients with acute, severe asthma.

Criteria for weaning patients from mechanical ventilation

Clinical assessment is the best way of deciding whether a patient can be weaned from the ventilator. The patient's conscious level, mood, the effects of drugs and cardiovascular performance must all be taken into account. A subjective evaluation by an experienced clinician of the patient's response to a short period of spontaneous breathing (spontaneous breathing trial) is the most reliable predictor of weaning success or failure. Objective criteria are based on an assessment of pulmonary gas exchange (blood gas analysis), lung mechanics and muscular strength.

Techniques for weaning

Patients who have received mechanical ventilation for <24–48 hours, e.g. after elective major surgery, can usually resume spontaneous respiration immediately and no weaning process is required. This procedure can also be adopted for those who have been ventilated for longer periods but who tolerate a spontaneous breathing trial and clearly fulfil objective criteria for weaning. Techniques of weaning include the following:

- The traditional method is to allow the patient to breathe entirely spontaneously for a short time, following which respiratory support is reinstituted. The periods of spontaneous breathing are gradually increased and the periods of respiratory support are progressively reduced. Initially it is usually advisable to ventilate the patient throughout the night. This method can be stressful and tiring for both patients and staff, although it is sometimes successful when other methods have failed.
- SIMV with progressive reduction in the frequency of mandatory breaths. Spontaneous breaths are usually pressure supported.
- Gradual reduction of the level of pressure support is currently considered by many to be the preferred technique.
- CPAP can prevent the alveolar collapse, hypoxaemia and fall in compliance that might otherwise occur when patients start to breathe spontaneously. It is therefore used during weaning with SIMV or pressure support, during spontaneous breathing trials and in spontaneously breathing patients prior to extubation.
- Tracheostomy is often used to facilitate weaning from mechanical ventilation.

- Non-invasive respiratory support (BiPAP, CPAP) can be used following extubation to prevent respiratory failure and re-intubation.

Extubation and tracheostomy decannulation

This should not be performed until patients can cough, swallow, protect their own airway and are sufficiently alert to be cooperative. Patients who fulfil these criteria can be extubated provided their respiratory function has improved sufficiently to sustain spontaneous ventilation indefinitely. Similar considerations guide the elective removal of tracheostomy tubes.

OUTCOMES: WITHHOLDING AND WITHDRAWING TREATMENT

(See also Ch. 10.)

For many critically ill patients, intensive care is undoubtedly life-saving and resumption of a normal lifestyle is to be expected. It is also widely accepted that the elective admission of high-risk patients into an ICU or HDU, particularly in the immediate postoperative period, can minimize morbidity and mortality and reduce costs, as well as reducing the demands on medical and nursing personnel on general wards. In the most seriously ill patients, however, immediate mortality rates are high and a significant number die soon after discharge from the intensive care unit. Mortality rates are particularly high in those who require readmission to intensive care. Moreover, the quality of life for some of those who do survive is poor and longer-term mortality rates (up to 5 years post discharge) are also higher than in the general population. Some centres have established specialist follow-up clinics to address long-term sequelae of critical illness.

Inappropriate use of intensive care facilities has other implications. The patient may experience unnecessary suffering and loss of dignity, while relatives may also have to endure considerable emotional pressures. In some cases, treatment may simply prolong the process of dying, or sustain life of dubious quality, and in others the risks of interventions outweigh the potential benefits. Lastly, intensive care is expensive, particularly for those with the worst prognosis, and resources are limited.

Both for a humane approach to the management of critically ill patients and to ensure that limited resources are used appropriately, it is necessary to:

- avoid admitting patients who cannot benefit from intensive care and
- limit further aggressive therapy when the prognosis is clearly hopeless.

Such decisions are extremely difficult; every case must be assessed individually, taking into account previous health and quality of life, primary diagnosis, medium- and long-term prognosis of the underlying condition, and survivability of the acute illness. Age alone should not be a consideration. When in doubt, active measures should continue but with regular review in the light of response to treatment and any other changes.

Decisions to limit therapy, not to resuscitate or to withdraw treatment should be made jointly by the medical staff of the unit, the primary physician or surgeon, the nurses and if possible the patient, normally in consultation with the patient's family. Limitation of active treatment is *not* the cessation of medical or nursing care: rather, a caring approach must be

adopted to ensure a dignified death, free of pain and distress, with support for family and friends (see Ch. 10).

Scoring systems

A variety of scoring systems have been developed that can be used to evaluate the severity of a patient's illness. Some have included an assessment of the patient's previous state of health and the severity of the acute disturbance of physiological function (*acute physiology, age, chronic health evaluation, APACHE and simplified acute physiology score, SAPS*). Other systems have been designed for particular categories of patient (e.g. the injury severity score for trauma victims).

The APACHE and SAPS scores are widely applicable and have been extensively validated. They can quantify accurately the severity of illness and predict the overall mortality for large groups of critically ill patients, and are therefore useful for defining the 'casemix' of patients when auditing a unit's clinical activity, for comparing results nationally or internationally, and as a means of characterizing groups of patients in clinical studies. Although the APACHE and SAPS methodologies can also be used to estimate risks of mortality, no scoring system has yet been devised that can predict with certainty the outcome in an individual patient. They must not, therefore, be used in isolation as a basis for limiting or discontinuing treatment.

BRAIN DEATH

Brain death means 'the irreversible loss of the capacity for consciousness combined with the irreversible loss of the capacity to breathe'. Both of these are essentially functions of the brainstem. Death, if thought of in this way, can arise either from causes outside the brain (i.e. respiratory and cardiac arrest) or from causes within the cranial cavity. With the advent of mechanical ventilation it became possible to support such a dead patient temporarily, although in all cases cardiovascular failure eventually supervenes and progresses to asystole.

Before deciding on a diagnosis of brainstem death, it is essential that certain preconditions and exclusions are fulfilled.

Preconditions

- The patient must be in apnoeic coma (i.e. unresponsive and on a ventilator, with no spontaneous respiratory efforts).
- Irremediable structural brain damage due to a disorder that can cause brainstem death must have been diagnosed with certainty (e.g. head injury, intracranial haemorrhage).

Exclusions

- The possibility that unresponsive apnoea is the result of poisoning, sedative drugs or neuromuscular blocking agents must be excluded.
- Hypothermia must be excluded as a cause of coma. The central body temperature should be more than 35°C.
- There must be no significant metabolic or endocrine disturbance that could produce or contribute to coma or cause it to persist.
- There should be no profound abnormality of the plasma electrolytes, acid-base balance or blood glucose levels.

Outcomes: withholding and withdrawing treatment

Brain death

Diagnostic tests for the confirmation of brainstem death

All brainstem reflexes are absent in brainstem death.

Tests

The following tests should not be performed in the presence of seizures or abnormal postures.

- Oculocephalic reflexes should be absent. In a comatose patient whose brainstem is intact, the eyes will rotate relative to the orbit (i.e. doll's eye movements will be present). In a brainstem dead patient, when the head is rotated from side to side, the eyes move with the head and therefore remain stationary relative to the orbit.
- The pupils are fixed and unresponsive to bright light. Both direct and consensual light reflexes are absent. The size of the pupils is irrelevant, although most often they will be dilated.
- Corneal reflexes are absent.
- There are no vestibulo-ocular reflexes on caloric testing (see p. 1078).
- There is no motor response within the cranial nerve territory to painful stimuli applied centrally or peripherally. Spinal reflex movements may be present.
- There is no gag or cough reflex in response to pharyngeal, laryngeal or tracheal stimulation.
- Spontaneous respiration is absent. The patient should be ventilated with 100% O₂ (or 5% CO₂ in 95% O₂) for 10 minutes and then temporarily disconnected from the ventilator for up to 10 minutes. Oxygenation is maintained by insufflation with 100% oxygen via a catheter placed in the endotracheal tube. The patient is observed for any signs of spontaneous respiratory efforts. A blood gas sample should be obtained during this period to ensure that the $P_a\text{CO}_2$ is sufficiently high to stimulate spontaneous respiration (>6.7 kPa; 50 mmHg).

The examination should be performed and repeated by two senior doctors.

In the UK, it is not considered necessary to perform confirmatory tests such as EEG and carotid angiography.

The primary purpose of establishing a diagnosis of brainstem death is to demonstrate beyond doubt that it is futile to continue mechanical ventilation and other life-supporting measures.

In suitable cases, and provided the assent of relatives has been obtained (easier if the patient was carrying an organ donor card or is on the organ donor register), the organs of those in whom brainstem death has been established may be used for transplantation. In the UK, each region has a transplant coordinator who can help with the process, as well as providing information, training and advice about organ donation. They should be informed of all potential donors. In all cases in the UK, the coroner's consent must be obtained.

DRUG THERAPY

Introduction

This chapter provides an introduction to the principles of rational therapeutics whose cardinal features were encompassed in the 1984 'Nairobi Declaration'. This emphasizes the importance of prescribing:

- to the right patient
- the right drug
- at the right dose
- and at an affordable cost.

The patient

The prerequisite of any form of therapeutic intervention is a reliable diagnosis or, at least, an assessment of clinical need. An accurate diagnosis ensures that a patient is not exposed, unnecessarily, to the hazards or costs of a particular intervention. Nevertheless, there are some circumstances when treatment is used in the absence of a clear diagnosis, for example:

- the symptomatic treatment of severe pain
- the initiation of 'blind' antimicrobial therapy where delay would expose a patient to hazard or discomfort (e.g. antimicrobial therapy for a patient with a suspected lower urinary tract infection).

In some instances a particular medicine is only effective in subgroups of patients who have a particular disorder. Trastuzumab, for example, is only of value in women with breast cancer whose malignant cells express the HER2 epidermal

growth factor receptor. *Tailoring treatment*, depending on an individual's specific genetic characteristics or gene expression, is increasingly used. This promising approach has become known as '*personalized medicine*'.

Medicines are also given to otherwise healthy individuals. In such circumstances there must be a very clear imperative to ensure that the benefits to the individual outweigh the harm. Examples include:

- Immunization against serious microbial infections (e.g. influenza vaccination)
- The reduction of individual risk factors to prevent later disease (e.g. the use of antihypertensive, or lipid-lowering, agents, to reduce the chances of ischaemic heart disease and stroke)
- Oral contraceptives in sexually active women wishing to avoid pregnancy.

Co-morbidity may also significantly alter the way in which conditions are treated particularly in the elderly. Some examples are shown in [Table 17.1](#).

Prescribing in neonates, infants, children and adolescents

The use of drugs in young people poses special problems. Extrapolating from adult dosage regimens, merely adjusting for weight, leads to excessive (and potentially toxic) doses because:

- The rates of hepatic metabolism and renal excretion of drugs are reduced in neonates and infants.

Table 17.1 Examples of drugs to be avoided in people with co-morbidity

Co-morbidity	Avoid	Effect
Parkinson's disease	Neuroleptics	Exacerbates Parkinsonian symptoms (including tremor)
Hypertension	Non-steroidal anti-inflammatory drugs	Sodium retention
Asthma	Beta-blockers, adenosine	Bronchospasm
Respiratory failure	Morphine, diamorphine	Respiratory depression
Renovascular disease	ACE inhibitors/antagonists	Reduction in glomerular filtration
Chronic heart failure	Trastuzumab	Worsening of heart failure
Chronic infections (e.g. tuberculosis, hepatitis C, histoplasmosis)	Cytokine modulators (e.g. etanercept)	Increased risk of exacerbation

- Premature babies have approximately 1% of their body weight as fat (compared with 20% in adults), leading to a marked increase in plasma drug levels of fat-soluble drugs.

There are other difficulties in prescribing for children:

- Many treatments have never been subject to formal trials in either children or adolescents and their benefits and risks have not, therefore, been appropriately assessed in these age groups. Efforts are being made, internationally, to redress this.
- For many drugs, there are no paediatric preparations or formulations. Instead, adult products are used.
- Precise oral dosing is often impossible in babies who spit out unpleasant-tasting products!
- Adverse effect profiles of medicines may be different in children compared with adults (e.g. Reye's syndrome in children given aspirin, suicidal ideas in depressed adolescents treated with selective serotonin reuptake inhibitors).

Prescribing for the elderly

The use of drugs in the elderly is often a problem:

- Rates of hepatic drug metabolism and renal excretion decline with age. Extrapolation of drug dosages, from those appropriate in younger adults, may therefore lead to toxic plasma levels.
- Changes in drug distribution due to changes in body composition, and the preferential distribution of the cardiac output to the brain, may also predispose to toxicity.
- Co-morbidity, often associated with polypharmacy, leads to increased opportunities for disease–drug and drug–drug interactions.
- Concordance with treatment regimens diminishes as the number of prescribed drugs increases, and is especially poor in the face of cognitive impairment.

Table 17.2 Common adverse effects of drugs in the elderly

Drug	Effect
Beta-blockers (including eye drops) Digoxin	Bradycardia
Nitrates α -Adrenoceptor-blockers Diuretics	Postural hypotension
Diuretics (thiazides)	Glucose intolerance, gout
Antimuscarinic drugs Tricyclic antidepressants Neuroleptics Minor tranquilizers Anticonvulsants Hypnotics Opioids	Confusion, cognitive dysfunction
Bisphosphonates (mainly alendronic acid)	Oesophageal ulceration and stricture formation
NSAIDs	Gastric erosions Small bowel and colonic lesions (less frequently) Upper gastrointestinal bleeding Perforated peptic ulcer Salt and water retention Renal impairment

- Exaggerated pharmacodynamic effects of drugs acting on the central nervous, cardiovascular and gastrointestinal systems are common.

Examples of common problems encountered in the use of drugs amongst older people are shown in Table 17.2.

Drug use in pregnancy

Clinicians should be extremely cautious about prescribing drugs to pregnant women, and only essential treatments should be given. When a known teratogen is needed during pregnancy (e.g. an anticonvulsant drug or lithium), the potential adverse effects should be discussed with the parents, preferably before conception. If parents wish to go ahead with the pregnancy, they should be offered an appropriate ultrasound scan to assess whether there is any fetal damage. Some known human teratogens are shown in Table 17.3.

Breast-feeding

Although most drugs can be detected in breast milk, the quantity is generally small. This is because, for most drugs, the concentration in milk is in equilibrium with plasma water (i.e. the non-protein-bound fraction). A few drugs (e.g. aspirin, carbimazole) may, however, cause harm to the infant if ingested in breast milk. Relevant drug literature should be consulted when prescribing for nursing mothers.

The drug

Selecting the right drug involves three elements:

- The drug's clinical efficacy for the proposed use
- The balance between the drug's efficacy and safety
- Patient preference.

Table 17.3 Some human teratogens

Drug	Effect
ACE inhibitors/antagonists	Oligohydramnios
Retinoids, e.g. acitretin	Multiple abnormalities
Carbamazole	Neonatal hypothyroidism Abnormalities of bone growth
Antiepileptics Carbamazepine Lamotrigine Phenytoin Valproate	Cleft palate Neural tube defects
NSAIDs	Delayed closure of the ductus arteriosus
Cytotoxic drugs	Most are presumed teratogens
Lithium	Ebstein's anomaly
Misoprostol	Moebius's syndrome
Thalidomide (and possibly lenalidomide)	Phocomelia
Note: All drugs should be avoided in pregnancy unless benefit clearly outweighs the risk.	

The most common approach to assessing a drug's efficacy is the randomized controlled trial (RCT), although other approaches (see p. 907) can be informative. The demonstration of absolute efficacy (against placebo) may, itself, be insufficient. Where there is more than one treatment for the same indication these should be compared with one another, taking account of the magnitude of their benefits, their individual adverse reaction profiles, and their costs.

Direct comparisons of one treatment versus another are particularly useful but are often unavailable. So-called indirect techniques, which involve comparing each drug against placebo and then imputing the comparison, are commonly used.

Patients' own preferences should be discussed to enable them to be equal partners in decision-making about whether, and how, they wish to be treated. Moreover, a full understanding of the reasons for considering treatment, the likely benefits and the possible adverse reactions, has repeatedly been shown to improve 'concordance' with treatment regimens.

The dose

Appropriate drug dosages will have usually been determined from the results of so-called '*dose-ranging*' studies during the original development programme. Such studies are generally conducted as RCTs covering a range of potential doses. Drug doses and dosage regimens may be fixed or adjusted.

Fixed dosage regimens

Drugs suitable (in adults) for prescribing at the same 'fixed' dose, for all patients, share common features. Efficacy is optimal in virtually all patients; and the risks of dose-related (type A) adverse reactions (see p. 904) are normally low. These drugs have a high 'therapeutic ratio' (i.e. the ratio between toxic and therapeutic doses). Examples of drugs prescribed at a fixed dose are shown in Table 17.4.

Titrated dosage regimens

For many drugs, there are wide interindividual variations in response. As a consequence, whilst a particular dose may

Table 17.4 Examples of fixed dose prescribing

Drug	Indication
Aspirin Clopidogrel	Secondary prevention of myocardial infarction
Bendroflumethiazide	Hypertension
Broad spectrum penicillins Cephalosporins	Lower urinary tract infection
Macrolides	Upper and lower respiratory tract infection
Levonorgestrel Ulipristal	Emergency contraception
Oestrogen antagonists Aromatase inhibitors	Secondary prevention of breast cancer
Vaccines	e.g. Diphtheria, pertussis, mumps, measles, rubella, influenza, etc.

in one person lack any therapeutic effect, the same dose in another may cause serious toxicity. The reasons for such variability are partly due to pharmacokinetic factors (differences in the rates of drug absorption, distribution or metabolism) and partly due to pharmacodynamic factors (differences in the sensitivity of target organs).

Pharmacokinetics

Pharmacokinetics is the study of what the body does to a drug. The intensity of a drug's action, immediately after parenteral administration, is largely a function of its volume of distribution. This, in turn, is predominantly governed by body composition and regional blood flow. Dosage adjustments, for body weight or surface area, are therefore common (e.g. in cancer chemotherapy) in order to optimize treatment.

The main determinants of a drug's plasma concentration after oral administration are its bioavailability (the proportion of the unchanged drug that reaches the systemic circulation) and its rate of systemic clearance (by hepatic metabolism or renal excretion). A drug's oral bioavailability depends on the extent to which it is:

- destroyed in the gastrointestinal tract
- able to cross the gastrointestinal epithelium
- metabolized by the liver before reaching the systemic circulation (so-called presystemic or 'first pass' metabolism). First pass metabolism can be avoided by the intravascular (i.v.), intramuscular (i.m.) or sublingual routes.

Liver drug metabolism occurs in two stages:

- **Phase I** is the modification of a drug, by oxidation, reduction or hydrolysis. Of these, oxidation is the most frequent route and is largely undertaken by a family of isoenzymes known as the cytochrome P450 system (see p. 902). Inhibition or induction of cytochrome P450 isoenzymes are major causes of drug interactions (Table 17.5).
- **Phase II** involves conjugation with glucuronate, sulphate, acetate or other substances to render the drug more water soluble and therefore able to be excreted in the urine.

Genetic causes of altered pharmacokinetics

Both presystemic hepatic metabolism, and the rate of systemic hepatic clearance, may vary markedly between healthy individuals.

Table 17.5 Some inducers and inhibitors of cytochrome P450

Inducers	Carbamazepine Hyperforin ^a Nifedipine Non-nucleoside reverse transcriptase inhibitors (NNRTIs) Omeprazole Phenobarbital Phenytoin Rifampicin Ritonavir (see p. 180)
Inhibitors	Allopurinol Amiodarone Cimetidine Erythromycin, clarithromycin Fluoxetine, paroxetine Grapefruit juice (contains flavonoids) Imidazoles Quinolones Saquinavir Sulphonamides
^a Hyperforin is one of the ingredients of the herbal product known as St John's wort used by herbalists to treat depression. Although it is marketed as a licensed medicine, it is a reminder that drug interactions can occur with alternative, as well as conventional, medicines.	

Variability in the genes that encode drug-metabolizing enzymes (Table 17.6) is a major determinant of the inter-individual differences in the therapeutic and adverse responses to drug treatment. The most common involve polymorphisms of the cytochrome P450 family of enzymes, CYP. The first to be discovered was the polymorphism in the hydroxylation of the antihypertensive agent debrisoquin (CYP2D6). Defective catabolism was shown to be a mono-genetically inherited trait, involving 5–10% of Caucasian populations, and leading to an exaggerated hypotensive response.

A substantial number of other drugs – estimated at 15–25% of all medicines in use – are substrates for CYP2D6. The frequencies of the variant alleles show racial variation and a small proportion of individuals may have two or more copies of the active gene. The phenotypic consequences of the defective CYP2D6 include the increased risk of toxicity with those antidepressants or antipsychotics that undergo metabolism by this pathway. Conversely, in individuals with multiple copies of the active gene, there are extremely rapid rates of metabolism and therapeutic failure at conventional doses.

Warfarin is predominantly metabolized by CYP2C9. In most populations, between 2% and 10% are homozygous for an allele that results in low enzyme activity. Such individuals will therefore metabolize warfarin more slowly leading to higher plasma levels, a greater risk of bleeding, and a requirement for lower doses if the international normalized ratio (INR) is to be maintained within the therapeutic range.

Cytochrome P450 is inhibited by the proton pump inhibitors but the consensus view is that co-prescribing with clopidogrel does not cause a significant increase in cardiovascular risk.

Individual differences in the activity of thiopurine methyltransferase (TPMT) determine the doses of mercaptopurine and azathioprine that are used. TPMT activity is therefore undertaken routinely in children undergoing treatment for acute lymphatic leukaemia and people with Crohn's disease (see p. 233).

Table 17.6 Some genetic polymorphisms involving drug metabolism

Enzyme	Drug
P450	
Cytochrome CYP1A2	Amitriptyline Clozapine
Cytochrome CYP3A4	Amlodipine Ciclosporin Nifedipine Sildenafil Simvastatin Protease inhibitors Tacrolimus
Cytochrome CYP2C9	Warfarin Glipizide Losartan Phenytoin
Cytochrome CYP2D6	Beta-blockers Codeine Risperidone SSRIs Tramadol Venlafaxine
Cytochrome CYP2C19	Clopidogrel ^a Cyclophosphamide Diazepam Lansoprazole Omeprazole
Plasma pseudocholinesterase	Succinylcholine Mivacurium
Thiopurine methyltransferase	Azathioprine Mercaptopurine
UDP-glucuronosyl transferase	Irinotecan
N-acetyl transferase	Isoniazid
CYP, cytochrome; SSRIs, Selective serotonin reuptake inhibitors. ^a Clopidogrel is a prodrug and impaired metabolizers have a reduced response.	

Many drugs undergo metabolism by more than one member of the cytochrome P450 family. Individuals deficient in one enzyme may have normal, or over-expressed, activities of others. Current knowledge (and cost) does not therefore permit predictions of an individual's dosage requirements for the wide range of drugs for which polymorphisms in metabolism have been identified.

This may, however, become possible in the future, and would contribute – in part – to the prospect of 'personalized prescribing' (see p. 899).

Other causes of altered pharmacokinetics

Rates of hepatic drug clearance can also be influenced by environmental factors including diet, alcohol consumption and concomitant therapy with drugs capable of inducing or inhibiting (Table 17.5) drug metabolism. Hepatic drug clearance also decreases with age. By contrast, renal drug clearance does not show substantial variation between healthy individuals although it declines with age and in people with intrinsic renal disease.

Pharmacodynamics

Pharmacodynamics is the study of what the drug does to the body. Pharmacodynamic sources of variability in the intensity of drug action are at least partly due to drug receptor polymorphisms (Table 17.7). At present, the pharmacodynamic tests used in clinical practice to target therapy are largely confined to the expression of:

Table 17.7 Some pharmacodynamic genetic polymorphisms

Receptor	Drug	Drug effect
ACE	ACE inhibitors, e.g. ramipril	Blood pressure reduction
Bradykinin B ₂ receptor	ACE inhibitors	Cough
β ₂ -Adrenoceptor	Salbutamol	Bronchodilatation
Dopamine receptors (D ₂ , D ₃ , D ₄)	Haloperidol Clozapine Risperidone	Antipsychotic response Tardive dyskinesia Akathisia
Serotonin transporter	Fluoxetine Paroxetine	Antidepressant response
Oestrogen receptor-α	Oestrogens	Bone mineral density

Table 17.8 Drugs for which therapeutic drug monitoring is used

Drug	Therapeutic plasma concentration range	Toxic level	Optimum post-dose sampling time (h)
Carbamazepine	20–50 µmol/L	>50 µmol/L	>8
Ciclosporin	50–200 µg/L	>200 µg/L	Pre-dose
Digoxin	1.3–2.6 nmol/L	>2.6 nmol/L	>8
Gentamicin	Trough <2 mg/L Peak 5–10 mg/L	>14 mg/L >12 mg/L	Pre-dose >1
Lithium	0.6–1.0 mmol/L	>1.5 mmol/L	>10
Phenytoin	40–80 µmol/L	>80 µmol/L	>10
Theophylline	55–110 µmol/L	>110 µmol/L	>4
Vancomycin	15–20 mg/L	–	Pre-dose

- oestrogen and HER2 receptors in women with breast cancer (to determine, respectively, responsiveness to anti-oestrogens and trastuzumab)
- epidermal growth factor receptor in lung cancer and glioblastomas (to predict responsiveness to gefitinib).

The prospect for 'personalized prescribing' will be enhanced further, when pharmacodynamic polymorphisms can be elicited by gene scanning. The interplay between pharmacokinetics and pharmacodynamics will then permit drug selection and dosing to become much more precise.

Monitoring the effects of treatment

The combination of pharmacokinetic and pharmacodynamic causes of variability makes monitoring of the effects of treatment essential. Three approaches are used.

Pre-treatment dose selection

In patients who have known, or suspected, impaired renal function, it is usually possible to predict dose requirements from their serum creatinine concentrations. If treatment needs to be started before the serum creatinine concentration is available, in patients who have very advanced renal impairment, or if renal function is fluctuating, then treatment can be started with conventional doses but the prescriber should be prepared to make adjustments within 24 hours.

Measuring plasma drug concentrations

For a few drugs, dosages can be effectively monitored by reference to their plasma concentrations (Table 17.8). This technique is only useful, however, if both the following criteria are fulfilled:

- There is a reliable and available drug assay.
- Plasma concentrations correlate well with both therapeutic efficacy and toxicity.

Measuring drug effects

For many drugs, dosage adjustments are made in line with patients' responses. Monitoring can involve dose titration against a therapeutic end-point or a toxic effect. Objective measures (such as monitoring antihypertensive therapy by measuring blood pressure, or cytotoxic therapy with serial white blood cell counts) are most helpful, but subjective ones are necessary in many instances (as with antipsychotic therapy in people with schizophrenia).

Affordability

The money available for healthcare varies widely across the world and there are marked differences (Fig. 17.1). All healthcare systems try to provide their populations with the highest standards of care within the resources they have at their disposal. The expenditure of large sums on a few people may deprive many of cost-effective remedies – a phenomenon known as the 'opportunity cost'. The differences in healthcare expenditure shown in Figure 17.1 can be very largely accounted for by their differences in national wealth as reflected by their gross domestic products.

In many countries cost-containment measures are encouraged (or mandated). For example, to reduce costs, all drugs should be prescribed by their generic (approved) names rather than their 'brand' ones because, once their patents have expired, generics products are cheaper. Despite

occasional claims to the contrary, generic products are required to go through the same stringent regulatory processes as their branded counterparts.

Some countries, including Australia, Canada and Britain, assess the cost-effectiveness of new drugs (value for money) before they are available under their publicly funded health-care systems.

Adverse drug reactions

Adverse drug reactions (ADRs), defined as 'the unwanted effects of drugs occurring under normal conditions of use', are a significant cause of morbidity and mortality. Around 5% of acute medical emergencies are admitted with ADRs, and around 10–20% of hospital inpatients suffer an ADR during their stay. Unwanted effects of drugs are five to six times more likely in the elderly than in young adults; and the risk of an ADR rises sharply with the number of drugs administered.

Classification

Two types of ADR are recognized.

Type A (augmented) reactions (Table 17.9) are:

- qualitatively normal, but quantitatively abnormal, manifestations of a drug's pharmacological or toxicological properties
- predictable from its known pharmacological or toxicological actions
- generally dose-dependent
- usually common
- only occasionally serious.

Whilst some such reactions as hypotension with ACE inhibitors may occur after a single dose, others may develop only after months (pulmonary fibrosis with amiodarone) or years (second malignancies with anti-cancer drugs).

Type B (idiosyncratic) reactions (Table 17.9) have no resemblance to the recognized pharmacological or toxicological effects of the drug. They are:

- qualitatively abnormal responses to the drug
- unpredictable from its known pharmacological or toxicological actions
- generally dose-independent
- usually rare
- often serious.

Table 17.9 Examples of adverse drug reactions

Type of reaction and drug	Adverse reaction
Type A (augmented)	
ACE inhibitors	Hypotension Chronic cough
ACE antagonists	Hypotension
Anticoagulants	Gastrointestinal bleeding Intracerebral haemorrhage
Antipsychotics	Acute dystonia/dyskinesia Parkinsonian symptoms Tardive dyskinesia
Cytotoxic agents	Bone marrow dyscrasias Cancer
Erythromycin	Nausea, vomiting
Glucocorticosteroids	Hypoadrenalism Osteoporosis
Insulin	Hypoglycaemia
Tricyclic antidepressants	Dry mouth
Type B (bizarre)	
Benzylpenicillin Radiological contrast media	Anaphylaxis
Broad-spectrum penicillins	Maculopapular rash
Carbamazepine Lamotrigine Phenytoin Sulphonamides	Toxic epidermal necrolysis Stevens–Johnson syndrome
Carbamazepine Diclofenac Isoniazid Phenytoin Rifampicin	Hepatotoxicity
Isotretinoin SSRIs ^a	Depression Suicidal ideation

ACE, angiotensin-converting enzyme; SSRIs, selective serotonin reuptake inhibitors.

^aIn children and adolescents.

Diagnosis

All ADRs mimic some naturally occurring disease and the distinction between an iatrogenic aetiology, and an event unrelated to the drug, is often difficult. Although some effects are obviously iatrogenic (e.g. acute anaphylaxis occurring a

few minutes after intravenous penicillin), many are less so. There are six characteristics that can help distinguish an adverse reaction from an event due to some other cause:

- **Appropriate time interval.** The time interval between the administration of a drug and the suspected adverse reaction should be appropriate. Acute anaphylaxis usually occurs within a few minutes of administration, whilst aplastic anaemia will only become apparent after a few weeks (because of the life-span of erythrocytes). Drug-induced malignancy, however, will take years to develop.
- **Nature of the reaction.** Some conditions (maculopapular rashes, angio-oedema, fixed drug eruptions, toxic epidermal necrolysis) are so typically iatrogenic that an adverse drug reaction is very likely.
- **Plausibility.** Where an event is a manifestation of the known pharmacological property of the drug, its recognition as a type A adverse drug reaction can be made (e.g. hypotension with an antihypertensive agent, or hypoglycaemia with an antidiabetic drug). Unless there have been previous reports in the literature, the recognition of type B reactions may be very difficult. The first cases of depression with isotretinoin, for example, were difficult to recognize as an ADR even though a causal association is now acknowledged.
- **Exclusion of other causes.** In some instances, particularly suspected hepatotoxicity, an iatrogenic diagnosis can only be made after the exclusion of other causes of disease.
- **Results of laboratory tests.** In a few instances, the diagnosis of an adverse reaction can be inferred from the plasma concentration (Table 17.8). Occasionally, an ADR produces diagnostic histopathological features. Examples include putative reactions involving the skin and liver.
- **Results of dechallenge and rechallenge.** Failure of remission when the drug is withdrawn (i.e. 'dechallenge') is unlikely to be an ADR. The diagnostic reliability of dechallenge, however, is not absolute: if the ADR has caused irreversible organ damage (e.g. malignancy) then dechallenge will result in a false-negative response. Rechallenge, involving re-institution of the suspected drug to see if the event recurs, is often regarded as an absolute diagnostic test. This is, in many instances, correct but there are two caveats. First, it is rarely justifiable to subject a patient to further hazard. Second, some adverse drug reactions develop because of particular circumstances which may not necessarily be replicated on rechallenge (e.g. hypoglycaemia with an antidiabetic agent).

Management

As a general rule, type A reactions can usually be managed by a reduction in dosage whilst type B reactions almost invariably require the drug to be withdrawn (and never re-instituted).

Specific therapy is sometimes required for ADRs such as bleeding with warfarin (vitamin K), acute dystonias (benztropine) or acute anaphylaxis (see Emergency Box 3.1, p. 69).

Evidence-based medicine

There is general acceptance that clinical practice should, as far as possible, be based on evidence of benefit rather than theoretical speculation, anecdote or pronouncement.

One of the main applications of 'evidence-based medicine' is in therapeutics. Treatments should be introduced into,

and used in, routine clinical care only if they have been demonstrated to be effective in appropriate studies. Three approaches are used:

1. Randomized controlled trials
2. Controlled observational trials
3. Uncontrolled observational studies.

Randomized controlled trials

In this type of study, people with a particular condition are allocated to one of two (and sometimes more) treatments randomly. At the end of the study, the outcomes in the groups are compared. The purpose of the randomized controlled trial is to minimize bias and confounding. In order to minimize patient bias, the patients themselves are generally unaware of their treatment allocations (a '*single-blind*' trial); and in order to reduce doctor bias, treatment allocations are also withheld from the investigators (a '*double-blind*' trial). To recruit sufficient numbers of patients, and to examine the effects of treatment in different settings, it is often necessary to conduct the trial at several locations (a '*multicentre*' trial).

Randomized controlled trials are designed to assess whether one treatment is better than another (a '*superiority*' trial); or whether one treatment is similar to another (an '*equivalence*' trial).

- In a **superiority trial** the study treatment is usually compared to placebo or to current standard practice.
- In an **equivalence trial** the treatment under study is compared to another treatment for the same condition.

Although RCTs were originally introduced to investigate the efficacy of drugs, the methodology can be used for surgical (and other) procedures and medical devices.

There are a number of variants of the conventional randomized controlled trial including cross-over trials, cluster randomized controlled trials, inferiority trials and futility trials (see Further Reading).

Assessing randomized controlled trials

In assessing the relevance and reliability of an RCT a number of features need to be taken into account.

Randomization

In any RCT the method of randomization should be robust. In particular, the investigator should be unaware of which treatment a patient entering a trial will receive. This avoids selection bias.

Maintaining blindness

Although, ideally, in RCTs neither the investigator nor the patient is aware of the treatment allocation until the end of the study, this is not always possible. Adverse drug reactions, for example, may make it obvious which treatment a patient has been given. Nevertheless maintaining 'blindness' is necessary where the outcome is subjective (e.g. relief of pain, alleviation of depression) if bias is to be avoided.

Were the treated and control groups comparable?

Were they similar in their 'baseline' characteristics? Were they, for example, of similar age, severity and duration of illness? If not, are the differences likely to influence the results? Has the statistical analysis (using analysis of covariance, or Cox's proportional hazards model) (see below) tried to adjust for them? Table 17.10 shows some of the baseline characteristics of a trial comparing prednisolone with placebo in the treatment of Bell's palsy (idiopathic facial paralysis).

Table 17.10 Summary of a multicentre randomized placebo-controlled trial of prednisolone (25 mg twice daily), for 10 days, in the treatment of Bell's palsy

	Placebo (n = 245)		Prednisolone (n = 251)	
	n	(%)	n	(%)
Baseline characteristics				
Gender				
Male	118	48.2	135	53.8
Female	127	51.8	116	46.2
Age (years) (mean \pm SD)	44.9 \pm 16.6		43.2 \pm 16.2	
Score on House–Brackmann scale ^a (mean \pm SD)	3.8 \pm 1.3		3.5 \pm 1.2	
Time between onset of symptoms and start of treatment				
Within 24 h	147	60.0	120	47.8
>24 to <48 h	64	26.1	95	37.8
>48 to <72 h	18	7.3	25	10.0
Unknown (but <72 h)	16	6.5	11	4.4
Results at 3 and 12 months				
Grade 1 on House–Brackmann scale ^a				
At 3 months ^b	152/239	63.1	205/247	83.0
At 12 months ^b	200/245	81.6	237/251	94.4

^aThe House–Brackmann scale scores facial nerve function from 1 = normal to 6 = complete paralysis. ^b $p < 0.001$. (From Sullivan FM, Swan IRC, Donnan PT et al 2007. Early treatment with prednisolone of aciclovir in Bell's palsy. *N Engl J Med* 357:1598–1607, with permission)

Outcomes

There are two ways to look at the outcomes of an RCT.

- **Per protocol analysis:** this includes only those who completed the study.
- **Intention-to-treat analysis:** this includes all patients from the time of randomization.

Ideally, there should be no difference but in reality the results of a per protocol analysis are usually more advantageous to a treatment than an intention-to-treat analysis. The reason is that the intention-to-treat analysis will take account of patients who have withdrawn from the trial because of intolerance of the treatment or adverse drug reactions. It is therefore a much more robust approach. The results of the intention-to-treat analysis, in the trial of prednisolone in Bell's palsy, are shown in Table 17.10. The trial results indicate, with a high probability, that treatment of Bell's palsy with prednisolone will increase the chances of a full recovery of facial nerve function.

Are the results generalizable?

Were the patients enrolled into the study a reasonable reflection of those likely to be treated in routine clinical practice (a so-called pragmatic trial)? Or were they a selected population that excluded significant patient groups (such as the elderly)? If the latter, view the results with caution.

Analysis of a superiority trial

The analysis of a superiority trial is based on the premise – the '**null hypothesis**' – that there is no difference between the treatments. The null hypothesis is rejected if the probability of the observed result occurring by chance, the p value, is less than 1 in 20 (i.e. $p < 0.05$). There are three caveats.

- Any difference may still be due to chance; and it is often better to await the results of at least two independent studies before adopting a new treatment.
- A trial may show no 'statistically significant' difference, when one in fact exists, because too few patients have been included, in other words the trial lacked sufficient 'power'. The '**power**' of a study (the number of patients needed in each treatment group to detect a predefined

difference) should have been defined at the outset. If the study was underpowered, the results of the study should be interpreted with extreme care.

- A statistically significant difference may not, necessarily, be clinically relevant.

Scrutiny of the magnitude of the effect, and its 95% confidence intervals (CI), is a far better guide than the p value.

- **Effect size.** The results of the well-designed trial in Table 17.10 show, very convincingly, that the treatment of Bell's palsy with prednisolone increases the chances of complete recovery of facial nerve function, at 12 months, from 81.6% to 94.4%. This is a far more convincing description of the benefits of treatment than the p value.
- Another expression of the benefit of a treatment such as prednisolone can be derived from the **number needed to treat** (NNT). This is an estimate of the numbers of patients needed to be treated with a drug to achieve one positive result. In the study shown in Table 17.10, the NNT to enable one patient with Bell's palsy to regain normal facial nerve function, after prednisolone treatment, is eight.

Analysis of an equivalence trial

The aim of an equivalence trial is to determine whether two (or possibly more) treatments produce similar benefits. During the design of such trials, it is necessary to decide what difference is unimportant and then to calculate the number of patients needed in order to have an 80% or 90% chance of showing this. In equivalence trials such power calculations show that the number of patients required is invariably greater than those needed for superiority trials. In such studies the comparator itself must, of course, already have been shown to be effective.

Meta-analysis

It is possible to summate all the controlled trials that have been performed in the treatment of a particular condition so as to refine the estimate of effectiveness. This technique minimizes random error in the assessment of the effect size

of a treatment because more patients are included than could be accommodated in any single trial. A meta-analysis should be performed (and interpreted) carefully because of the heterogeneity of the individual studies used in it.

Controlled observational trials

Three types of observational study have been used to test the clinical effectiveness of therapeutic interventions:

- Historical controlled trials
- Case-control studies
- Before-and-after studies.

Historical controlled trials

Despite the value of the prospective randomized controlled trial there are many treatments that have never been subjected to this technique, yet their efficacy is unquestioned. Examples include insulin in the treatment of diabetic ketoacidosis, thyroxine for hypothyroidism, vitamin B₁₂ in pernicious anaemia and defibrillation for ventricular fibrillation. In a historical controlled trial the outcome in patients treated with the study drug is compared to that of previously untreated people with the same disease. Treatments can be accepted into routine use on the basis of favourable comparisons with historical controls when the following criteria are met:

- There should be a biologically plausible basis for the observed benefits.
- There should be no appropriate treatment that could be reasonably used as a control.
- The condition should have a known and predictable natural history.
- The treatment should not be expected to have adverse effects that would compromise its potential benefits.
- There should be a reasonable expectation that the magnitude of the therapeutic effects of treatment will be large enough to make the interpretation of its benefits unambiguous.

Case-control studies

This type of study design compares people with a particular condition (the 'cases') with those without (the 'controls'). The approach has predominantly been used to identify epidemiological 'risk factors' for specific conditions such as lung cancer (smoking) or sudden infant death syndrome (lying prone); or in the evaluation of potential adverse drug reactions (such as deep venous thrombosis with oral contraceptives).

A case-control design allows an estimation of the **odds ratio** (OR), which is the ratio of the probability of an event occurring to the probability of the event not occurring (Box 17.1).

An OR that is significantly greater than unity indicates a statistical association that may be causal. The OR for deep venous thrombosis and current use of oral contraceptives equals 2–4 (depending on the preparation): this indicates that the risk of developing a deep venous thrombosis on oral contraceptives is between 2 and 4 times greater than the background rate.

In some studies, the OR for a particular observation has been found to be significantly less than unity, suggesting 'protection' from the condition under study. Some studies of women with myocardial infarction indicated protection in those using hormone-replacement therapies but it has been subsequently shown that the result was due to bias. On the other hand, case-control studies have consistently shown that aspirin and other non-steroidal anti-inflammatory drugs

Box 17.1 Estimation of odds ratio

	Cases	Controls
Risk factor present	a	c
Risk factor absent	b	d
The odds ratio (OR) = (a ÷ b) / (c ÷ d)		

are associated with a reduced risk of colon cancer. This seems to be a causal effect.

Case-control studies claiming to demonstrate the efficacy of a drug need to be interpreted with great care: the possibility of bias and confounding is substantial as was seen in the studies of hormone-replacement therapy and myocardial infarction. Confirmation from one or more RCTs is usually essential.

Before-and-after studies

It has sometimes been inferred that observed improvements seen in patients before, and after, the application of a particular treatment is evidence of efficacy. Such an approach is fraught with difficulties: the combination of a placebo effect, as well as regression to the mean, is likely to negate most studies using this type of design. Nevertheless, there are some circumstances where genuine efficacy can be confidently observed with such designs: the consequences of hip replacement, and cataract surgery, are good examples. Such instances can be regarded as special examples of the use of implicit historical controls.

Uncontrolled observational studies

Uncontrolled case series cannot be considered as providing primary evidence of efficacy unless they are undertaken in circumstances that are virtually those of historical controlled trials. When used in this way to demonstrate clinical effectiveness their validity relies on the use of implicit historical trials. Case series can, however, sometimes be of value in demonstrating the generalizability of the results of RCTs.

Dangers

Drug trials are carried out in specific groups of selected patients under strict supervision. The results, particularly when dramatic, are often used outside the strict inclusion criteria for clinical trials. The dramatic effect of spironolactone in heart failure (30% reduction in all-cause mortality) has not always been replicated in routine clinical practice because the wrong patients have been treated, often with higher doses, leading to hyperkalaemia and death.

Evaluation of new drugs

New drugs are subjected to a vigorous programme of pre-clinical and clinical testing before they are licensed for general use (Table 17.11) and are also monitored for safety following licensing. Doctors are recommended to fill in yellow cards when they suspect an adverse reaction has taken place.

Statistical analyses

The relevance of statistics is not confined to those who undertake research but also to anyone who wants to understand the relevance of research studies to their clinical practice.

Table 17.11 Evaluation of new drugs

Phase I: Healthy human subjects (usually men)
First use in man Evaluation of safety and toxicity Pharmacokinetic assessment Sometimes pharmacodynamic assessment Approximately 100 subjects
Phase II: First assessment in patients
Safety and toxicity evaluated Dose range identified Pharmacokinetic and pharmacodynamic monitoring Approximately 500 subjects
Phase III: Use in wider patient population
Efficacy main objective Safety and toxicity also carefully monitored Often multicentre trials Approximately 2000 patients involved
Phase IV: Post-marketing surveillance
All patients prescribed drug monitored Efficacy, safety and toxicity measured Quantification of unusual drug adverse effects Yellow Card and Prescription Event Monitoring Often very large numbers of patients observed

The average

Clinical studies may describe, quantitatively, the value of a particular variable (e.g. height, weight, blood pressure, haemoglobin) in a sample of a defined population. The 'average' value (or 'central tendency' in statistical language) can be expressed as the mean, median or mode depending on the circumstances:

- The **mean** is the average of a distribution of values that are grouped symmetrically around the central tendency.
- The **median** is the middle value of a sample. It is used, particularly, where the values in a sample are asymmetrically distributed around the central tendency.
- The **mode** is the interval, in a frequency distribution of values, that contains more values than any other.

In a symmetrically distributed population, the mean, median and mode are the same.

The average value of a sample, on its own, is of only modest interest. Of equal (and often greater) relevance is the confidence we can place on the sample average as truly reflecting the average value of the population from which it has been drawn. This is most often expressed as a **confidence interval**, which describes the probability of a sample mean being a certain distance from the population mean. If, for example, the mean systolic blood pressure of 100 undergraduates is 124 mmHg, with a 95% confidence interval of ± 15 mmHg, we can be confident that if we replicated the study 100 times the value of the mean would be within the range 109–139 mmHg on 95 occasions. It is intuitively obvious that the larger the sample the smaller will be the size of the confidence interval.

Correlation

In clinical studies two, or more, independent variables may be measured in the same individuals in a sample population (e.g. weight and blood pressure). The degree of correlation between the two can be investigated by calculating

the *correlation coefficient* (often abbreviated to '*r*'). The correlation coefficient measures the degree of association between the two variables and may range from 1 to -1:

- If $r = 1$, there is complete and direct concordance between the two variables
- If $r = -1$, there is complete but inverse concordance
- If $r = 0$ there is no concordance.

Statistical tables are available to inform investigators as to the probability that *r* is due to chance. As in other areas of statistics, if the probability is less than 1 in 20 ($p < 0.05$) then by custom and practice it is regarded as **statistically significant**. There are, however, two caveats:

- The 1 in 20 rule is a convention and does not exclude the possibility that a presumed association is due to chance
- The fact that there is an association between two variables does not necessarily mean that it is causal. For example, a correlation between blood pressure and weight, with $r = 0.75$ and $p < 0.05$, does not mean that weight has a direct effect on blood pressure (or vice versa).

Correlation analyses can become complicated. The simplest (least squares regression analysis) presumes a straight-line relationship between the two variables. More complicated techniques can be used to estimate *r* where a non-linear relationship is presumed (or assumed); where the distributions deviate from normal; where the scales of one or both variables are intervals or ranks; or where a correlation between three or more variables is sought.

Expressions of benefit and harm

There are three ways in which the outcomes, in clinical studies, are expressed:

1. Binary (dichotomous) outcomes
2. Survival analyses
3. Continuous outcomes.

Binary outcomes are often used in the design and analysis of RCTs. Such outcomes are dichotomous (such as alive or dead). The results are usually expressed as the **relative risk** (or **risk ratio** – RR). In a trial where the outcome is (say) mortality, the relative risk is the ratio of the proportion of treated patients dying to the proportion of control patients dying. Usually, RR of <1 is suggestive of benefit; an RR of >1 is suggestive of harm. RRs are almost invariably reported with their 95% confidence intervals. If the boundaries of the 95% confidence intervals do not cross unity the results are generally statistically significant (at least at the 5% level).

Survival analyses. In studies in which individuals are observed over a long(ish) period of time, and in which it is unreasonable (or erroneous) to assume that event rates are constant, the technique of survival analysis is used. This is most commonly reported as the **hazard ratio** (HR) and its 95% confidence interval. The HR is the probability that, if an event in question has not already occurred, it will happen in the next (short) time interval. It has, broadly, a comparable interpretation to the RR.

Continuous outcomes. Studies such as that in Table 17.10 may report outcomes using one or more continuous scales. In this study of the effects of prednisolone in the treatment of Bell's palsy, the House–Brackmann measure of facial nerve function was used as the outcome measure.

a
Symmetrical data (normal)

b
Skewed data

Averages. In symmetrical data the mean, mode and median are the same.

Conventional tests of statistical significance using Student's *t*-test, for example, can be calculated to assess whether the null hypothesis should be rejected.

Number needed to treat (NNT). As discussed earlier, the NNT is an estimate of the number of patients that need to be treated for one to benefit compared to no treatment. If the probabilities of the end-points with the active drug and no treatment (i.e. placebo) are respectively p_{active} and $p_{\text{no treatment}}$ then the NNT can be calculated thus:

$$\text{NNT} = 1 / (p_{\text{active}} - p_{\text{no treatment}})$$

An analogous measure – the number needed to harm (NNH) – is the number of patients that need to be treated with a drug to cause one patient to be subject to a specific harm.

Other statistical techniques

Statisticians have developed a range of sophisticated methods to handle a wide variety of biomedical problems. Unless an investigator is supremely (and usually unwisely) confident it is wise to seek professional advice in analysing numerical data that look complicated. In doing so, it is invariably wiser to do so at the time the study is being designed rather than after the results have been generated!

POISONING

The nature of the problem

Exposure to a substance is often equated with poisoning. However, absorption is necessary for there to be a toxic effect and, even if this occurs, poisoning does not necessarily result, because the amount absorbed may be too small. In developed countries, poisoning causes approximately 10% of acute hospital medical presentations. In such cases poisoning is usually by self-administration of prescribed and over-the-counter medicines, or illicit drugs. Poisoning in children aged less than 6 months is most commonly iatrogenic and involves overtreatment with, e.g. paracetamol. Children between 8 months and 5 years of age also ingest poisons accidentally, or they may be administered deliberately to cause harm, or for financial or sexual gain. Occupational poisoning as a result of dermal or inhalational exposure to chemicals is a common occurrence in the developing world and still occurs in the developed world. Sometimes inappropriate treatment of a patient by a doctor is responsible for the development of poisoning, e.g. in the case of digoxin toxicity.

In adults, self-poisoning is commonly a 'cry for help'. Those involved are most often females under the age of 35 who are in good physical health. They take an overdose in circumstances where they are likely to be found, or in the presence of others. In those older than 55 years of age, men predominate and the overdose is usually taken in the course of a depressive illness or because of poor physical health.

The type of agent taken in overdose is also heavily influenced by availability and culture. In the UK, paracetamol poisoning is responsible for approximately one-third of all admissions, whereas in Sri Lanka, for example, the agents ingested are more often pesticides or plants, such as oleander, and in South India, copper sulphate is a problem. In addition, ingestion of heating fuels (e.g. petroleum distillates), antimalarials, antituberculous drugs and traditional medicine is reported frequently in the developing world.

Current information sources

Pharmacotherapy moves at a very rapid pace and it is impossible for anyone to keep up with contemporary advances. Details of current prescribing advice can be found in:

- The Summary of Product Characteristics (SmPCs) produced by manufacturers but vetted by drug regulatory authorities (for the UK, these are the Medicines and Healthcare Products Regulatory Agency and the European Medicines Agency).
- The relevant national formulary. Many countries have their own formularies, for example the UK has the British National Formulary (BNF), produced jointly by the British Medical Association and the Royal Pharmaceutical Society.
- Guidance produced by the Technology Appraisals Guidance series from the UK's National Institute for Health and Clinical Excellence (NICE).

Advice on the management of individual conditions is available in the form of clinical guidelines (systematically developed statements to assist practitioner and patient decisions about appropriate healthcare for specific clinical circumstances).

Self-poisoning can kill

All must be aware of the dangers of drugs and chemicals. Education on safe storage and careful handling of household and workplace chemicals is necessary on a continuing basis.

A third of patients admitted with an overdose in the UK state that they are unaware of the toxic effects of the substance involved; the majority take whatever drug is easily available at home (Box 17.2). Studies reveal that:

- Acute overdoses often involve more than one agent; alcohol is the most commonly implicated second agent.
- There is often a poor correlation between the drug history and the toxicological analytical findings. Therefore, a patient's statement about the type and amount of drug ingested cannot always be relied upon.

The majority of cases of self-poisoning do not require intensive medical management, but all patients require a sympathetic and caring approach, a psychiatric and social assessment and, sometimes, psychiatric treatment. However,

Box 17.2 Prevention of self-poisoning

Patients usually take what is readily available at home.

- Only small amounts of drugs should be bought
- Foil-wrapped drugs are less likely to be taken in overdose
- Keep drugs in a safe place
- Keep drugs and liquids in their original containers
- Child-resistant drug containers should be used
- Doctors should be careful in prescribing all drugs
- Prescriptions for any susceptible patient (e.g. the depressed) must be monitored carefully
- Household products should be labelled and kept safely away from children

POISONING

National Institute for Clinical Excellence (NICE): <http://www.nice-org.uk>.

Scottish Intercollegiate Guidelines Network (SIGN): <http://www.sign.ac.uk/>.

National Guidelines Clearing House in the USA: <http://www.guideline.gov>.

SIGNIFICANT WEBSITES

Patient information leaflets are supplied with all prescribed medication.

Table 17.12 Diagnostic process in acute poisoning

Obtain history, if possible, from the patient, relative, friend or paramedics
 Is there circumstantial evidence of an overdose?
 Are the circumstances in which the patient has been found suggestive?
 Was a suicide note left?
 Are the symptoms suggestive of an overdose?
 Do the physical signs suggest an overdose? (Tables 17.13 and 17.14)

as the majority of patients ingest relatively non-toxic agents, receive good supportive care and, when appropriate, the administration of specific antidotes, the in-hospital mortality in most developed countries is now less than 1%. Fatalities in the UK are due predominantly to carbon monoxide, antidepressants, paracetamol, analgesic combinations containing paracetamol and an opioid, heroin, methadone or cocaine. Deaths from poisoning in children are usually accidental and due to inappropriate storage of drugs such as digoxin and quinine and from drugs of abuse purchased or prescribed for a parent or carer.

THE APPROACH TO THE PATIENT

History

More than 80% of adults are conscious on arrival at hospital and the diagnosis of self-poisoning can usually be made from the history (Table 17.12). In the unconscious patient a history from friends or relatives is helpful, and the diagnosis can often be inferred from the medicine containers or a 'suicide note' brought by the paramedics. In any patient with an altered level of consciousness, acute poisoning must always be considered in the differential diagnosis.

Examination

On arrival at hospital, the patient must be assessed urgently (Airways, Breathing and Circulation). The following should be evaluated:

- **Level of consciousness:** the Glasgow Coma Scale should be used (see p. 1092)
- **Ventilation:** pulse oximetry can be used to measure oxygen saturation. The displayed reading may be inaccurate when the saturation is below 70%, there is poor peripheral perfusion and in the presence of carboxyhaemoglobin and methaemoglobin. Only measurement of arterial blood gases will indicate the presence both of hypercapnia and hypoxia
- **Blood pressure and pulse rate**
- **Pupil size and reaction to light**
- **Evidence of intravenous drug use**
- **A head injury** complicating poisoning.
 If the patient is unconscious, the following should also be checked:
 - **Cough and gag reflex:** present or absent.
 - **Temperature:** measured with a low-reading rectal thermometer if the ear temperature suggests it is low.

Some of the physical signs that may aid identification of the agents responsible for poisoning are shown in Table 17.13. The cluster of features on presentation may be distinctive and diagnostic. For example, sinus tachycardia, fixed

Table 17.13 Some physical signs of poisoning

Features	Likely poisons
Constricted pupils (miosis)	Opioids, organophosphorus insecticides, nerve agents
Dilated pupils (mydriasis)	Tricyclic antidepressants, amfetamines, cocaine, antimuscarinic drugs
Divergent strabismus	Tricyclic antidepressants
Nystagmus	Carbamazepine, phenytoin
Loss of vision	Methanol, quinine
Papilloedema	Carbon monoxide, methanol
Convulsions	Tricyclic antidepressants, theophylline, opioids, mefenamic acid, isoniazid, amfetamines
Dystonic reactions	Metoclopramide, phenothiazines
Delirium and hallucinations	Amfetamines, antimuscarinic drugs, cannabis, recovery from tricyclic antidepressant poisoning
Hypertonia and hyperreflexia	Tricyclic antidepressants, antimuscarinic drugs
Tinnitus and deafness	Salicylates, quinine
Hyperventilation	Salicylates, phenoxyacetate herbicides, theophylline
Hyperthermia	Ecstasy (MDMA), salicylates
Blisters	Usually occur in comatose patients
MDMA, 3,4-methylenedioxymetamphetamine.	

dilated pupils, exaggerated tendon reflexes, extensor plantar responses and coma suggest tricyclic antidepressant poisoning (Table 17.13 and Table 17.14).

PRINCIPLES OF MANAGEMENT OF POISONING (Table 17.15)

Most people with self-poisoning require only general care and support of the vital systems. However, for a few drugs additional therapy is required.

Care of the unconscious patient (see also p. 1135)

In all cases the patient should be nursed in the lateral position with the lower leg straight and the upper leg flexed; in this position the risk of aspiration is reduced. A clear passage for air should be ensured by the removal of any obstructing object, vomit or dentures, and by backward pressure on the mandible. Nursing care of the mouth and pressure areas should be instituted. Immediate catheterization of the bladder in unconscious patients is usually unnecessary as it can be emptied by gentle suprapubic pressure. Insertion of a venous cannula is usual, but administration of intravenous fluids is unnecessary unless the patient has been unconscious for more than 12 hours or is hypotensive.

Ventilatory support

If respiratory depression is present, as determined by pulse oximetry or preferably by arterial blood gas analysis, an oropharyngeal airway should be inserted, and supplemental-oxygen should be administered. Pulse oximetry alone will

Table 17.14 Common feature clusters in acute poisoning

Feature clusters	Poisons
Coma, hypertonia, hyperreflexia, extensor plantar responses, myoclonus, strabismus, mydriasis, sinus tachycardia	Tricyclic antidepressants; less commonly antihistamines, orphenadrine, thioridazine
Coma, hypotonia, hyporeflexia, plantar responses (flexor or non-elicitable), hypotension	Barbiturates, benzodiazepine and alcohol combinations, tricyclic antidepressants
Coma, miosis, reduced respiratory rate	Opioid analgesics
Nausea, vomiting, tinnitus, deafness, sweating, hyperventilation, vasodilatation, tachycardia	Salicylates
Hyperthermia, tachycardia, delirium, agitation, mydriasis	Ecstasy (MDMA) or other amphetamine
Miosis, hypersalivation, rhinorrhoea, bronchorrhoea	Organophosphorus and carbamate insecticides, nerve agents

Table 17.15 Management strategy in acute poisoning

Provide supportive treatment
 Is the use of an antidote appropriate? (Table 17.16)
 Is it appropriate to attempt to reduce poison absorption?
 Is it appropriate to perform toxicological investigations?
 Will non-toxicological investigations assist? (Table 17.17)
 Should urine alkalinization, multiple-dose activated charcoal, haemodialysis or haemodiafiltration be employed to increase poison elimination?

not detect hypercapnia. Loss of the cough or gag reflex is the prime indication for intubation. The gag reflex can be assessed by positioning the patient on one side and making him or her gag using a suction tube. In many severely poisoned patients, the reflexes are depressed sufficiently to allow intubation without the use of sedatives or relaxants. The complications of endotracheal tubes are discussed on page 885 in Chapter 16. If ventilation remains inadequate after intubation, as shown by hypoxaemia and hypercapnia, intermittent positive-pressure ventilation (IPPV) should be instituted.

Cardiovascular support

Although hypotension (systolic blood pressure below 80 mmHg) is a recognized feature of acute poisoning, the classic features of shock: tachycardia and pale cold skin, are observed only rarely.

Hypotension and shock may be caused by:

- A direct cardio-depressant action of the poison (e.g. beta-blockers, calcium channel blockers, tricyclic antidepressants)
- Vasodilation and venous pooling in the lower limbs (e.g. ACE inhibitors, phenothiazines)
- A decrease in circulating blood volume because of gastrointestinal losses (e.g. profuse vomiting in theophylline poisoning), increased insensible losses (e.g. salicylate poisoning), increased renal losses (e.g. poisoning due to diuretics) and increased capillary permeability.

Hypotension may be exacerbated by co-existing hypoxia, acidosis and dysrhythmias. In people with marked hypotension, volume expansion with crystalloids should be used, guided by monitoring of central venous pressure (CVP). Urine output (aiming for 35–50 mL/h) is also a useful guide to the adequacy of the circulation. If a patient fails to respond to the above measures, more intensive therapy is required. In such patients, it is helpful to undertake invasive haemodynamic monitoring to confirm that adequate volume replacement has been administered. Volume replacement and the use of inotropes are discussed on page 874. All patients with cardiogenic shock should have ECG monitoring.

Systemic hypertension can be caused by a few drugs when taken in overdose. If this is mild and associated with agitation, a benzodiazepine may suffice. In more severe cases, for example those due to a monoamine oxidase inhibitor, there may be a risk of arterial rupture, particularly intracranially. To prevent this, an α -adrenergic blocking agent such as phentolamine, 2–5 mg i.v. every 10–15 min, or intravenous isosorbide dinitrate 2–10 mg/h up to 20 mg/h if necessary, or sodium nitroprusside 0.5–1.5 μ g/kg per min by intravenous infusion, should be administered until the blood pressure is controlled.

Arrhythmias can occur, e.g. tachyarrhythmias following ingestion of a tricyclic antidepressant or theophylline; bradyarrhythmias with digoxin poisoning. Known arrhythmogenic factors such as hypoxia, acidosis and hypokalaemia should be corrected.

Other problems

Hypothermia and hyperthermia

A rectal temperature below 35°C is a recognized complication of poisoning, especially in older patients or those who are comatose. The patient should be covered with a 'space blanket' and, if necessary, given intravenous and intragastric fluids at normal body temperature. The administration of heated (37°C), humidified oxygen delivered by face mask is also useful.

Rarely, body temperature may increase to potentially fatal levels after poisoning with central nervous system stimulants such as cocaine, amphetamines including ecstasy (MDMA), monoamine oxidase inhibitors or theophylline. Muscle tone is often increased and convulsions and rhabdomyolysis are common. Cooling measures, sedation with diazepam and, in severe cases, i.v. dantrolene 1 mg/kg body weight should be given.

Skin blisters

Skin blisters may be found in poisoned patients who are, or have been, unconscious. Such lesions are not diagnostic of specific poisons, but are sufficiently common in poisoned patients (and sufficiently uncommon in patients unconscious from other causes) to be of diagnostic value.

Rhabdomyolysis

Rhabdomyolysis can occur from pressure necrosis in drug-induced coma, or it may complicate, e.g. ecstasy (MDMA) abuse in the absence of coma. People with rhabdomyolysis are at risk of developing, firstly, acute kidney injury from myoglobinaemia, particularly if they are hypovolaemic and have an acidosis and, secondly, wrist or ankle drop from the development of a compartment syndrome (see p. 509).

Convulsions

These may occur, e.g. in poisoning due to tricyclic antidepressants, mefenamic acid or opioids. Usually the seizures are short-lived but, if they are prolonged, diazepam 10–20 mg

The approach to the patient

Principles of management of poisoning

i.v. or lorazepam 4 mg i.v. should be administered. Persistent fits must be controlled rapidly to prevent severe hypoxia, brain damage and laryngeal trauma. If diazepam or lorazepam in repeated dose is ineffective, the patient should also receive a loading dose of phenytoin (20 mg/kg) administered intravenously at not more than 50 mg/min, with ECG monitoring.

Stress ulceration and bleeding

Measures to prevent stress ulceration of the stomach should be started on admission in all patients who are unconscious and require intensive care. A proton pump inhibitor should be administered intravenously.

Body 'packers' and body 'stuffers'

Body 'packers' (sometimes called 'mules' or 'swallowers') are those who swallow a substantial number of packages containing illicit drugs for the purpose of smuggling. Heroin used to be the drug of choice but this has been superseded by cocaine. Although each package contains a potentially lethal amount of drug, packets are now usually machine manufactured using a material which usually does not leak. Body packers may ingest up to 100–200 packages.

Body 'stuffers' are those who swallow a small number of packages containing an illicit drug, usually heroin, cocaine, cannabis or an amphetamine, in an unplanned attempt to conceal evidence when on the verge of being arrested. These drugs are usually either unpackaged or poorly packaged and as a consequence leakage may occur over the ensuing 3–6 hours and cause significant symptoms. Some also hide illicit drug packages in their rectum or vagina with the same intent (these are sometimes known as body 'pushers').

The role of imaging is confined to body packers; imaging has little role in the care of body stuffers or pushers. Ultrasound is of similar accuracy to abdominal X-ray in locating packages and less accurate than CT. A urine screen for drugs of misuse should be performed. A screen that is positive for one or more drugs of misuse suggests that either the patient has used the drug in the previous few days, or at least one packet is leaking. A negative screen strongly suggests that no packet is leaking. Screens should be repeated daily, or immediately if the patient develops features of intoxication, to confirm the diagnosis.

Packages can be removed most expeditiously in body stuffers by employing whole bowel irrigation (see p. 913). In the past early surgery was advocated in body packers. However, with the development of improved packaging, a more conservative approach (the use of lactulose or whole bowel irrigation) can now be adopted with which there is a complication rate of <5%. Immediate surgery is indicated if acute intestinal obstruction develops, or when packets can be seen radiologically and there is clinical or analytical evidence to suggest leakage, particularly if the drug involved is cocaine.

Packets in the vagina can usually be removed manually.

Specific management

Antidotes

Specific antidotes are available for only a small number of poisons (Table 17.16).

Antidotes may exert a beneficial effect by:

- **Forming an inert complex** with the poison (e.g. desferrioxamine (deferoxamine), D-penicillamine, dicobalt edetate, digoxin-specific antibody fragments,

Table 17.16 Antidotes of value in poisoning

Poison	Antidotes
Aluminium (aluminum)	Desferrioxamine (deferoxamine)
Arsenic	DMSA, dimercaprol
Benzodiazepines	Flumazenil
β-adrenoceptor blocking drugs	Atropine, glucagon
Calcium channel blockers	Atropine
Carbamate insecticides	Atropine
Carbon monoxide	Oxygen
Copper	D-penicillamine, DMPS
Cyanide	Oxygen, dicobalt edetate, hydroxocobalamin, sodium nitrite, sodium thiosulphate
Diethylene glycol	Fomepizole, ethanol,
Digoxin and digitoxin	Digoxin-specific antibody fragments
Ethylene glycol	Fomepizole, ethanol
Hydrogen sulphide	Oxygen
Iron salts	Desferrioxamine
Lead (inorganic)	DMSA (succimer), sodium calcium edetate
Methaemoglobinaemia	Methylthionium chloride (methylene blue)
Methanol	Fomepizole, ethanol
Mercury (inorganic)	Unithiol (DMPS)
Nerve agents	Atropine, HI-6, obidoxime, pralidoxime
Oleander	Digoxin-specific antibody fragments
Opioids	Naloxone
Organophosphorus insecticides	Atropine, HI-6, obidoxime, pralidoxime
Paracetamol	Acetylcysteine
Thallium	Berlin (Prussian) blue
Warfarin and similar anticoagulants	Phytomenadione (vitamin K)
DMSA, dimercaptosuccinic acid; DMPS, dimercaptopropanesulphonate.	

dimercaprol, HI-6, hydroxocobalamin, obidoxime, pralidoxime, protamine, Prussian (Berlin) blue, sodium calcium edetate, succimer (DMSA), unithiol (DMPS))

- **Accelerating detoxification** of the poison (e.g. acetylcysteine, sodium thiosulphate)
- **Reducing the rate of conversion** of the poison to a more toxic compound (e.g. ethanol, fomepizole)
- **Competing with the poison** for essential receptor sites (e.g. oxygen, naloxone, phytomenadione)
- **Blocking essential receptors** through which the toxic effects are mediated (e.g. atropine)
- **By-passing the effect** of the poison (e.g. oxygen, glucagon).

Reducing poison absorption

To reduce poison absorption through the lungs, remove the casualty from the toxic atmosphere, making sure that rescuers themselves are not put at risk. Contaminated clothing should be removed to reduce dermal absorption and contaminated skin washed thoroughly with soap and water.

Gut decontamination. While it appears logical to assume that removal of unabsorbed drug from the gastrointestinal tract will be beneficial (gut decontamination), the efficacy of gastric lavage and syrup of ipecacuanha remains unproven and efforts to remove small amounts of non-toxic drugs are clinically not worthwhile or appropriate.

Gastric lavage should only be performed if a patient has ingested a potentially life-threatening amount of a poison, e.g. iron, and the procedure can be undertaken within 60 minutes of ingestion. Intubation is required if airway protective reflexes are lost. Lavage is also contraindicated if a hydrocarbon with high aspiration potential or a corrosive substance has been ingested.

Syrup of ipecacuanha should not be used as the amount of drug recovered is highly variable, diminishes with time and there is no evidence that it improves the outcome of poisoned patients.

Single-dose activated charcoal. Activated charcoal is able to adsorb a wide variety of compounds. Exceptions are strong acids and alkalis, ethanol, ethylene glycol, iron, lithium, mercury and methanol.

In studies in volunteers given 50 g activated charcoal, the mean reduction in absorption was 40%, 16% and 21%, at 60 min, 120 min and 180 min, respectively after ingestion. Based on these studies, activated charcoal should be given in those who have ingested a potentially toxic amount of a poison (known to be adsorbed by charcoal). There are insufficient data to support or exclude its use after 1 hour. There is no evidence that administration of activated charcoal improves the clinical outcome.

Cathartics have no role in the management of the poisoned patient.

Whole bowel irrigation requires the insertion of a nasogastric tube into the stomach and the introduction of polyethylene glycol electrolyte solution 1500–2000 mL/h in an adult, which is continued until the rectal effluent is clear. Whole bowel irrigation may be used for potentially toxic ingestions of sustained-release or enteric-coated drugs or to remove illicit drug packets.

Increasing poison elimination

Multiple-dose activated charcoal (MDAC) involves the repeated administration of oral activated charcoal to increase the elimination of a drug that has already been absorbed into the body. Drugs are secreted in the bile and re-enter the gut by passive diffusion if the concentration in the gut is lower than that in the blood. The rate of passive diffusion depends on the concentration gradient and the intestinal surface area, permeability and blood flow. Activated charcoal will bind any drug that is in the gut lumen.

Elimination of drugs with a small volume of distribution (<1 L/kg), low pK_a (which maximizes transport across membranes), low binding affinity and prolonged elimination half-life following overdose is particularly likely to be enhanced by MDAC. MDAC also improves total body clearance of the drug when endogenous processes are compromised by liver and/or renal failure.

Although MDAC has been shown to significantly increase drug elimination, it has not reduced morbidity and mortality in controlled studies. At present, MDAC should only be used in patients who have ingested a life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine or theophylline.

Dosage. In *adults*, charcoal should be administered in an initial dose of 50–100 g and then at a rate of not less than 12.5 g/h, preferably via a nasogastric tube. If the patient has

ingested a drug that induces protracted vomiting (e.g. theophylline), intravenous ondansetron 4–8 mg is effective as an antiemetic and thus enables administration of MDAC.

Urine alkalinization. Increasing the urine pH enhances elimination of salicylate, phenobarbital, chlorpropamide and chlorophenoxy herbicides (e.g. 2,4-dichlorophenoxyacetic acid) by mechanisms which are not clearly understood. Urine alkalinization is not recommended as first-line therapy for poisoning with phenobarbital as MDAC is superior, and supportive care is invariably adequate for chlorpropamide. A substantial diuresis is required in addition to urine alkalinization to achieve clinically relevant elimination of chlorophenoxy herbicides.

Urine alkalinization is a metabolically invasive procedure requiring frequent biochemical monitoring and medical and nursing expertise. Before commencing urine alkalinization, correct plasma volume depletion, electrolytes (administration of sodium bicarbonate exacerbates pre-existing hypokalaemia) and metabolic abnormalities. Sufficient bicarbonate is administered to ensure that the pH of the urine, which is measured by narrow range indicator paper or a pH meter, is more than 7.5 and preferably close to 8.5. In one study, sodium bicarbonate 225 mmol was the mean amount required initially. This is most conveniently administered as 225 mL of an 8.4% solution (1 mmol bicarbonate/mL) i.v. over 1 hour.

Haemodialysis and haemodiafiltration. Haemodialysis and haemodiafiltration are of little value in patients poisoned with drugs with large volumes of distribution (e.g. tricyclic antidepressants), because the plasma contains only a small proportion of the total amount of drug in the body. These methods are indicated in people with severe clinical features and high plasma concentrations of ethanol, ethylene glycol, isopropanol, lithium, methanol and salicylate.

Toxicological investigations

On admission, or at an appropriate time post overdose, a timed blood sample should be taken if it is suspected that aspirin, digoxin, ethylene glycol, iron, lithium, methanol, paracetamol, paraquat, quinine or theophylline has been ingested. The determination of the concentrations of these drugs will be valuable in management. Drug screens on blood and urine are occasionally indicated in severely poisoned patients in whom the cause of coma is unknown. A poison information service will advise.

Non-toxicological investigations (Table 17.17)

Some routine investigations are of value in the differential diagnosis of coma or the detection of poison-induced hypokalaemia, hyperkalaemia, hypoglycaemia, hyperglycaemia, hepatic or renal failure or acid-base disturbances (Table 17.18). Measurement of carboxyhaemoglobin, methaemoglobin and cholinesterase activities are of assistance in the diagnosis and management of cases of poisoning due to carbon monoxide, methaemoglobin-inducing agents such as nitrites and organophosphorus insecticides, respectively.

ECG

Routine ECG is of limited diagnostic value, but continuous ECG monitoring should be undertaken in those ingesting potentially cardiotoxic drugs; for example, sinus tachycardia with prolongation of the PR and QRS intervals in an unconscious patient suggests tricyclic antidepressant overdose. Q-T interval prolongation is an adverse effect of several drugs (e.g. quetiapine and quinine).

Diethylene glycol	Topiramate
Ethanol	Tricyclic antidepressants
Ethylene glycol	

Radiology

Routine radiology is of little diagnostic value. It can confirm ingestion of metallic objects (e.g. coins, button batteries) or injection of globules of metallic mercury. Rarely, hydrocarbon solvents (e.g. carbon tetrachloride) may be seen as a slightly opaque layer floating on the top of the gastric contents with the patient upright, or outlining the small bowel. Some enteric-coated or sustained-release drug formulations may be seen on plain abdominal radiographs, but, with the exception of iron salts, ordinary formulations are seldom seen. Ingested packets of illicit substances can sometimes be seen on CT (see p. 912). Radiology can confirm complications of poisoning, e.g. aspiration pneumonia, non-cardiogenic pulmonary oedema (salicylates), acute respiratory distress syndrome (ARDS).

Specific poisons: drugs

In this section, only specific treatment regimens will be discussed. The general principles of management of self-poisoning will always be required.

Amfetamines including ecstasy (MDMA)

The medicinal product is usually the dextro-isomer, dexamfetamine. The *N*-methylated derivative, metamfetamine (the crystalline form of this salt is known as 'crystal meth' or 'ice'), and 3,4-methylenedioxymetamfetamine (MDMA), commonly known as ecstasy, are used worldwide.

Amfetamines are CNS and cardiovascular stimulants. These effects are mediated by increasing synaptic concentrations of adrenaline (epinephrine) and dopamine.

Clinical features

Amfetamines cause euphoria, extrovert behaviour, a lack of desire to eat or sleep, tremor, dilated pupils, tachycardia and hypertension. More severe intoxication is associated with agitation, paranoid delusions, hallucinations and violent behaviour. Convulsions, rhabdomyolysis, hyperthermia and cardiac arrhythmias may develop in severe poisoning. Rarely, intracerebral and subarachnoid haemorrhage occur and can be fatal.

MDMA poisoning is characterized by agitation, tachycardia, hypertension, widely dilated pupils, trismus and sweating. In more severe cases, hyperthermia, disseminated intravascular coagulation, rhabdomyolysis, acute kidney injury and hyponatraemia (secondary to inappropriate anti-diuretic hormone secretion) predominate.

Treatment

Agitation is controlled by diazepam 10–20 mg i.v. or chlorpromazine 50–100 mg i.m. The peripheral sympathomimetic actions of amfetamines are antagonized by β -adrenoceptor blocking drugs. If hyperthermia is present, dantrolene 1 mg/kg body weight i.v. is used.

Anticonvulsants**Clinical features**

The clinical features of poisoning with anticonvulsant drugs are summarized in Table 17.19.

Treatment

Multiple-dose activated charcoal has been shown to significantly increase elimination of carbamazepine. Early intravenous supplementation with L-carnitine should be used in severe valproate poisoning if hepatotoxicity and encephalopathy are present. Haemodialysis should also be instituted if severe hyperammonaemia and electrolyte and acid–base disturbances occur.

Antidepressants: MAOIs

Monoamine oxidase inhibitors are now used less frequently in the treatment of depression because of the dangers of dietary and drug interactions.

Clinical features

Features after overdose may be delayed for 12–24 hours and include excitement, restlessness, hyperpyrexia, hyperreflexia, convulsions, opisthotonos, rhabdomyolysis and coma. Sinus tachycardia and either hypo- or hypertension have also been observed.

Treatment

Treatment is supportive with control of convulsions and marked excitement; diazepam 10–20 mg i.v. should be given as necessary and repeated. Dantrolene 1 mg/kg i.v. should be administered if hyperpyrexia develops. Hypotension should be treated with plasma expansion and hypertension by the administration of an α -adrenoceptor blocker such as chlorpromazine.

Antidepressants: tricyclics and SSRIs

Tricyclic antidepressants block the reuptake of noradrenaline (norepinephrine) into peripheral and intracerebral neurones, thereby increasing the concentration of monoamines in these

Table 17.19 Clinical features of poisoning with anticonvulsant drugs

Anticonvulsant drug	Clinical features of poisoning
Carbamazepine	Dry mouth, coma, convulsions, ataxia, incoordination, hallucinations (particularly in the recovery phase) Ocular: nystagmus dilated pupils (common), divergent strabismus, complete external ophthalmoplegia (rare)
Phenytoin	Nausea, vomiting, headache, tremor, cerebellar ataxia, nystagmus, loss of consciousness (rare)
Sodium valproate	Most frequent: drowsiness, impairment of consciousness, respiratory depression Uncommon complications: liver damage, hyperammonaemia, metabolic acidosis Very severe poisoning: myoclonic jerks and seizures; cerebral oedema has been reported
Gabapentin and pregabalin	Lethargy, ataxia, slurred speech and gastrointestinal symptoms
Lamotrigine	Lethargy, coma, ataxia, nystagmus, seizures, cardiac conduction abnormalities
Levetiracetam	Lethargy, coma, respiratory depression
Tiagabine	Lethargy, facial grimacing, nystagmus, posturing, agitation, coma, hallucinations, seizures
Topiramate	Lethargy, ataxia, nystagmus, myoclonus, coma, seizures, non-anion gap metabolic acidosis Metabolic acidosis can appear within hours of ingestion and persist for days

areas, and also have antimuscarinic actions and class 1 antiarrhythmic (quinidine-like) activity. Citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline are selective serotonin reuptake inhibitors (SSRIs) and lack the antimuscarinic actions of tricyclic antidepressants.

Clinical features

Even large overdoses of SSRIs appear to be relatively safe unless potentiated by ethanol. Most patients will show no signs of toxicity but drowsiness, nausea, diarrhoea and sinus tachycardia have been reported. Rarely, junctional bradycardia, seizures and hypertension have been encountered and influenza-like symptoms may develop. In contrast, drowsiness, sinus tachycardia, dry mouth, dilated pupils, urinary retention, increased reflexes and extensor plantar responses are the most common features of mild tricyclic antidepressant poisoning. Severe intoxication leads to coma, often with divergent strabismus and convulsions. Plantar, oculocephalic and oculovestibular reflexes may be abolished temporarily. An ECG will often show a wide QRS interval and there is a reasonable correlation between the width of the QRS complex and the severity of poisoning. Metabolic acidosis and cardiorespiratory depression are observed in severe cases.

Treatment

The majority of patients recover with supportive therapy alone (adequate oxygenation, control of convulsions and correction of acidosis), although a small percentage of patients who ingest a tricyclic will require assisted ventilation for 24–48 hours. The onset of supraventricular tachycardia and ventricular tachycardia should be treated with sodium bicarbonate (8.4%) 50 mmol intravenously over 20 min, even if there is no acidosis present. If ventricular tachycardia is compromising cardiac output, amiodarone 300 mg i.v. over 20–60 min should be administered.

Antidiabetic drugs

Insulin (if injected but not if ingested) and sulfonylureas cause hypoglycaemia, not seen with metformin, since its mode of action is to increase glucose utilization, but lactic acidosis is a potentially serious complication of metformin poisoning.

Clinical features

Features of severe hypoglycaemia include drowsiness, coma, convulsions, depressed limb reflexes, extensor plantar responses and cerebral oedema. Hypokalaemia may be associated. Neurogenic diabetes insipidus and persistent vegetative states are possible long-term complications if hypoglycaemia is prolonged. Cholestatic jaundice has been described as a late complication of chlorpropamide poisoning.

Treatment

The blood or plasma glucose concentration should be measured urgently and intravenous glucose given, if necessary. Glucagon produces only a slight rise in blood glucose, although it can reduce the amount of glucose required (see p. 1001).

Severe insulin poisoning. A continuous infusion of 10–20% glucose (with K⁺ 10–20 mmol/L) together with carbohydrate-rich meals are required, though there may be difficulty in maintaining normoglycaemia.

Sulfonylurea poisoning. The administration of glucose increases already high circulating insulin concentrations. Octreotide (50 µg i.v.), which inhibits insulin release, should be given as well as glucose.

Antimalarials

Clinical features

Chloroquine. Hypotension is often the first clinical manifestation of chloroquine poisoning. It may progress to acute heart failure, pulmonary oedema and cardiac arrest. Agitation and acute psychosis, convulsions and coma may ensue. Hypokalaemia is common and is due to chloroquine-induced potassium channel blockade. Bradyarrhythmias and tachyarrhythmias are common and ECG conduction abnormalities are similar to those seen in quinine poisoning.

Quinine. Cinchonism (tinnitus, deafness, vertigo, nausea, headache and diarrhoea) is common. In more severe poisoning, convulsions, hypotension, pulmonary oedema and cardiorespiratory arrest is seen (due to ventricular arrhythmias which are often preceded by ECG conduction abnormalities, particularly QT prolongation). Quinine cardiotoxicity is due to sodium channel blockade. Patients may also

develop ocular features, including blindness, which can be permanent.

Primaquine. The main concern regarding primaquine is its propensity to cause methaemoglobinaemia and haemolytic anaemia.

Treatment

Multiple-dose oral activated charcoal increases quinine and probably chloroquine clearance. Hypokalaemia should be corrected. Sodium bicarbonate 50–100 mmol i.v. is given if the ECG shows intraventricular block but will exacerbate hypokalaemia, which should be corrected first. Mechanical ventilation, the administration of an inotrope and high doses of diazepam (1 mg/kg as a loading dose and 0.25–0.4 mg/kg per hour maintenance) may reduce the mortality in severe chloroquine poisoning. Overdrive pacing may be required if torsades de pointes (p. 710) occurs in quinine poisoning and does not respond to magnesium sulphate infusion. If clinically significant methaemoglobinaemia (generally above 30%) develops in primaquine poisoning, methylthioninium (methyl-ene blue) 1–2 mg/kg body weight should be administered.

β -Adrenoceptor blocking drugs

Clinical features

In mild poisoning, sinus bradycardia is the only feature, but if a substantial amount has been ingested, coma, convulsions and hypotension develop. Less commonly, delirium, hallucinations and cardiac arrest supervene.

Treatment

Glucagon 50–150 μ g/kg (typically 5–10 mg in an adult) followed by an infusion of 1–5 mg/h is the most effective agent. It acts by by-passing the blocked beta-receptor thus activating adenylyl cyclase and promoting formation of cyclic AMP from ATP; cyclic AMP in turn exerts a direct beta-stimulant effect on the heart. Atropine 0.6–1.2 mg i.v. can be used to treat bradycardia but is usually less effective.

Benzodiazepines

Benzodiazepines are commonly taken in overdose but rarely produce severe poisoning except in the elderly or those with chronic respiratory disease.

Clinical features

Benzodiazepines produce drowsiness, ataxia, dysarthria and nystagmus. Coma and respiratory depression develop in severe intoxication.

Treatment

If respiratory depression is present in patients who have severe benzodiazepine poisoning, flumazenil 0.5–1.0 mg i.v. is given in an adult and this dose often needs repeating. Flumazenil use often avoids ventilation. It is contraindicated in mixed tricyclic antidepressant (TCA)/benzodiazepine poisoning and in those with a history of epilepsy because it may cause convulsions.

Calcium channel blockers

Calcium channel blockers all act by blocking voltage-gated calcium channels. Dihydropyridines (e.g. amlodipine, felodipine, nifedipine) are predominantly peripheral vasodilators while verapamil and, to a lesser extent, diltiazem also have significant cardiac effects. Poisoning, particularly with verapamil and diltiazem, causes heart block and hypotension and there is a substantial fatality rate.

Clinical features

Hypotension occurs due to peripheral vasodilatation, myocardial depression and conduction block. The electrocardiogram may progress from sinus bradycardia through first, then higher, degrees of block, to asystole. Cardiac and non-cardiac pulmonary oedema may ensue in severely poisoned patients. Other features include nausea, vomiting, seizures and a lactic acidosis. When a sustained-release preparation has been ingested the onset of severe features is delayed, sometimes for more than 12 hours. Overdose with even small amounts can have profound effects.

Treatment

Intravenous atropine 0.6–1.2 mg, repeated as required, should be given for bradycardia and heart block. The initial dose can be repeated every 3–5 min but if there is no response in pulse rate or blood pressure after three such doses it is unlikely that further boluses will be helpful. The response to atropine is sometimes improved following intravenous 10% calcium chloride, 5–10 mL (at 1–2 mL/min). If there is an initial response to calcium, a continuous infusion is warranted; this is given as 10% calcium chloride, 1–10 mL/h.

Cardiac pacing has a role if there is evidence of AV conduction delay but failure to capture occurs.

Treat hypotension initially with intravenous crystalloid. If significant hypotension persists despite volume replacement, administer glucagon (see p. 409) as it activates myosin kinase independent of calcium. Give i.v. glucagon 10 mg (150 μ g/kg) as a slow bolus and repeat. If there is a favourable response in blood pressure, an infusion of 5–10 mg/h can be commenced; if there is no response after the initial boluses, discontinue.

Insulin–glucose euglycaemia has been shown to improve myocardial contractility and systemic perfusion. If hypotension persists despite the above measures, insulin is given as a bolus dose of 1 U/kg, followed by an infusion of 1–10 U/kg per hour with 10% glucose and frequent monitoring of blood glucose and potassium.

Acidosis impairs L-type channel function (see p. 708) and is corrected by the administration of sodium bicarbonate, which has been shown experimentally to improve myocardial contractility and cardiac output.

Cannabis (marijuana)

Cannabis is usually smoked but may be ingested as a 'cake', made into a tea or injected intravenously. Apart from alcohol, it is the drug most widely used in developed countries. The major psychoactive constituent is delta-11-tetrahydrocannabinol (THC). THC possesses activity at the benzodiazepine, opioid and cannabinoid receptors. Street names include pot, grass, ganga, reefs and spliff. It is prepared as marijuana (ganga) from the female flowers; hashish or charas – a concentrated resin of glandular trichomes; kief – chopped female plants; and bhang – a drink prepared from cannabis leaves boiled in milk with spices.

Clinical features

Initially there is euphoria, followed by distorted and heightened images, colours and sounds, altered tactile sensations and sinus tachycardia. Visual and auditory hallucinations and acute psychosis are particularly likely to occur after substantial ingestion in naive cannabis users. Intravenous injection leads to watery diarrhoea, tachycardia, hypotension and arthralgia.

Heavy users suffer impairment of memory and attention and poor academic performance. There is an increased risk of anxiety and depression. Regular users are at risk of dependence. Cannabis use results in an overall increase in the relative risk for later schizophrenia and psychotic episodes (see p. 1185). Cannabis smoke is probably carcinogenic.

Treatment

Reassurance is usually the only treatment required, although sedation with intravenous diazepam 10–20 mg i.v. in an adult or chlorpromazine 50–100 mg i.m. in an adult is sometimes required. Hypotension requires i.v. fluids.

Cocaine

Cocaine hydrochloride ('street' cocaine, 'coke') is a water-soluble powder or granule that can be taken orally, intravenously or intranasally. 'Freebase' or 'crack' cocaine comprises crystals of relatively pure cocaine without the hydrochloride moiety and is obtained in rocks (150 mg of cocaine). It is more suitable for smoking in a pipe or mixed with tobacco and can also be heated on foil and the vapour inhaled (approximately 35 mg of drug per 'line' or a 'rail'). The 'effects' of cocaine are experienced almost immediately with i.v. or smoking routes, about 10 min in the intranasal route and 45–90 min when taken orally. The effects start resolving in about 20 min and last up to 90 min. In severe poisoning, death occurs in minutes but survival beyond 3 hours is not usually fatal.

Cocaine blocks the reuptake of biogenic amines. Inhibition of dopamine reuptake is responsible for the psychomotor agitation which commonly accompanies cocaine use. Blockade of noradrenaline (norepinephrine), reuptake produces tachycardia, and inhibition of serotonin reuptake induces hallucinations. Cocaine also enhances CNS arousal by potentiating the effects of excitatory amino acids. Cocaine is also a powerful local anaesthetic and vasoconstrictor.

Clinical features

After initial euphoria, cocaine produces agitation, tachycardia, hypertension, sweating, hallucinations, convulsions, metabolic acidosis, hyperthermia, rhabdomyolysis and ventricular arrhythmias. Dissection of the aorta, myocarditis, myocardial infarction, dilated cardiomyopathy, subarachnoid haemorrhage, and cerebral haemorrhage and infarction also occur. If a young person presents with a stroke or myocardial infarction, cocaine poisoning, because of its vasoconstrictor effect, is a possible diagnosis.

Treatment

Diazepam 10–20 mg i.v. is used to control agitation and convulsions. Active external cooling should be used for hyperthermia. Hypertension and tachycardia usually respond to sedation and cooling. If hypertension persists, give i.v. nitrates such as glyceryl trinitrate starting at 1–2 mg/h and gradually increase the dose (maximum 12 mg/h) until BP is controlled. Calcium channel blockers such as nifedipine, verapamil or diltiazem are an alternative as second-line therapy. The use of beta-blockers is controversial. Early use of a benzodiazepine is often effective in relieving cocaine-associated non-cardiac chest pain. Aspirin and nitrates should be given to all people with chest pain suspected of being cardiac in origin. Treat myocardial ischaemia/infarction conventionally.

Digoxin

Toxicity occurring during chronic administration is common, though acute poisoning is infrequent.

Clinical features

These include nausea, vomiting, dizziness, anorexia and drowsiness. Rarely, confusion, visual disturbances and hallucinations occur. Sinus bradycardia is often marked and may be followed by supraventricular arrhythmias with or without heart block, ventricular premature beats and ventricular tachycardia. Hyperkalaemia occurs due to the inhibition of the sodium-potassium activated ATPase pump.

Treatment

Sinus bradycardia, atrioventricular block and sinoatrial standstill are often reduced or even abolished by atropine 1.2–2.4 mg i.v. If cardiac output is compromised, however, digoxin-specific antibody fragments (digoxin-Fab) should be administered. In both acute and chronic poisoning, only half the estimated dose (calculated from amount of drug taken or serum digoxin concentration) required for full neutralization need be given initially; a further dose is given if clinically indicated.

Gamma-hydroxybutyric acid (GHB)

Gamma-hydroxybutyric acid occurs naturally in mammalian brain where it is derived metabolically from gamma-aminobutyric acid (GABA). GHB has emerged as a major recreational drug for body building, weight loss and for producing a 'high'. Street names include cherry meth and liquid X. It is taken as a colourless liquid dissolved in water.

Clinical features

Poisoning with GHB is characterized by aggressive behaviour, ataxia, amnesia, vomiting, drowsiness, bradycardia, respiratory depression and apnoea, seizures and characteristically coma, which is short-lived.

Management

In a patient who is breathing spontaneously, the management of GHB poisoning is primarily supportive with oxygen supplementation and the administration of atropine for persistent bradycardia, as necessary. Those who are severely poisoned will require mechanical ventilation, although recovery is usually complete within 6–8 hours.

Iron

Unless more than 60 mg of elemental iron per kg of body weight is ingested (a ferrous sulphate tablet contains 60 mg of iron), features are unlikely to develop. As a result poisoning is seldom severe but deaths still occur. Iron salts have a direct corrosive effect on the upper gastrointestinal tract.

Clinical features

The initial features are characterized by nausea, vomiting (the vomit may be grey or black in colour), abdominal pain and diarrhoea. Severely poisoned patients develop haematemesis, hypotension, coma and shock at an early stage. Usually, however, most patients only suffer mild gastrointestinal symptoms. A small minority deteriorate 12–48 hours after ingestion and develop shock, metabolic acidosis, acute tubular necrosis and hepatocellular necrosis. Rarely, up to 6 weeks after ingestion, intestinal strictures due to corrosive damage occur. The serum iron concentration should be measured some 4 hours after ingestion and if the concentration exceeds the predicted normal iron binding capacity (usually >5 mg/L; 90 µmol/L), free iron is circulating and treatment with desferrioxamine is required.

Treatment

The majority of patients ingesting iron do not require desferrioxamine therapy. If a patient develops coma or shock, desferrioxamine should be given without delay in a dose of 15 mg/kg per hour i.v. (total amount of infusion usually not to exceed 80 mg/kg in 24 hours). If the recommended rate of administration is continued for several days, adverse effects including pulmonary oedema and ARDS have been reported.

Lithium

Lithium toxicity is usually the result of therapeutic overdosage (chronic toxicity) rather than deliberate self-poisoning (acute toxicity). However, single large doses are occasionally ingested by individuals on long-term treatment with the drug (acute on therapeutic toxicity).

Clinical features

Features of intoxication include thirst, polyuria, diarrhoea and vomiting and in more serious cases impairment of consciousness, hypertonia and convulsions; irreversible neurological damage occurs. Measurement of the serum lithium concentration confirms the diagnosis. Acute massive overdose may produce concentrations of 5 mmol/L (34.7 mg/L) without causing toxic features, whereas chronic toxicity is associated with neurological features at concentrations >1.5 mmol/L (6.94 mg/L).

Treatment

Forced diuresis with sodium chloride 0.9% is effective in increasing elimination of lithium, though haemodialysis is far superior and should be undertaken particularly if neurological features are present, if renal function is impaired and if chronic toxicity or acute on chronic toxicity are the modes of presentation.

Neuroleptics and atypical neuroleptics

Neuroleptic (antipsychotic) drugs are thought to act predominantly by blockade of the dopamine D₂ receptors. Older neuroleptics include the phenothiazines, the butyrophenones (benperidol, haloperidol) and the substituted benzamides (sulpiride). More selective 'atypical' antipsychotics include amisulpride, aripiprazole, clozapine, olanzapine, quetiapine and risperidone.

Clinical features

These include impaired consciousness, hypotension, respiratory depression, hypothermia or hyperthermia, antimuscarinic effects such as tachycardia, dry mouth and blurred vision, occasionally seizures, rhabdomyolysis, cardiac arrhythmias (both atrial and ventricular) and acute respiratory distress syndrome. Extrapyrimal effects, including acute dystonic reactions, occur but are not dose related. Most 'atypical' antipsychotics have less profound sedative actions than the older neuroleptics. Q-T interval prolongation and subsequent ventricular arrhythmias (including torsades de pointes) have occurred following overdose with the atypical neuroleptics. Unpredictable fluctuations in conscious level, with variations between agitation and marked somnolence, have been particularly associated with olanzapine overdose.

Treatment

Procyclidine 5–10 mg i.v. in an adult is occasionally required for the treatment of dyskinesia and oculogyric crisis. If hypotension is severe and does not respond to intravenous fluids,

a sympathomimetic amine such as noradrenaline (norepinephrine) is used. After correcting acidosis with sodium bicarbonate, the preferred treatment for arrhythmias caused by antipsychotic drugs (usually torsades de pointes) is intravenous magnesium or cardiac pacing. Amiodarone is used if multifocal ventricular arrhythmias occur.

Non-steroidal anti-inflammatory agents (NSAIDs)

Self-poisoning with NSAIDs has increased, particularly now that ibuprofen is available without prescription in many countries.

Clinical features and treatment

In most cases minor gastrointestinal disturbance is the only feature but, in more severe cases, coma, convulsions and acute kidney injury have occurred. Transient renal impairment is common after ibuprofen overdose. Poisoning with mefenamic acid commonly results in convulsions though these are usually short-lived.

Treatment is symptomatic and supportive.

Opiates and opioids**Clinical features**

Cardinal signs of opiate poisoning are pinpoint pupils, reduced respiratory rate and coma. Hypothermia, hypoglycaemia and convulsions are occasionally observed in severe cases. In severe heroin overdose, non-cardiogenic pulmonary oedema has been reported.

Treatment

Naloxone 1.2–2.0 mg i.v. will reverse at least partially severe respiratory depression and coma. In severe poisoning larger initial doses or repeat doses will be required. The duration of action of naloxone is often less than the drug taken in overdose, e.g. methadone, which has a very long half-life. For this reason an infusion of naloxone is often required. Non-cardiogenic pulmonary oedema should be treated with mechanical ventilation.

Paracetamol (acetaminophen)

Paracetamol is the most common form of poisoning encountered in the UK. In therapeutic dose, paracetamol is conjugated with glucuronide and sulphate. A small amount of paracetamol is metabolized by mixed function oxidase enzymes to form a highly reactive compound (*N*-acetyl-*p*-benzoquinoneimine, NAPQI), which is then immediately conjugated with glutathione and subsequently excreted as cysteine and mercapturic conjugates. In overdose, large amounts of paracetamol are metabolized by oxidation because of saturation of the sulphate conjugation pathway. Liver glutathione stores become depleted so that the liver is unable to deactivate the toxic metabolite. Paracetamol-induced renal damage probably results from a mechanism similar to that which is responsible for hepatotoxicity.

The severity of paracetamol poisoning is dose related. There is, however, some variation in individual susceptibility to paracetamol-induced hepatotoxicity. People with pre-existing liver disease, those suffering from acute or chronic starvation (patients not eating for a few days for example due to a recent febrile illness or dental pain), those suffering from anorexia nervosa and other eating disorders, those receiving enzyme-inducing drugs, and those with HIV infection should be considered to be at greater risk and given treatment at

Jaeger A. Lithium. *Medicine* 2012; 40:131–132.

plasma paracetamol concentrations lower than those normally used for interpretation (Fig. 17.2).

Clinical features

Following the ingestion of an overdose of paracetamol, patients usually remain asymptomatic for the first 24 hours

Figure 17.2 Nomogram of paracetamol. For definition of 'high-risk patients', see text.

or at the most develop anorexia, nausea and vomiting. Liver damage is not usually detectable by routine liver function tests until at least 18 hours after ingestion of the drug. Liver damage usually reaches a peak, as assessed by measurement of alanine transferase (ALT) activity and prothrombin time (INR), at 72–96 hours after ingestion. Without treatment, a small percentage of patients will develop fulminant hepatic failure. Acute kidney injury due to acute tubular necrosis occurs in 25% of patients who have severe hepatic damage and in a few without evidence of serious disturbance of liver function.

Treatment

The treatment protocol is dependent on the time of presentation and this is summarized in Table 17.20. Acetylcysteine has emerged as an effective protective agent provided that it is administered within 8–10 hours of ingestion of the overdose. It acts by replenishing cellular glutathione stores, though it may also repair oxidation damage caused by NAPQI. The treatment regimen is shown in Table 17.21. If a staggered overdose has been taken (multiple ingestions over several hours), acetylcysteine should be given when the paracetamol dose exceeds 150 mg/kg body weight in any one 24-hour period or 75 mg/kg body weight in those at high risk (see above).

Table 17.21 Regimen for acetylcysteine

Acetylcysteine 150 mg/kg in 200 mL 5% glucose over 15 min, then 50 mg/kg in 500 mL of 5% glucose over the next 4 h and then 100 mg/kg in 1000 mL of 5% glucose over the ensuing 16 h
Total dose 300 mg/kg over 20.25 h

Table 17.20 Management of people with paracetamol poisoning

≤8 h after ingestion

- Take blood for urgent estimation of the plasma paracetamol concentration as soon as 4 h or more have elapsed since ingestion. Check INR, plasma creatinine and alanine transferase (ALT) activity
- Assess whether the patient is at risk of liver damage
- Give treatment if needed (Fig. 17.2)
- If the plasma paracetamol concentration is not available within 8 h of the overdose and, if >150 mg/kg paracetamol has been ingested, treatment with acetylcysteine should be started at once and stopped if the plasma paracetamol concentration subsequently indicates that treatment is not required
- Check INR, plasma creatinine and ALT activity on the completion of treatment and before discharge

8–15 h after ingestion

- Urgent action is required because the efficacy of treatment declines progressively from 8 h after overdose. If >150 mg/kg paracetamol has been ingested, start treatment with acetylcysteine immediately
- Take blood for urgent estimation of the plasma paracetamol concentration, INR, plasma creatinine and ALT activity
- Assess whether the patient is at risk of liver damage
- The need for treatment is determined by using Fig. 17.2
- In patients already receiving acetylcysteine, only discontinue if the plasma paracetamol concentration is below the relevant treatment line (Fig. 17.2) and there is no abnormality of the INR, plasma creatinine or ALT activity and the patient is asymptomatic. Do not discontinue the infusion if there is any doubt as to the timing of the overdose
- At the end of treatment, measure INR, plasma creatinine and ALT activity. If any test is abnormal or the patient is symptomatic, further monitoring is required and expert advice should be sought
- People with normal INR, plasma creatinine and ALT activity and who are asymptomatic may be discharged

15–24 h after ingestion

- Urgent action is required because the efficacy of treatment is limited more than 15 h after overdose. Start treatment with acetylcysteine immediately if >150 mg/kg paracetamol has been ingested
- In all patients, take blood for urgent estimation of the plasma paracetamol concentration, INR, plasma creatinine and ALT activity
- Assess whether the patient is at risk of liver damage
- Give treatment if needed (Fig. 17.2). The prognostic accuracy of the '200 mg/L line' after 15 h is uncertain but a plasma paracetamol concentration above the extended treatment line should be regarded as carrying serious risk of severe liver damage
- At the end of treatment, check INR, plasma creatinine and ALT activity. If any test is abnormal or the patient is symptomatic, further monitoring is required and expert advice should be sought

FURTHER READING

Vale A. Paracetamol (acetaminophen). *Medicine* 2012; 40:144–146.

Up to 15% of patients treated with intravenous acetylcysteine (20.25-h regimen) develop rash, angio-oedema, hypotension and bronchospasm. These reactions, which are related to the initial bolus, are seldom serious and discontinuing the infusion is usually all that is required. In more severe cases, chlorphenamine 10–20 mg i.v. in an adult should be given.

If liver or renal failure ensues, this should be treated conventionally though there is evidence that a continuing infusion of acetylcysteine (continue 16-h infusion until recovery) will improve the morbidity and mortality. Liver transplantation has been performed successfully in patients who have paracetamol-induced fulminant hepatic failure (see p. 316).

Salicylates

Aspirin is metabolized to salicylic acid (salicylate) by esterases present in many tissues, especially the liver, and subsequently to salicyluric acid and salicyl phenolic glucuronide (Fig. 17.3); these two pathways become saturated with the consequence that the renal excretion of salicylic acid increases after overdose; this excretion pathway is extremely sensitive to changes in urinary pH.

Clinical features

Salicylates stimulate the respiratory centre, increase the depth and rate of respiration, and induce a respiratory alkalosis. Compensatory mechanisms, including renal excretion of bicarbonate and potassium, result in a metabolic acidosis. Salicylates also interfere with carbohydrate, fat and protein metabolism, and disrupt oxidative phosphorylation, producing increased concentrations of lactate, pyruvate and ketone bodies, all of which contribute to the acidosis.

Thus, tachypnoea, sweating, vomiting, epigastric pain, tinnitus and deafness develop. Respiratory alkalosis and metabolic acidosis supervene and a mixed acid–base disturbance is observed commonly. Rarely, in severe poisoning, non-cardiogenic pulmonary oedema, coma and convulsions ensue.

The severity of salicylate toxicity is dose-related.

Treatment

Fluid and electrolyte replacement is required and special attention should be paid to potassium supplementation. Severe metabolic acidosis requires at least partial correction with the administration of sodium bicarbonate intravenously. Mild cases of salicylate poisoning are managed with

parenteral fluid and electrolyte replacement only. Patients whose plasma salicylate concentrations are in excess of 500 mg/L (3.62 mmol/L) should receive urine alkalization (see p. 913). Haemodialysis is the treatment of choice for severely poisoned patients (plasma salicylate concentration >700 mg/L; >5.07 mmol/L), particularly those with coma and metabolic acidosis.

Theophylline

Poisoning may complicate therapeutic use as well as being the result of deliberate self-poisoning. If a slow-release preparation is involved, peak plasma concentrations are not attained until 6–12 hours after overdosage and the onset of toxic features is correspondingly delayed.

Clinical features

Nausea, vomiting, hyperventilation, haematemesis, abdominal pain, diarrhoea, sinus tachycardia, supraventricular and ventricular arrhythmias, hypotension, restlessness, irritability, headache, hyperreflexia, tremors and convulsions have been observed. Hypokalaemia probably results from activation of Na⁺/K⁺ ATPase. A mixed acid–base disturbance is common. Most symptomatic patients have plasma theophylline concentrations in excess of 25 mg/L (430 µmol/L). Convulsions are seen more commonly when concentrations are >50 mg/L (>860 µmol/L). Plasma potassium concentrations of <2.6 mmol/L, metabolic acidosis, hypotension, seizures and arrhythmias are indications of severe poisoning.

Treatment

There is good evidence that multiple-dose (12.5 g/h) activated charcoal enhances the elimination of theophylline. However, protracted theophylline-induced vomiting may mitigate the benefit of this therapy, unless vomiting is suppressed by a 5HT₃ antagonist such as ondansetron 4–8 mg i.v. Correction of hypokalaemia to prevent or treat tachyarrhythmias is of great importance. A non-selective β-adrenoceptor blocking drug, such as propranolol, is also useful in the treatment of tachyarrhythmias secondary to hypokalaemia, but should not be given if the patient has severe airways disease. Convulsions should be treated with diazepam 10–20 mg i.v. in an adult.

Specific poisons: chemicals**Carbamate insecticides**

Carbamate insecticides inhibit acetylcholinesterase, as do organophosphorus insecticides, but the duration of this inhibition is comparatively short-lived in comparison since the carbamate–enzyme complex tends to dissociate spontaneously. The clinical features and treatment are similar except that an oxime such as pralidoxime is not usually required because the enzyme complex dissociates spontaneously; recovery invariably occurs within 24 hours (see p. 923).

Carbon monoxide

The commonest source of carbon monoxide is an improperly maintained and poor, ventilated heating system. In addition, inhalation of methylene chloride (found in paint strippers) may also lead to carbon monoxide poisoning as methylene chloride is metabolized *in vivo* to carbon monoxide. The affinity of haemoglobin for carbon monoxide is some 240 times greater than that for oxygen. Carbon monoxide combines with haemoglobin to form carboxyhaemoglobin, thereby reducing the total oxygen carrying capacity of the blood and increasing the affinity of the remaining haem groups for oxygen. This

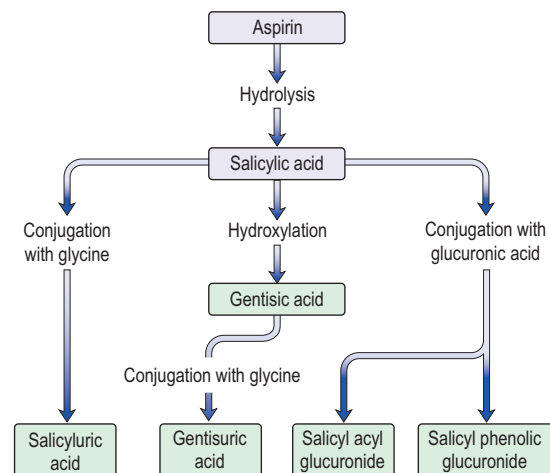

Figure 17.3 The metabolism of aspirin.

results in tissue hypoxia. In addition, carbon monoxide also inhibits cytochrome oxidase a_3 .

Clinical features

Symptoms of mild to moderate exposure to carbon monoxide may be mistaken for a viral illness. A peak carboxyhaemoglobin (COHb) concentration of less than 10% is not normally associated with symptoms and peak COHb concentrations of 10–30% usually result only in headache and mild exertional dyspnoea. Higher concentrations of COHb are associated with coma, convulsions and cardiorespiratory arrest. Metabolic acidosis, myocardial ischaemia, hypertonia, extensor plantar responses, retinal haemorrhages and papilloedema also occur. Neuropsychiatric features may develop after apparent recovery from carbon monoxide exposure.

Treatment

In addition to removing the patient from carbon monoxide exposure, high flow oxygen should be administered using a tightly fitting face mask. Endotracheal intubation and mechanical ventilation is required in those who are unconscious. Several controlled studies of hyperbaric oxygen have been published but none have shown long-term clinical benefit.

Cyanide

Cyanide and its derivatives are used widely in industry. Hydrogen cyanide is also released during the thermal decomposition of polyurethane foams. Cyanide reversibly inhibits cytochrome oxidase a_3 so that cellular respiration ceases.

Clinical features

Inhalation of hydrogen cyanide produces symptoms within seconds and death within minutes. By contrast, the ingestion of a cyanide salt may not produce features for 1 hour. After exposure initial symptoms are non-specific and include a feeling of constriction in the chest and dyspnoea. Coma, convulsions and metabolic acidosis may then supervene.

Treatment

Oxygen should be administered and, if available, dicobalt edetate 300 mg should be administered intravenously; the dose is repeated in severe cases. Dicobalt edetate (and the free cobalt contained in the preparation) complexes free cyanide. An alternative but expensive antidote is hydroxocobalamin, which enhances endogenous cyanide detoxification mechanisms: 5 g i.v. is administered, and a second dose may be required in severe cases. If these two antidotes are not available sodium thiosulphate 12.5 g i.v., which acts by enhancing endogenous detoxification, and sodium nitrite 300 mg i.v. should be administered. Sodium nitrite produces methaemoglobinaemia; methaemoglobin combines with cyanide to form cyanmethaemoglobin.

Ethanol

Ethanol is commonly ingested in beverages and deliberately with other substances in overdose. It is also present in many cosmetic and antiseptic preparations. Following absorption, ethanol is oxidized to acetaldehyde and then to acetate. Ethanol is a CNS depressant and the features of ethanol intoxication are generally related to blood concentrations (Table 17.22).

Clinical features

In children in particular severe hypoglycaemia may accompany alcohol intoxication due to inhibition of gluconeogenesis. Hypoglycaemia is also observed in those who are

Table 17.22 Clinical features of ethanol poisoning

Blood (ethanol)		Clinical features
mg/L	mmol/L	
500–1500	11.0–32.5	Emotional lability Mild impairment of coordination
1500–3000	32.5–65.0	Visual impairment Incoordination Slowed reaction time Slurred speech
3000–5000	65.0–108.5	Marked incoordination Blurred or double vision Stupor Occasionally hypoglycaemia, hypothermia and convulsions
>5000	>108.5	Depressed reflexes Respiratory depression Hypotension Hypothermia Death (from respiratory or circulatory failure or aspiration)

malnourished or who have fasted in the previous 24 hours. In severe cases of intoxication, coma and hypothermia are often present and lactic acidosis, ketoacidosis and acute kidney injury have been reported.

Treatment

As ethanol-induced hypoglycaemia is not responsive to glucagon, i.v. glucose 10–20% should be infused at a rate determined by the blood sugar. Haemodialysis is used if the blood ethanol concentration exceeds 7500 mg/L and if a severe metabolic acidosis is present, which has not been corrected by i.v. fluids and bicarbonate.

Ethylene and diethylene glycol

Ethylene and diethylene glycol are found in a variety of common household products including antifreeze, windshield washer fluid, brake fluid and lubricants. The features observed are due to metabolites predominantly, not the parent chemical. Ethylene glycol (Fig. 17.4) is metabolized to glycolate, the cause of the acidosis. A small proportion of glyoxylate is metabolized to oxalate. Calcium ions chelate oxalate to form insoluble calcium oxalate, which is responsible for renal toxicity. Diethylene glycol is metabolized to 2-hydroxyethoxyacetate (Fig. 17.5), which is the cause of metabolic acidosis, and diglycolic acid (the cause of renal failure).

Clinical features

Initially, the features of ethylene glycol poisoning are similar to ethanol intoxication (though there is no ethanol on the breath). Coma and convulsions follow and a variety of neurological abnormalities, including nystagmus and ophthalmoplegias, are seen. Severe metabolic acidosis, hypocalcaemia and acute kidney disease are well-recognized complications. In diethylene glycol poisoning nausea and vomiting, headache, abdominal pain, coma, seizures, metabolic acidosis and acute kidney injury commonly occur. Pancreatitis and hepatitis, together with cranial neuropathies and demyelinating peripheral neuropathy, are also seen.

Treatment

If the patient presents early after ingestion, the first priority is to inhibit metabolism using either intravenous fomepizole

FURTHER READING

Buckley NA, Isbister GK, Stokes B et al. Hyperbaric oxygen for carbon monoxide poisoning: a systematic review and critical analysis of the evidence. *Toxicol Rev* 2005; 24:75–92.

Figure 17.4 The metabolism of ethylene glycol. ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; AO, aldehyde oxidase; GO, glyoxylate oxidase; LDH, lactate dehydrogenase.

Figure 17.5 The metabolism of diethylene glycol. ADH, alcohol dehydrogenase.

or ethanol; the former does not require monitoring. Fomepizole 15 mg/kg body weight should be administered followed by four 12-hourly doses of 10 mg/kg, then 15 mg/kg every 12 hours until glycol concentrations are not detectable. Following a substantial ingestion, haemodialysis or haemodialfiltration should be employed to remove the glycol and metabolites. If dialysis is employed the frequency of fomepizole dosing should be increased to 4-hourly because fomepizole is dialysable. Alternatively, a loading dose of ethanol 50 g should be administered followed by an i.v. infusion of ethanol 10–12 g/h to produce blood ethanol concentrations of 500–1000 mg/L (11–22 mmol/L). The infusion is continued until the glycol is no longer detectable in the blood. If haemodialysis is employed, the rate of ethanol administration will need to be increased to 17–22 g/h as ethanol is dialysable. Supportive measures to combat shock, hypocalcaemia and metabolic acidosis should be instituted.

Household products

The agents most commonly involved are bleach, cosmetics, toiletries, detergents, disinfectants and petroleum distillates such as paraffin and white spirit. Ingestion of household products is usually accidental and is most common among children less than 5 years of age.

Clinical features

If the ingestion is accidental, features very rarely occur except in the case of petroleum distillates where aspiration is a recognized complication because of their low surface tension. Powder detergents, sterilizing tablets, denture cleaning tablets and industrial bleaches (which contain high concentrations of sodium hypochlorite) are corrosive to the mouth and pharynx if ingested. Nail polish and nail polish remover contain acetone that may produce coma if ingested in substantial quantities. Inhalation by small children of substantial quantities of talcum powder has occasionally given rise to severe pulmonary oedema and death.

Lead

Exposure to lead occurs occupationally, children may eat lead-painted items in their homes (pica) and the use of lead-containing cosmetics or 'drugs' has also resulted in lead poisoning.

Clinical features

Mild intoxication may result in no more than lethargy and occasional abdominal discomfort, though abdominal pain,

vomiting, constipation and encephalopathy (seizures, delirium, coma) may develop in more severe cases. Encephalopathy is more common in children than in adults but is now rare in the developed world. Typically, though very rarely, lead poisoning results in foot drop attributable to peripheral motor neuropathy. A bluish discoloration of the gum margins due to the deposition of lead sulphide is observed occasionally.

The characteristic haematological features include:

- **Normochromic normocytic anaemia**, due to inhibition by lead of several enzymes involved in haem synthesis, including ALA synthetase
- **Haemolysis**, which is usually mild, resulting from damage to the red cell membrane
- **Punctate basophilia** (or basophilic stippling: the blood film shows red cells with small, round, blue particles), due to aggregates of RNA in immature red cells owing to inhibition by lead of pyrimidine-5-nucleotidase, which normally disperses residual RNA to produce a diffuse blue staining seen in reticulocytes on blood films (polychromasia).

Treatment

The social and occupational dimensions of lead poisoning must be recognized. Simply giving the patient chelation therapy and then returning them to a contaminated environment is of no value.

The decision to use chelation therapy is based not only on the blood lead concentration but on the presence of symptoms. Parenteral sodium calcium edetate 75 mg/kg per day has been the chelating agent of choice for over 50 years, but there is now evidence to suggest that oral DMSA 30 mg/kg per day is of similar efficacy. At least 5 days' treatment is usually required.

Mercury

Mercury is the only metal that is liquid at room temperature. It exists in three oxidation states (elemental/metallic Hg^0 , mercurous Hg_2^{2+} and mercuric Hg^{2+}) and can form inorganic (e.g. mercuric chloride) and organic (e.g. methylmercury) compounds. Metallic mercury is very volatile and when spilled, has a large surface area so that high atmospheric concentrations may be produced in enclosed spaces, particularly when environmental temperatures are high. Thus, great care should be taken in clearing up a spillage. If ingested, metallic mercury will usually be eliminated per rectum, though small amounts may be found in the appendix. Mercury salts are well absorbed following ingestion as are organometallic compounds where mercury is covalently bound to carbon.

Clinical features

Inhalation of acute mercury vapour causes headache, nausea, cough, chest pain, bronchitis and occasionally pneumonia. Proteinuria and nephrotic syndrome are

observed rarely. In addition a fine tremor and neurobehavioural impairment occurs and peripheral nerve involvement has also been observed. Ingestion of inorganic and organic mercury compounds causes an irritant gastroenteritis with corrosive ulceration, bloody diarrhoea and abdominal cramps and may lead to circulatory collapse and shock. Mercurous compounds are less corrosive and toxic than mercuric salts.

Treatment

Dimercaptopropanesulphonate (DMPS) is the antidote of choice and is given intravenously in a dose of 30 mg/kg per day. At least 5 days' treatment is usually required.

Methanol

Methanol is used widely as a solvent and is found in anti-freeze solutions. Methanol is metabolized to formaldehyde and formate (Fig. 17.6). The concentration of formate increases greatly and is accompanied by accumulation of hydrogen ions causing metabolic acidosis.

Clinical features

Methanol causes inebriation and drowsiness. After a latent period coma supervenes. Blurred vision and diminished visual acuity occur due to formate accumulation. The presence of dilated pupils that are unresponsive to light suggests that permanent blindness is likely to ensue. A severe metabolic acidosis may develop and be accompanied by hyperglycaemia and a raised serum amylase activity. A blood methanol concentration of 500 mg/L (15.63 mmol/L) confirms severe poisoning. The mortality correlates well with the severity and duration of metabolic acidosis. Survivors may show permanent neurological sequelae including parkinsonian-like signs as well as blindness.

Treatment

Treatment is similar to that of ethylene glycol poisoning (see p. 921) with the addition of folic acid 30 mg i.v. 6-hourly, which accelerates formate metabolism thereby reducing ocular toxicity.

Nerve agents

Nerve agents are related chemically to organophosphorus insecticides (see below) and have a similar mechanism of toxicity, but a much higher mammalian acute toxicity, particularly via the dermal route. In addition to inhibition of acetylcholinesterase, a chemical reaction known as 'ageing' also occurs rapidly and more completely than in the case of insecticides. This makes the enzyme resistant to spontaneous reactivation or by treatment with oximes (pralidoxime, obidoxime or HI-6).

Two classes of nerve agent are recognized: G agents (named for Gerhardt Schrader who synthesized the first agents) and V agents (V allegedly stands for venomous).

G agents include tabun, sarin, soman and cyclosarin. The V agents were introduced later, e.g. VX. The G agents are both dermal and respiratory hazards, whereas the V agents, unless aerosolized, are contact poisons.

Agents used in bioterrorism are described on page 935.

Clinical features

Systemic features include increased salivation, rhinorrhoea, bronchorrhoea, miosis and eye pain, abdominal pain, nausea, vomiting and diarrhoea, involuntary micturition and defecation, muscle weakness and fasciculation, tremor, restlessness, ataxia and convulsions. Bradycardia, tachycardia and hypotension occur, dependent on whether muscarinic or nicotinic effects predominate. Death occurs from respiratory failure within minutes but mild or moderately exposed individuals usually recover completely. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity.

Treatment

The administration of atropine 2 mg i.v. repeated every 3–5 min as necessary to patients presenting with rhinorrhoea and bronchorrhoea may be life-saving. In addition, an oxime should be given to all patients requiring atropine as soon as possible after exposure before 'ageing' has occurred. For example, pralidoxime chloride 30 mg/kg i.v., followed by an infusion of pralidoxime chloride 8–10 mg/kg per hour; alternatively boluses of pralidoxime chloride 30 mg/kg may be given 4- to 6-hourly. Intravenous diazepam 10–20 mg, repeated as required, is useful in controlling apprehension, agitation, fasciculation and convulsions.

Organophosphorus insecticides

Organophosphorus (OP) insecticides are used widely throughout the world and are a common cause of poisoning, causing thousands of deaths annually, in the developing world. Intoxication may follow ingestion, inhalation or dermal absorption. Organophosphorus insecticides inhibit acetylcholinesterase causing accumulation of acetylcholine at central and peripheral cholinergic nerve endings, including neuromuscular junctions. Many OP insecticides require biotransformation before becoming active and so the features of intoxication may be delayed.

Clinical features

Poisoning is characterized by anxiety, restlessness, tiredness, headache, and muscarinic (cholinergic) features such as nausea, vomiting, abdominal colic, diarrhoea, tenesmus, sweating, hypersalivation and chest tightness. Miosis may be present. Nicotinic effects include muscle fasciculation and flaccid paresis of limb muscles, respiratory muscles, and, occasionally of extraocular muscles. Respiratory failure will ensue in severe cases and is exacerbated by the development of bronchorrhoea and pulmonary oedema. Coma and convulsions occur in severe poisoning. Diagnosis is confirmed by measuring the erythrocyte cholinesterase activity; plasma cholinesterase activity is less specific but may also be depressed. Delayed polyneuropathy is a rare complication of acute exposure to some OP insecticides not marketed in most countries. It is initiated by phosphorylation and subsequent ageing of at least 70% of neuropathy target esterase (NTE) in peripheral nerves.

The *intermediate syndrome* usually becomes established 2–4 days after exposure when the symptoms and signs of the acute cholinergic syndrome are no longer obvious. The characteristic features of the syndrome are weakness of the muscles of respiration (diaphragm, intercostal muscles and

Figure 17.6 The metabolism of methanol. ADH, alcohol dehydrogenase; FDH, formaldehyde dehydrogenase; 10-FTS, 10-formyl tetrahydrofolate synthetase.

accessory muscles including neck muscles) and of proximal limb muscles. Accompanying features often include weakness of muscles innervated by some cranial nerves.

Treatment

Mild cases require no specific treatment other than the removal of soiled clothing. Atropine 2 mg i.v. should be given every 3–5 min if necessary to reduce increased secretions, rhinorrhoea and bronchorrhoea. Symptomatic patients should also be given an oxime (pralidoxime, obidoxime or HI-6) to reactivate inhibited acetylcholinesterase: for example, pralidoxime chloride 30 mg/kg by slow i.v. injection followed by an infusion of pralidoxime mesylate 8–10 mg/kg per hour.

Phosphides

Aluminium and zinc phosphides are used as rodenticides and insecticides. They react with moisture in the air (and the gastrointestinal tract) to produce phosphine, the active pesticide. Acute poisoning with these compounds may be direct, due to ingestion of the salts, or indirect from accidental inhalation of phosphine generated during their approved use.

Clinical features

Ingestion causes vomiting, epigastric pain, peripheral circulatory failure, severe metabolic acidosis, acute kidney injury and disseminated intravascular coagulation, in addition to the features induced by phosphine. Exposure to phosphine causes lacrimation, rhinorrhoea, productive cough, breathlessness, chest tightness, dizziness, headache, nausea and drowsiness. Acute pulmonary oedema, hypertension, cardiac arrhythmias, convulsions and jaundice have been described in severe cases. Ataxia, intention tremor and diplopia are found on examination.

Treatment

Treatment is symptomatic and supportive. Gastric lavage should not be used as it can increase the rate of disintegration of the product ingested and increase toxicity. Activated charcoal may bind metal phosphides. The mortality is high despite supportive care.

Specific poisons: marine animals

Amnesic shellfish (domoic acid) poisoning

The syndrome should be known more accurately as domoic acid poisoning because amnesia is not always present. In one outbreak, the first symptoms were experienced between 15 minutes and 38 hours after mussel consumption.

Clinical features and treatment

The most common symptoms are nausea, vomiting, abdominal cramps, headache, diarrhoea and short-term memory loss. Axonal sensory motor neuropathy, seizures, coma and death have also been reported. Treatment is symptomatic and supportive.

Diarrhoeic shellfish (okadaic) poisoning

Okadaic acid is produced by dinoflagellates belonging to the genera *Dinophysis* spp. Okadaic acid inhibits the activity of the protein phosphatases 1 and 2a.

Clinical features and treatment

The predominant symptoms are diarrhoea, nausea, vomiting and abdominal pain. Symptoms tend to occur between

30 minutes and a few hours after shellfish consumption, with patients recovering within 2–3 days. Treatment is symptomatic and supportive.

Neurotoxic shellfish (brevetoxin) poisoning

Neurotoxic shellfish poisoning is caused by brevetoxins produced by the dinoflagellate *Gymnodinium breve*. Brevetoxins open voltage-gated sodium ion channels in cell walls and enhance the inward flow of sodium ions into the cell.

Clinical features and treatment

The symptoms of neurotoxic shellfish poisoning occur within 30 minutes to 3 hours, last a few days and include nausea, vomiting, diarrhoea, chills, sweats, reversal of temperature, hypotension, arrhythmias, numbness, tingling, paraesthesiae of the lips, face and extremities, cramps, bronchoconstriction, paralysis, seizures and coma. Treatment is symptomatic and supportive.

Paralytic shellfish (saxitoxin) poisoning

This is caused by bivalve molluscs being contaminated with neurotoxins, including saxitoxin, produced by toxic dinoflagellates on which the molluscs graze. Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes, thereby blocking nerve signal transmission.

Clinical features and treatment

Symptoms develop within 30 minutes. The illness is characterized by paraesthesiae of the mouth, lips, face and extremities and is often accompanied by nausea, vomiting and diarrhoea. In more severe cases, dystonia, dysphagia, muscle weakness, paralysis, ataxia and respiratory depression occur. In one outbreak involving 187 cases, there were 26 deaths. Treatment is symptomatic and supportive.

Ciguatera fish poisoning

Over 400 fish species have been reported as ciguatoxic (*Cigua* is Spanish for poisonous snail), though barracuda, red snapper, amberjack and grouper are most commonly implicated. Ciguatera fish contain ciguatoxin, maitotoxin and scaritoxin, which are lipid soluble, heat stable compounds that are derived from dinoflagellates such as *Gambierdiscus toxicus*. Ciguatoxin opens voltage-sensitive sodium channels at the neuromuscular junction and maitotoxin opens calcium channels of the cell plasma membrane.

Clinical features and treatment

The onset of symptoms occurs from a few minutes to 30 hours after ingestion of toxic fish. Typically features appear between one and six hours and include abdominal cramps, nausea, vomiting and watery diarrhoea. In some cases, numbness and paraesthesiae of the lips, tongue and throat occur. Other features described include malaise, dry mouth, metallic taste, myalgia, arthralgia, blurred vision, photophobia and transient blindness. In more severe cases, hypotension, cranial nerve palsies and respiratory paralysis have been reported. Treatment is symptomatic and supportive. Recovery takes from 48 hours to 1 week in the mild form and from 1 to several weeks in the severe form. The mortality in severe cases may be as high as 12%.

Scombroid fish poisoning

This is due to the action of bacteria such as *Proteus morgani* and *Klebsiella pneumoniae* in decomposing flesh of fish such

FURTHER READING

FURTHER READING

Proudfoot AT. Aluminium and zinc phosphide poisoning. *Clin Toxicol* 2009; 47:89–100.

as tuna, mackerel, mahi-mahi, bonito and skipjack if the fish are stored at insufficiently low temperatures. The spoiled fish can contain excessively high concentrations of histamine (muscle histidine is broken down by the bacteria to histamine), though the precise role of histamine in the pathogenesis of the clinical syndrome is uncertain.

Clinical features and treatment

Clinically, the mean incubation period is 30 min. The illness is characterized by flushing, headache, sweating, dizziness, burning of the mouth and throat, abdominal cramps, nausea, vomiting and diarrhoea and is usually short-lived; the mean duration is 4 hours. Treatment is symptomatic and supportive. Antihistamines may alleviate the symptoms.

Stings from marine animals

Several species of fish have venomous spines in their fins. These include the weaver fish, short-spine cottus, spiny dogfish and the stingray. Bathers and fishermen may be stung if they tread on or handle these species. The immediate result of a sting is intense local pain, swelling, bruising, blistering, necrosis and, if the poisoned spine is not removed, chronic sepsis (although this is uncommon). Occasionally systemic symptoms including, vomiting, diarrhoea, hypotension and tachycardia occur. Treatment by immersing the affected part in hot water may relieve local symptoms as this denatures the thermolabile toxin.

Jellyfish

Most of the jellyfish found in North European coastal waters are non-toxic as their stings cannot penetrate human skin. A notable exception is the 'Portuguese man-o-war' (*Physalia physalis*) whose sting contains a toxic peptide, phospholipase A, and a histamine-liberating factor. Toxic jellyfish are found more frequently in Australia and some cause the Irukandji syndrome.

Clinical features and treatment

Local pain occurs followed by myalgia, nausea, gripping abdominal pain, dyspnoea and even death. The cluster of severe systemic symptoms that constitute the Irukandji syndrome occur some 30 min after the jellyfish sting. The symptoms include severe low back pain, excruciating muscle cramps in all four limbs, the abdomen and chest, sweating, anxiety, restlessness, nausea, vomiting, headache, palpitations, life-threatening hypertension, pulmonary oedema and toxic global heart dilatation.

Adhesive tape may be used to remove any tentacles still adherent to the bather. Local application of 5% acetic acid is said to prevent stinging cells adherent to the skin discharging. Local analgesia and antihistamine creams provide symptomatic relief. Other features should be treated symptomatically and supportively.

Specific poisons: venomous animals

Insect stings and bites

Insect stings from wasps and bees, and bites from ants, produce pain and swelling at the puncture site. Following the sting or bite, patients should be observed for 2 hours for any signs of evolving urticaria, pruritus, bronchospasm or oropharyngeal oedema. The onset of anaphylaxis requires urgent treatment (see p. 69).

Scorpions

Scorpion stings are a serious problem in North Africa, the Middle East and the Americas. Scorpion venoms stimulate the release of acetylcholine and catecholamines causing both cholinergic and adrenergic symptoms.

Clinical features and treatment

Severe pain occurs immediately at the site of puncture, followed by swelling. Signs of systemic involvement, which may be delayed for 24 hours, include vomiting, sweating, piloerection, abdominal colic, diarrhoea. In some cases, depending on the species, shock, respiratory depression and pulmonary oedema may develop.

Local infiltration with anaesthetic or a ring block will usually alleviate local pain, though systemic analgesia may be required. Specific antivenom, if available, should be administered as soon as possible.

Spiders

The black widow spider (*Latrodectus mactans*) is found in North America and the tropics and occasionally in Mediterranean countries.

Clinical features and treatment

The bite quickly becomes painful and generalized muscle pain, sweating, headache and shock may occur. No systemic treatment is required except in cases of severe systemic toxicity, when specific antivenom should be given, if this is available.

Venomous snakes

Approximately 15% of the 3000 species of snake found worldwide are considered to be dangerous to humans. Snake bite is common in some tropical countries (Table 17.23).

There are three main groups of venomous snakes, representing some 200 species, which have in their upper jaws a pair of enlarged teeth (fangs) that inject venom into the tissues of their victim. These are:

- *Viperidae* (with two subgroups: Viperinae: European adders and Russell's vipers; and Crotalinae: American rattlesnakes, moccasins, lance-headed vipers and Asian pit vipers)
- *Elapidae* (cobras, kraits, mambas, coral snakes, Australian venomous snakes)
- *Hydrophiidae* (sea snakes).

In addition, some members of the family *Colubridae* are mildly venomous (mongoose snake).

Table 17.23 Examples of snake bite incidence and mortality

Sri Lanka	6 bites per 100 000 population and 900 deaths per year
Nigeria	500 bites per 100 000 population with a 12% mortality
Myanmar	15 deaths per 100 000 population
USA	45 000 bites per year (in a population of 301 million), 8000 by venomous species, with 6 deaths annually
UK	Approximately 100 people admitted to hospital annually (population 60 million) but only one death since 1970
Australia	2 or 3 deaths annually (population 20 million)

Figure 17.7 Snake bite showing swelling at site.

Clinical features

Viperidae (Viperinae and Crotalinae)

Russell's viper causes most of the snake-bite mortality in India, Pakistan and Myanmar. There is local swelling at the site of the bite (Fig. 17.7) which may become massive. Local tissue necrosis may occur. Evidence of systemic involvement (envenomation) occurs within 30 minutes, including vomiting, evidence of shock and hypotension. Haemorrhage due to incoagulable blood can be fatal.

Elapidae

There is not usually any swelling at the site of the bite, except with Asian cobras and African spitting cobras – here the bite is painful and is followed by local tissue necrosis. Vomiting occurs first followed by shock and then neurological symptoms and muscle weakness, with paralysis of the respiratory muscles in severe cases. Cardiac muscle can be involved.

Hydrophiidae

Envenomation produces muscle involvement, myalgia and myoglobinuria, which can lead to acute kidney injury. Cardiac and respiratory paralysis may occur.

Treatment

As a first aid measure, a firm pressure bandage should be placed over the bite and the limb immobilized. This may delay the spread of the venom. Arterial tourniquets should *not* be used, and incision or excision of the bite area should not be performed. Local wounds often require little treatment. If necrosis is present, antibiotics should be given. Skin grafting may be required later. Antitetanus prophylaxis must be given. The type of snake should be identified if possible.

In about 50% of cases, no venom has been injected by the bite. Nevertheless, careful observation for 12–24 hours is necessary in case envenomation develops. General supportive measures should be given, as necessary. These include intravenous fluids with volume expanders for hypotension and diazepam for anxiety. Treatment of acute respiratory, cardiac and kidney injury is instituted as necessary.

Antivenoms are not generally indicated unless envenomation is present, as they can cause severe allergic reactions. Antivenoms can rapidly neutralize venom, but only if an amount in excess of the amount of venom is given. Large quantities of antivenom may be required. As antivenoms cannot reverse the effects of the venom, they must be given early to minimize some of the local effects and may prevent necrosis at the site of the bite. Antivenoms should be administered intravenously by slow infusion, the same dose being given to children and adults.

Allergic reactions are frequent, and adrenaline (epinephrine) 1 in 1000 solution should be available. In severe

cases, the antivenom infusion should be continued even if an allergic reaction occurs, with subcutaneous injections of adrenaline being given as necessary. Some forms of neurotoxicity, such as those induced by the death adder, respond to anticholinesterase therapy with neostigmine and atropine.

Specific poisons: plants

Life-threatening poisoning from plant ingestion is rare though many plants contain potentially toxic substances. These include antimuscarinic agents, calcium oxalate crystals, cardiogenic glycosides, pro-convulsants, cyanogenic compounds, mitotic inhibitors, nicotine-like alkaloids, alkylating agent precursors, sodium channel activators and toxic proteins (toxalbumins). While many plants contain gastrointestinal toxins, these rarely give rise to life-threatening sequelae. In contrast, other botanical poisons may cause specific organ damage and death may occur from only small ingestions of yew (genus: *Taxus*), oleander (*Thevetia peruviana* and *Nerium oleander*) and cowbane (genus: *Cicuta*).

Atropa belladonna

Atropa belladonna (deadly nightshade) contains hyoscyamine and atropine and causes antimuscarinic effects – a dry mouth, nausea and vomiting – leading to blurred vision, hallucinations, confusion and hyperpyrexia.

Cicuta species

Cicuta spp. (water hemlock) and the related genus *Oenanthe* contain cicutoxin, a potent central nervous system (CNS) stimulant that produces violent seizure activity. The CNS effects of cicutoxin are similar to those of picrotoxin, a known inhibitor of GABA. Severe gastrointestinal symptoms, diaphoresis, salivation and skeletal muscle stimulation may precede the seizure activity.

Conium maculatum

Conium maculatum (poison hemlock) contains a variety of volatile pyridine alkaloids, including coniine, *N*-methylconiine and gammaconiceine. Coniceine is significantly more toxic than coniine and is thought to be the precursor to coniine. The toxic activity of the alkaloids is similar to that of nicotine. Large doses produce non-polarizing neuromuscular blockade which may result in respiratory depression and death.

Datura stramonium

Datura stramonium (jimsonweed) and other *Datura* species contain L-hyoscyamine and atropine. These alkaloids are potent antagonists of acetylcholine at muscarinic receptors and produce the anticholinergic syndrome. While morbidity is significant, fatalities are rare and are the consequence of hyperthermia, seizures and/or arrhythmias.

Digitalis purpurea, *Nerium oleander*, *Thevetia peruviana*

Ingestion of *Digitalis purpurea*, or the common (*Nerium oleander*) or yellow (*Thevetia peruviana*) oleander can produce a syndrome similar to digoxin poisoning (see p. 917). A randomized controlled trial has shown that digoxin-specific antibody fragments rapidly and safely reverse yellow oleander-induced arrhythmias, restore sinus rhythm, and rapidly reverse bradycardia and hyperkalaemia. The administration

of multiple doses of activated charcoal is used, but the effect on survival is debated.

Specific poisons: mushrooms

Poisoning due to mushrooms is usually accidental, though ingestion of hallucinogenic ('magic') mushrooms is invariably intentional.

Cytotoxic mushrooms

Cytotoxic mushroom poisoning is caused by amatoxins and orellanin. Amatoxins are found in *Amanita phalloides*, *A. virosa* and *A. verna*, and in some *Galerina* and *Lepiota* spp. Amatoxins inhibit transcription from DNA to mRNA by the blockade of nuclear RNA polymerase II; this results in impaired protein synthesis and cell death.

Clinical features and treatment

Intense watery diarrhoea starts 8–24 hours after ingestion and persists for 24 hours or longer. Patients often become severely dehydrated. Signs of liver damage appear during the 2nd day and hepatic failure may ensue. Impaired kidney function is often seen both because of fluid loss and as a result of direct kidney injury. In all patients, fluid, electrolyte and acid–base disturbances should be corrected and renal and hepatic function supported. The value of silibinin and benzylpenicillin is not proven. Occasionally, liver transplantation is necessary.

Gyromitrin poisoning

Gyromitrin is found in *Gyromitra* spp., including in particular the false morel (*Gyromitra esculenta*) and *Cudonia circinans*. Gyromitrin decomposes in the stomach, to form hydrazines that reduce pyridoxine in the CNS and, hence, GABA synthesis, causing glutathione depletion in red blood cells and may form free oxygen radicals that bind to hepatic macromolecules.

Clinical features and treatment

Vapours from the mushrooms are irritating to the eyes and respiratory tract. Gastrointestinal symptoms appear 5–8 hours after exposure. Vertigo, sweating, diplopia, headache, dysarthria, incoordination and ataxia may follow. Symptomatic and supportive care are required. Pyridoxine 25 mg/kg as an infusion over 30 min, should be given if severe CNS toxicity develops; repeat doses may be required.

Hallucinogenic mushroom poisoning

Psilocybin produces pharmacological effects similar to those of LSD and is found in *Psilocybe* and *Panaeolus* spp.

Clinical features and treatment

Symptoms occur within 20–60 min. Effects include altered time and space sense, depersonalization, hallucinations, derealization and euphoria. Symptoms are usually maximal within 2 hours and disappear within 4–6 hours, though 'flash-backs' may recur after weeks or months. Anxiety and agitation should be treated with diazepam, 10–20 mg i.v., repeated if necessary.

Isoxazole poisoning

Isoxazoles (e.g. ibotenic acid, muscimol, muscazone) occur in *Amanita muscaria* and *A. pantherina* and act as γ -aminobutyric acid agonists.

Clinical features and treatment

Nausea, vomiting, inebriation, euphoria, confusion, anxiety, visual disturbances and hallucinations occur often within 30 minutes. Severe agitation and violent behaviour are occasionally seen. Other features include myoclonic jerks, muscle fasciculation, seizures and coma. Symptomatic and supportive care should be given as necessary. Diazepam, 10–20 mg, repeated as required, should be administered for anxiety, agitation and seizures.

Neurotoxic mushroom poisoning

Muscarine is found in, for example, *Inocybe* spp., *Clitocybe* spp. and *Mycena pura*. Muscarine stimulates cholinergic receptors in the autonomic nervous system.

Clinical features and treatment

Diarrhoea, abdominal pain, diaphoresis, salivation, lacrimation, miosis, bronchorrhoea, bronchospasm, bradycardia and hypotension occur. Atropine, 0.6–2 mg i.v. should be given to manage the cholinergic syndrome.

Orellanin poisoning

Orellanin is a potent nephrotoxin found in, for example, *Cortinarius orellanus* and *C. speciosissimus*. A metabolite of orellanin inhibits protein synthesis in the kidneys.

Clinical features and treatment

Symptoms are typically delayed for 2–4 days. Some patients suffer a mild gastrointestinal disturbance before developing signs of renal impairment, headache, fatigue, intense thirst, chills, muscular discomfort, and abdominal, lumbar and flank pain. Transient polyuria with proteinuria, haematuria and, characteristically, leucocyturia is followed by oliguria and then anuria. Renal function may recover only partially; chronic kidney disease is reported in about 10–40% of cases. Management involves careful monitoring and haemodialysis/haemofiltration if renal failure supervenes. Renal transplantation may be required.

DISEASE AND THE ENVIRONMENT

The incidence and prevalence of disease and causes of death within a community are a reflection of interrelated factors:

- Genetic predisposition
- Nutrition, poverty and affluence
- Purity of water sources, sanitation and atmospheric pollution
- Environmental disasters and accidents
- Background ionizing radiation and man-made radiation exposure, deliberate or accidental
- Environmental temperature
- Patterns of infective disease
- Political forces determining levels of healthcare, preventative strategies and effects of war on civilian populations.

Some of these environmental effects have been clearly documented within the last decade, e.g. the massive civilian mortality and morbidity during the current Afghan and previous Iraq wars, and loss of life and disease prevalence following the 2006 *tsunami*, the earthquakes in Sechuan (2008) and Haiti (2010) and cyclone *Nargis* in the Irawaddy delta. Flooding caused by *El Niño* in East Africa not only resulted in an increase in breeding sites for mosquito vectors but a major outbreak of Rift Valley fever due to the enforced close proximity of cattle with humans.

Smoking (active and passive), obesity and excess alcohol consumption also play a significant role in disease. Worldwide health programmes have been established in most countries to reduce their effects.

Environmental temperature

The effect of environmental temperature (T_{Env}) is paramount in infective diseases; changes as small as 1°C cause major changes in disease vectors. Climate change is an unquestionable phenomenon. Patterns of infective disease are likely to change radically within the next 20 years. There are suggestions that climate effects are already becoming apparent, e.g.:

- Patterns of malaria in South-east Asia
- The occurrence of dengue fever in southern Italy
- Outbreaks of cholera, and seasonal variation in diarrhoea and vomiting.

Research into the effect of climate change on the changing patterns of infective diseases will point to potential ways in which national and international efforts can be targeted.

HEAT

Body core temperature (T_{Core}) is maintained at 37°C by the thermoregulator centre in the hypothalamus.

Heat is produced by cellular metabolism and is dissipated through the skin by both vasodilatation and sweating and in expired air via the alveoli. When the environmental temperature (T_{Env}) is >32.5°C, profuse sweating occurs. *Sweat evaporation* is the principal mechanism for controlling T_{Core} following exercise or in response to an increase in T_{Env} .

Heat acclimatization. Acclimatization to heat takes place over several weeks. The sweat volume increases and the sweat salt content falls. Increased evaporation of sweat reduces T_{Core} .

Heat cramps. Painful muscle cramps, usually in the legs, often occur in fit people when they exercise excessively,

FURTHER READING

Sheridan RL, Goldstein MA, Stoddard FJ Jr et al. Case records of the Massachusetts General Hospital. Case 41-2009. A 16-year-old boy with hypothermia and frostbite. *N Engl J Med* 2009; 361: 2654–2662.

especially in hot weather. Cramps are probably due to low extracellular sodium caused by excess intake of water over salt. Cramps can be prevented by increasing dietary salt. They respond to combined salt and water replacement, and in the acute stage to stretching and muscle massage. T_{Core} remains normal.

Heat illness. At any environmental temperature (especially with T_{Env} of $>25^{\circ}\text{C}$), and with a high humidity, strenuous exercise in clothing that inhibits sweating such as a wetsuit can cause an elevation in T_{Core} in <15 minutes. Weakness/exhaustion, cramps, dizziness and syncope, with $T_{Core} >37^{\circ}\text{C}$, define heat illness (heat exhaustion). Elevation of T_{Core} is more critical than water and sodium loss. Heat illness may progress to *heat injury*, a serious emergency.

Management of heat illness

Reduce (T_{Env}) if possible. Cool with sponging and fans. Give O_2 by mask. Other causes of high T_{Core} , e.g. malaria, should be ruled out if appropriate.

Oral rehydration with *both* salt and water (25 g of salt per 5 L of water/day) is given in the first instance, with adequate replacement thereafter. In severe heat illness, i.v. fluids are needed; 0.9% saline is given; monitor serum sodium and correct secondary potassium loss.

Heat injury

Heat injury (heat stroke) is an acute life-threatening situation when T_{Core} rises above 41°C . There is headache, nausea, vomiting and weakness, progressing to confusion, coma and death. The skin *feels* intensely hot to the touch. Sweating is often absent, but not invariably.

Heat injury can develop in unacclimatized people in hot, humid windless conditions, even without exercise. Sweating may be limited by prickly heat (plugging or rupture of the sweat ducts, leading to a pruritic papular erythematous rash). Excessive exercise in inappropriate clothing, e.g. exercising on land in a wetsuit, can lead to heat injury in temperate climates. Diabetes, alcohol and drugs, e.g., antimuscarinics, diuretics and phenothiazines, can contribute. *Heat injury* can lead to a fall in cardiac output, lactic acidosis and intravascular coagulation.

Prevention

Acclimatization, fluids, avoiding inappropriate clothing and common sense.

Management

- Reduce T_{Env} if possible
- Cool: sponging, icepacks, fanning. Give O_2 by mask
- Manage in intensive care: monitor cardiac output, respiration, biochemistry, clotting and muscle enzymes
- Give fluids intravenously so the intravascular volume can remain normal.

Prompt treatment is essential and can be curative even with T_{Core} of $>41^{\circ}\text{C}$. Delay can be fatal. Complications are hypovolaemia, intravascular coagulation, cerebral oedema, rhabdomyolysis, and renal and hepatic failure.

Malignant hyperpyrexia

See page 1153.

COLD

Hypothermia is defined as a core temperature of $<32^{\circ}\text{C}$. It is frequently lethal when T_{Core} falls below 30°C . Survival, with

full recovery has however been recorded with T_{Core} of $<16^{\circ}\text{C}$. *Cold injury* includes:

- **Frostbite:** the local cold injury that follows freezing of tissue
- **Non-freezing cold injury:** the damage – usually to feet – following prolonged exposure to T_{Env} between 0 and 5°C , usually in damp conditions.

Hypothermia

Hypothermia occurs in many settings.

At home. Hypothermia can occur when T_{Env} is below 8°C , when there is poor heating, inadequate clothing and poor nutrition. Depressant drugs, e.g. hypnotics, as well as alcohol, hypothyroidism or intercurrent illness also contribute. Hypothermia is commonly seen in the poor, frail and elderly. The elderly have diminished ability to sense cold and also have little insulating fat. Neonates and infants become hypothermic rapidly because of a relatively large surface area in proportion to subcutaneous fat.

Outdoors on land. Hypothermia is a prominent cause of death in climbers, skiers, polar travellers and in wartime. Wet, cold conditions with wind chill, physical exhaustion, injuries and inadequate clothing are contributory. Babies and children are at risk because they cannot take action to warm them themselves.

Cold water immersion. Dangerous hypothermia can develop following immersion for more than 30 min to 1 hour in water temperatures of $15\text{--}20^{\circ}\text{C}$. In T_{Water} below 12°C limbs rapidly become numb and weak. Recovery takes place gradually, over several hours following rescue.

Clinical features

Mild hypothermia ($T_{Core} <32^{\circ}\text{C}$) causes shivering and initially intense discomfort. However, the hypothermic subject, though alert, may not act appropriately to rewarming, e.g. by huddling, wearing extra clothing or exercising. As the T_{Core} falls below 32°C , severe hypothermia causes impaired judgement – including lack of awareness of cold – drowsiness and coma. Death follows, usually from ventricular fibrillation.

Diagnosis

Diagnosis is straightforward, if a low-reading thermometer is available. If not, rapid clinical assessment is reliable. Someone who *feels* icy to touch – abdomen, groin, axillae – is *probably* substantially hypothermic. If they are clammy, uncooperative or sleepy, T_{Core} is almost certainly $<32^{\circ}\text{C}$.

Sequelae

Pulse rate and systemic BP fall. Cardiac output and cerebral blood flow are low in hypothermia and can fall further if the upright position is maintained, the thorax restrained by a harness or by hauling during evacuation. This is why helicopter and lifeboat winch rescues are often carried out with a stretcher, rather than a chest harness.

Respiration becomes shallow and slow. Muscle stiffness develops; tendon reflexes become sluggish, then absent. As coma ensues, pupillary and other brainstem reflexes are lost; pupils are fixed and may be dilated in severe hypothermia. Metabolic changes are variable, with either metabolic acidosis or alkalosis. Arterial PO_2 may appear normal, i.e. falsely high.

There is shift of the oxygen dissociation curve to the left because of the reduction in temperature of haemoglobin. Thus, if an arterial blood sample from a hypothermic patient

FURTHER READING

Hajat S, O'Connor M, Kosatsky T. Health effects of hot weather: from awareness of risk factors to effective health protection. *Lancet* 2010; 375: 856–863.

is analysed at 37°C, the PO_2 will be falsely high. Within the range 37–33°C this factor is around 7% per °C. Many blood gas machines also calculate the arterial saturation; this too will be falsely high. When a patient is monitored using a pulse oximeter, the level of arterial oxygen saturation (S_aO_2) will however be correct – but if S_aO_2 is then converted by calculation to P_aO_2 , a downwards correction must be applied – simply due to hypothermia.

Bradycardia with 'J' waves (rounded waves above the isoelectric line at the junction of the QRS complex and ST segment) are pathognomonic of hypothermia. Prolongation of PR and QT intervals and QRS complex also occur. Ventricular dysrhythmias (tachycardia/fibrillation) or asystole are the usual causes of death.

Principles of hypothermia management

- Maintain the patient horizontal, or slightly head down.
- Rewarm gradually.
- Correct metabolic abnormalities.
- Anticipate and treat dysrhythmias.
- Check for hypothyroidism (see p. 962).

If the patient is awake, with a core temperature of >32°C, place them in a warm room, use a foil wrap and give warm fluids orally. Outdoors, add extra dry clothing, huddle together and use a warmed sleeping bag. Rewarming may take several hours. Avoid alcohol: this adds to confusion, boosts confidence factitiously, causes peripheral vasodilatation and further heat loss, and can precipitate hypoglycaemia.

Severe hypothermia

In severe hypothermia, people look dead. Always exclude hypothermia before diagnosing brainstem death (see p. 897). Warm gradually, aiming at a 1°C/hour increase in T_{core} . Direct mild surface heat from an electric blanket can be helpful. Treat any underlying condition promptly, e.g. sepsis. Monitor all vital functions. Correct dysrhythmias. Check for sedative drugs.

Give warm i.v. fluids slowly. Correct metabolic abnormalities. Hypothyroidism, if present, should be treated with liothyronine. Various methods of artificial rewarming exist – inhaled warm humidified air, gastric or peritoneal lavage, and haemodialysis. These are rarely used.

Prevention

Hypothermia in the field can often be prevented by forethought and action. For the elderly, improved home heating and insulation, central heating in bedrooms and electric blankets are helpful in cold spells. This can be expensive and unaffordable for some people, so supplemental finance is required.

Cold injury

Frostbite

Ice crystals form within skin and superficial tissues when the temperature of the tissue (T_{tissue}) falls to –3°C: T_{env} generally must be below –6°C. Wind chill is frequently a factor. Typically, fingers, toes, nose and ears become frostbitten.

Frostbitten tissue is pale, greyish and initially doughy to touch. Later, tissue freezes hard, looking like meat from a freezer. Frostbite can easily occur when working or exercising in low temperatures and typically develops without the patient's knowledge. Below T_{env} 5°C, hands or feet that have lost their feeling are at risk of cold injury.

Management

Transport the patient – or if this is impossible, make them walk, even on frostbitten feet – to a place of safety before commencing warming. Warm the frozen part by immersion in hand hot water at 39–42°C, if feasible. Assess hypothermia. Continue warming until obvious thawing occurs; this can be painful. Vasodilator drugs have no part in management. Blisters form within several days and, depending on the depth of frostbite, a blackened shell – the *carapace* – develops as blisters regress or burst. Dry, non-adherent dressings and aseptic precautions are essential, though hard to achieve. Frostbitten tissues are anaesthetic and at risk from further trauma and infection. Recovery takes place over many weeks, and may be incomplete. Surgery may be needed, but should be avoided in the early stages.

Chilblains

These are small, purplish itchy inflammatory lesions, occurring on toes and fingers. They occur in cold, wet conditions. They are more common in women and heal in 7–14 days. Prevention is by keeping warm and wearing gloves and warm footwear.

Non-freezing cold injury (NFCI)

NFCI (trench foot) describes tissue damage following prolonged exposure, usually for several hours or more, at T_{env} around or slightly above freezing, but without frostbite. Wet socks and boots are the usual cause. There is severe vasoconstriction, blotchiness of the lower limbs, with pain and oedema on rewarming. Recovery usually follows over several weeks. There may be prolonged late susceptibility to cold. NFCI is a prominent cause of morbidity in troops operating in low temperatures, and a subsequent cause of litigation.

Prevention of frostbite and NFCI is largely by education and common sense: avoid damp feet and wet boots. Always carry spare dry socks, gloves and headgear.

HIGH ALTITUDES

The partial pressure of atmospheric oxygen – and hence alveolar and arterial oxygen – falls in a near-linear relationship as barometric pressure falls with increasing altitude (Fig. 18.1).

Figure 18.1 The decrease in oxygen and barometric pressure with increasing altitude.

Table 18.1 Conditions caused by sustained hypoxia

Condition	Incidence (%)	Usual altitude (m)
Acute mountain sickness	70	3500–4000
Acute pulmonary oedema	2	4000
Acute cerebral oedema	1	4500
Retinal haemorrhage	50	5000
Deterioration	100	6000 and above
Chronic mountain sickness	Rare	3500–4000

Commercial aircraft are pressurized to 2750 m (lowering the oxygen saturation by 3–4%). The incidence of deep venous thrombosis and pulmonary embolism is slightly greater in sedentary passengers on long-haul flights than in a similar population at sea level. Dehydration and alcohol probably contribute. Prophylactic aspirin is not recommended.

On land, below 3000 m there are few clinical effects. The resulting hypoxaemia causes breathlessness only in those with severe cardiorespiratory disease. Above 3000–3500 m hypoxia causes a spectrum of related syndromes that affect high-altitude visitors, principally climbers, trekkers, skiers and troops (Table 18.1), especially when they exercise. These conditions occur largely during acclimatization, a process that takes several weeks and once completed can enable man to live – permanently if necessary – up to about 5600 m. At greater heights, although people can survive for days or weeks, deterioration due to chronic hypoxia is inevitable.

The world's highest railway is to Lhasa, reaching altitudes over 5000 m. Emergency oxygen is provided in the carriages. Roads at similar altitudes in central Asia are used extensively but since road passengers do not exercise, serious altitude-related illnesses are unusual. Climbing the world's highest summits is just possible without supplementary oxygen, though it is often used on peaks above 7500 m. At the summit of Everest (8848 m) the barometric pressure is 34 kPa (253 mmHg). An acclimatized mountaineer has an alveolar PO_2 of 4.0–4.7 kPa (30–35 mmHg) – near man's absolute physiological limit.

Acute mountain sickness (AMS)

AMS describes malaise, nausea, headache and lassitude and affects the majority of people for a few days, above 3500 metres. Following arrival at this altitude there is usually a latent interval of 6–36 hours before symptoms begin. Treatment is rest, with analgesics if necessary. Recovery is usually spontaneous over several days.

Prophylactic treatment with acetazolamide, a carbonic anhydrase inhibitor and a respiratory stimulant, is of some value in preventing AMS. Acclimatizing, i.e. ascending gradually, provides better and more natural prophylaxis.

In the minority, more serious sequelae – high-altitude pulmonary oedema and high-altitude cerebral oedema develop.

High-altitude pulmonary oedema

Predisposing factors include youth, rapidity of ascent, heavy exertion and severe AMS. Breathlessness, occasionally with

frothy blood-stained sputum, indicates established oedema. Unless treated rapidly this leads to cardiorespiratory failure and death. Milder forms are common. Breathlessness at rest should raise the suspicion of pulmonary oedema.

High-altitude cerebral oedema

Cerebral oedema is the result of abrupt increase in cerebral blood flow that occurs even at modest altitudes of 3500–4000 metres. It is unusual below 4500 metres, and occurs typically in the first 2 weeks, during acclimatization. Cerebral oedema can also develop suddenly in well-acclimatized climbers above 7000 metres. Headache is followed by drowsiness, ataxia and papilloedema, with coma and death if brain oedema progresses.

Treatment

Any but the milder forms of AMS require urgent treatment. Oxygen should be given by mask if available, and descent should take place as quickly as possible. Nifedipine reduces pulmonary hypertension and is used in pulmonary oedema. Dexamethasone is effective in reducing brain oedema. Portable pressure bags inflated by a foot pump are widely used; the patient is enclosed in the bag.

Retinal haemorrhages

Small flame haemorrhages within the retinal nerve fibre layer are common above 5000 metres, and usually symptomless. Rarely a haemorrhage will cover the macula, causing painless loss of central vision. Recovery is usual.

Deterioration

Prolonged residence between 6000 and 7000 metres leads to weight loss, anorexia and listlessness after several weeks. Above 7500 metres, the effects of deterioration become apparent over several days, although it is possible to survive for a week or more at altitudes near 8000 metres without supplementary oxygen.

Chronic mountain sickness

Chronic mountain sickness occurs in long-term residents at high altitudes, usually after several decades and is seen in the Andes and in central Asia.

Headache, polycythaemia, lassitude, cyanosis, finger clubbing, congested cheeks and ear lobes, and right ventricular enlargement develop. Chronic mountain sickness is gradually progressive.

Coronary artery disease and hypertension are rare in high-altitude native populations.

DIVING

Free diving by breath-holding is possible to around 5 metres, or with practice to greater depths. Air can be supplied to divers by various methods. With a snorkel, providing air to a depth of c. 0.5 metres, inspiratory effort is the limiting factor. At depths >0.5 metres, i.e. with a longer snorkel tube, forced negative-pressure ventilation can cause pulmonary capillary damage with haemorrhagic alveolar oedema. Scuba divers, i.e. recreational sports divers descending to 30 metres, carry bottled compressed air, or a nitrogen–oxygen mixture. Divers who work at great depths commercially breathe helium–oxygen or nitrogen–oxygen mixtures, delivered by hose from the surface. Ambient pressures at various depths are shown in Table 18.2.

Table 18.2 Depth and pressure

Water depth (m)	Pressure	
	Atmospheres	mmHg
0	1	760
10	2	1520
50	6	4560
90	10	7600

Problems during descent

Middle ear barotrauma (squeeze) is common and caused by inability to equalize pressure in the middle ear – Eustachian tube blockage is the usual cause. Pain and hearing loss occur, sometimes with tympanic membrane rupture and acute vertigo.

Sinus squeeze is intense local pain due to blockage of the nasal and paranasal sinus ostia.

Treatment is by holding the nostrils closed and swallowing, or similar manoeuvres – and decongestants. Diving with a respiratory or sinus infection should be avoided.

Oxygen narcosis

Pure oxygen is not used for diving because of oxygen toxicity. Lung atelectasis, endothelial cell damage and pulmonary oedema occur when alveolar oxygen pressure exceeds 1.5 atmospheres, at depths around 5 metres. At around 10 metres the CNS becomes affected: apprehension, nausea and sweating are followed by muscle twitching and generalized convulsions.

Nitrogen narcosis

When compressed air is breathed below 30 metres, narcotic effects of nitrogen begin to impair brain function. Poor judgement is hazardous; this also occurs with nitrogen–oxygen mixtures in recreational diving. Nitrogen narcosis is avoided by replacing air with helium–oxygen mixtures, enabling descent to 700 metres. At these extreme depths, direct effect of pressure on neurones can cause tremor, hemiparesis and cognitive impairment.

Problems during and following ascent

Free divers who breath-hold often hyperventilate deliberately prior to plunging in. This drives off CO_2 – reducing the stimulus to inspire. During the subsequent breath-hold $P_a\text{CO}_2$ rises; $P_a\text{O}_2$ falls. On surfacing, decompression lowers $P_a\text{O}_2$ further. This can lead to syncope, known as a shallow water blackout. Since loss of consciousness can take place in the water, this can lead to fatalities.

Decompression sickness

Decompression sickness (the bends) are caused by release of bubbles of nitrogen or helium and follow returning too rapidly to the surface. Decompression tables indicate the duration for safe return from a given depth to the surface.

The bends can be mild (type 1, non-neurological bends), with skin irritation and mottling and/or joint pain. Type 2, neurological bends, are more serious – cortical blindness, hemiparesis, sensory disturbances or cord lesions develop.

If bubbles form in pulmonary vessels, divers experience retrosternal discomfort, breathlessness and cough, known as *the chokes*. These develop within minutes or hours of a dive. Decompression problems do not only occur immediately on

reaching the surface, they may take some hours to become apparent. Over the subsequent 24 h, further ascent, e.g. air travel, can occasionally provoke the bends.

Other problems during ascent include paranasal sinus pain and nosebleeds – medically minor but dramatic, with excruciating pain and a mask full of bloody fluid. Toothache can be caused by gas bubbles within rotten fillings.

Management. All but the mildest forms of decompression sickness, e.g. skin mottling alone, require recompression in a pressure chamber, following strict guidelines. Recovery is usual. A long-term problem is aseptic necrosis of the hip due to nitrogen bubbles causing infarction. Focal neurological damage may persist, but complaints of fatigue and poor concentration are issues compounded by litigation that commonly follows diving accidents. Objective, evidence-based assessments are essential.

Lung rupture, pneumothorax and surgical emphysema

These emergencies occur when divers breath-hold during emergency ascents after gas supplies become exhausted. There is dyspnoea, cough and haemoptysis. Pneumothorax and surgical emphysema resolve with 100% oxygen. Air embolism can also occur and is treated with recompression.

DROWNING AND NEAR-DROWNING

Drowning is a common cause of accidental death worldwide. In the UK, some 40% of drownings occur in children under 5 years of age. Drowning can also follow a seizure or a myocardial infarct. Exhaustion, alcohol, drugs and hypothermia all contribute to deaths following immersion.

Dry drowning

Between 10% and 15% of drownings occur without water aspiration into the lungs. Laryngeal spasm develops acutely, followed by apnoea and cardiac arrest.

Wet drowning

Fresh or seawater aspiration destroys pulmonary surfactant, leading to alveolar collapse, ventilation/perfusion mismatch and hypoxaemia. Aspiration of hypertonic seawater (5% NaCl) pulls additional fluid into the alveoli with further ventilation/perfusion mismatch. In practice, there is little difference between saltwater and freshwater aspiration. In both, severe hypoxaemia develops rapidly. Severe metabolic acidosis develops in the majority of survivors.

Treatment and prognosis

Cardiopulmonary resuscitation should be started immediately (see p. 691). Patients have survived for up to 30 minutes underwater without suffering brain damage – and sometimes for longer periods if T_{water} is near 10°C . Survival is probably related to the protective role of the *diving reflex*; submersion causes bradycardia and vasoconstriction. Oxygen consumption is also decreased by hypothermia.

Resuscitation should always be attempted, even with absent pulse and fixed dilated pupils. Patients frequently make a dramatic recovery. All survivors should be admitted to hospital for intensive monitoring – lung injury can develop during the subsequent 48 hours.

Recovery is frequently complete if consciousness is regained within several minutes of commencing resuscitation but poor if a patient remains stuporose or in coma at 30 minutes.

IONIZING RADIATION

Ionizing radiation is either penetrating (X-rays, γ -rays or neutrons) or non-penetrating (α - or β -particles). Penetrating radiation affects the skin and deeper tissues, while non-penetrating radiation affects the skin alone. All radiation effects depend on the type of radiation, the distribution of dose and the dose rate.

Dosage is measured in *joules per kilogram* (J/kg); 1 J/kg = 1 gray (1 Gy) = 100 rads.

Radioactivity is measured in *becquerels* (Bq). 1 Bq is defined as the activity of a quantity of radioactive material in which one nucleus decays per second; 3.7×10^{10} Bq = one curie (Ci), the older, non-SI unit.

Radiation differs in the density of ionization it causes. Therefore a dose-equivalent called a *sievert* (Sv) is used. This is the absorbed dose weighted for the damaging effect of the radiation. The annual background radiation is approximately 2.5 mSv. A chest X-ray delivers 0.02 mSv, and CT of the abdomen/pelvis about 10 mSv (see Table 9.5). A cumulative risk of cancer following repeated imaging procedures has been established and reduction of X-ray exposures should be made if possible.

Excessive exposure to ionizing radiation follows accidents in industry, nuclear power plants and hospitals and deliberate nuclear explosions designed to eliminate populations – and exceptionally, by poisoning, e.g. with polonium.

Mild acute radiation sickness

Nausea, vomiting and malaise follow doses of approximately 1 Gy. Lymphopenia occurs within several days, followed 2–3 weeks later by a fall in all white cells and platelets.

Acute radiation sickness

Many systems are affected; the extent depends on the dose of radiation (Table 18.3).

Haemopoietic syndrome

Absorption of 2–10 Gy is followed by transient vomiting in some individuals, followed by a period of improvement. Lymphocytes are particularly sensitive to radiation damage; severe lymphopenia develops over several days. A decrease in granulocytes and platelets follows 2–3 weeks later, since no new cells are formed in the marrow. Thrombocytopenia with bleeding develops and frequent overwhelming infections, with a high mortality.

Gastrointestinal syndrome

Doses >6 Gy cause vomiting several hours after exposure. This then stops, only to recur some 4 days later accompanied by diarrhoea. The villous lining of the intestine becomes

denuded. Intractable bloody diarrhoea follows, with dehydration, secondary infection and sometimes death.

CNS syndrome

Exposures of >30 Gy are followed rapidly by nausea, vomiting, disorientation and coma. Death due to cerebral oedema can follow, usually within 36 hours.

Radiation dermatitis

Skin erythema, purpura, blistering and secondary infection occur. Total loss of body hair is a bad prognostic sign and usually follows an exposure >5 Gy.

Late effects of radiation exposure

Survivors of the nuclear bombing of Hiroshima and Nagasaki in 1945 provided data on long-term radiation effects. Risks of acute myeloid leukaemia and cancer, particularly of skin, thyroid and salivary glands, increase. Infertility, teratogenesis and cataract are also late sequelae, developing years after exposure.

The sequelae of *therapeutic radiation* – early, early-delayed and late-delayed radiation effects are discussed on page 448. Focussing techniques are used to target radiation towards the field being treated; radiosensitive structures such as the ovaries are protected by shielding.

Treatment

Acute radiation sickness is an emergency. Absorption of the initial radiation dose can be reduced by removing contaminated clothing.

Treatment is largely supportive – prevention and treatment of infection, haemorrhage and fluid loss. Harvesting of blood products is sometimes carried out.

Accidental ingestion of, or exposure to, bone-seeking radioisotopes (e.g. strontium-90 and caesium-137) are treated with chelating agents, e.g. EDTA and massive doses of oral calcium. Radioiodine contamination should be treated immediately with potassium iodide to block radioiodine absorption by the thyroid.

ELECTRIC SHOCK

Electric shock can produce:

- **Pain and psychological sequelae.** The common domestic electric shock is typically painful, rarely fatal or followed by serious sequelae. Nevertheless, it is an unpleasant and intensely frightening experience. A brief immediate jerking episode can occur, that is not an epileptic seizure. There is usually no lasting neurological, cardiac or skin damage. More serious effects are distinctly rare following accidents in the home or in industry, but claims by survivors following industrial accidents are frequently made.
- **Cardiac, neurological and muscle damage.** Ventricular fibrillation, muscular contraction and spinal cord damage can follow a major shock. These are seen typically following lightning strikes with exceedingly high voltage and amperage.
- **Electrical burns.** These are commonly restricted to the skin – non-fatal lightning strikes cause fern-shaped burns. Muscle necrosis and spinal cord damage can also occur.
- **Electrocution.** This means death following ventricular fibrillation, either accidentally, or deliberately as a

FURTHER READING

method of execution. In the USA, at executions an initial voltage of >2000 volts was applied for some 15 seconds in the electric chair, causing loss of consciousness and ventricular fibrillation before the voltage was lowered. The T_{core} during the execution process would sometimes reach >50°C, leading to severe damage to internal organs.

SMOKE

Smoke is air containing toxic and/or irritant gases and carbon particles, coated with organic acids, aldehydes and synthetic materials. Carbon monoxide, sulphur dioxide, sulphuric and hydrochloric acids and other toxins may also be present. The highly toxic polyvinyl chloride is no longer used in household goods. Air pollution is discussed on [page 807](#).

On smoke inhalation, patients become breathless and tachypnoeic immediately. Choking and stridor may require intubation. Pulmonary oedema and hypoxia can be fatal.

Breathing through a wet towel or clothing is the best emergency treatment. Remove the victim from the scene as rapidly as possible. Give oxygen, and arrange ITU support.

Prevention. Smoke alarms should be in every household.

NOISE

Sound *intensity* is expressed as the square of *sound pressure*. The *bel* is the ratio equivalent to a 10-fold increase in sound intensity; a *decibel* (dB) is one-tenth of a bel. Sound is made up of a number of frequencies ranging from 30 Hz to 20 kHz, with most being between 1 and 4 kHz. In practice, a scale known as *A-weighted sound* is used; sound levels are reported as dB(A). A hazardous sound source is defined as one with an overall sound pressure of >90 dB(A).

Repeated prolonged exposure to loud noise, particularly between 2 and 6 kHz, causes first temporary and later permanent hearing loss, by physically destroying hair cells in the organ of Corti and, eventually, auditory neurones. Noise-induced hearing loss is a common occupational problem, not only in industry and the armed forces, but also in the home (drills and sanders), in sport (motor racing) and in entertainment (musicians, DJs and their audiences).

Serious noise-induced hearing loss is almost wholly preventable by personal protection (ear muffs, ear plugs). Little can be offered once hearing loss has become established.

Other effects of noise

Noise is intensely irritative, increasing or producing anxiety and anger. Excessive, repetitive noise is used in torture. Excess noise possibly affects child development and reading skills.

BIOTERRORISM/BIOWARFARE

Interest in biological warfare and bioterrorism intensified during the 1991 Iraq war and later following the destruction of the Twin Towers in New York in 2001. The potential of bacteria as weapons is illustrated by a suggestion that several kilograms of anthrax spores might kill as many people as a Hiroshima-sized nuclear weapon.

Table 18.4 Critical biological agents

Category	Pathogens
A. Very infectious and/or readily disseminated organisms: high mortality with a major impact on public health	Smallpox, anthrax, botulinism, plague
B. Moderately easy to disseminate organisms causing moderate morbidity and mortality	Q fever, brucellosis, glanders, food-/water-borne pathogens, influenza
C. Emerging and possible genetically engineered pathogens	Viral haemorrhagic fevers, encephalitis viruses, drug-resistant TB

Figure 18.2 Smallpox rash.

Potential pathogens

The US Centers for Disease Control and Prevention in Atlanta, Georgia, have developed a classification of potential biological agents ([Table 18.4](#)).

Smallpox

Smallpox is a highly infectious disease with a mortality >30%. There is no proven therapy, but there is an effective vaccine. Universal vaccination was stopped in the early 1970s: the vast majority of the world's population is now unprotected against the *variola* virus (see [p. 101](#)). The potential exists for a worldwide epidemic of smallpox, possibly initiated by a bioterrorist act.

Smallpox has an incubation period of around 12 days, allowing any initial source of infection to go undetected until the rash ([Fig. 18.2](#)), similar to chickenpox, develops on the 2nd or 3rd day of the illness. Infection is transmitted by the airborne route; the patient becomes infectious to others 12–24 hours before the rash appears, thus allowing a potential infected volunteer to pass infection to others before being recognized as suffering from smallpox. If vaccines were to be administered widely to those potentially infected within 3 days of contact, an epidemic might well be prevented. Smallpox virus is stored in two secure laboratories – in Russia and in the USA. Supplies of vaccine are potentially available worldwide.

Anthrax

In late 2001, anthrax organisms (see [p. 132](#)) were sent through the US mail and infected 22 individuals. Of these, 11 developed pulmonary anthrax, five of whom died; 11 suffered from cutaneous anthrax.

A simulated anthrax attack postulated release of anthrax powder from a truck passing a sports stadium with 74 000 spectators; 16 000 were estimated to have become infected, with a death rate of 25%. In Russia, following accidental release of anthrax from a bioweapons factory, the death rate was substantial in those nearby, especially downwind.

Botulism

The toxin produced by *Clostridium botulinum* is one of the most potent poisons known (see p. 86).

As a bioweapon, botulinum toxin could be transmitted in food or by air, e.g. from a crop-spraying light aircraft. The toxin is inactivated by chlorine in domestic water supplies. There is no vaccine available.

Plague

Plague (see p. 136) could be transmitted as a bioweapon either by air-borne dissemination or by infected rats. Immunization is of limited value.

Other potential infective agents are listed in Table 18.4.

Emergency planning

Many countries have plans to deal with bioterrorist attacks. These include training of healthcare staff and police. Such plans indicate the awareness of governments of the possibility of these threats. Stockpiling of vaccines, antibiotics and protective clothing is essential.

TRAVEL**Motion sickness**

This common problem is caused by repetitive stimulation of the labyrinth. Motion sickness occurs frequently at sea and in cars (especially in children), but also with less usual forms of transport such as camels or elephants. Nowadays, motion sickness is rare during commercial flights, but it is a problem during space travel, and on airships – one reason why the airship industry has not flourished.

Nausea, sweating, dizziness, vertigo and profuse vomiting occur, accompanied by an irresistible desire to stop moving. Prostration and intense incapacitating malaise can develop, e.g. in seasickness.

Prophylactic antihistamines, vestibular sedatives (hyoscine or cinnarizine) and stem ginger are of some value.

Jet-lag

Jet-lag (circadian dyschronism) is the well-known phenomenon that follows travelling through time-zones, particularly from West to East. Intense insomnia, fatigue, poor

concentration, irritability and loss of appetite are common. Headaches may occur. Symptoms last several days.

Mechanisms relate to the hypothalamic body clock within the suprachiasmatic nuclei. The clock is regulated by various *zeitgebers* (time-givers), e.g. light and melatonin.

Management of jet-lag includes its acceptance as a phenomenon causing poor performance – and thus waiting for 3–5 days to recover. Drink plenty of fluid, avoiding alcohol. Various hypnotics can help insomnia, but their value is disputed. Oral melatonin is widely used to reduce jet-lag but is not available on prescription in the UK. Melatonin probably hastens resetting the body clock.

BUILDING-RELATED ILLNESSES**Nonspecific building-related illness**

Multi-storey buildings typically have a controlled environment, often with automated heating and air-conditioning, and without ready access to external ventilation. More than half the adult workforce in developed countries work in such offices.

Headache, fatigue and difficulty concentrating, sometimes in epidemics, are the main complaints – but have become less frequent. Psychological factors are thought to have a substantial role. Temperature, humidity, dust, volatile organic compounds, e.g. paints and solvents, and even low level carbon monoxide toxicity have all been blamed, none with any scientific foundation.

Specific building-related illnesses

Legionnaires' disease (see p. 836) can follow contamination of air-conditioning systems.

Humidifier fever (see p. 854) is also due to contaminated systems, probably by fungi, bacteria and protozoa. Many common viruses are potentially transmissible in an enclosed environment, e.g. the common cold, influenza and rarely pulmonary TB. Allergic disorders, e.g. rhinitis, asthma and dermatitis, also occur following exposure to indoor allergens such as dust mites and plants. Office equipment, e.g. fumes from photocopiers, has also been implicated. Passive smoking (see p. 807) is no longer an issue in Europe and North America, following legislation against smoking.

INTRODUCTION

The endocrine system consists of glands that exert their actions at distant parts of the body via the production of biologically active hormones secreted into the bloodstream. Unlike the neurological system, which produces an immediate response, the endocrine system typically has a slower and longer lasting effect on the body. The main endocrine glands are the pituitary, thyroid, adrenals, gonads, parathyroids and pancreas and the common endocrine problems seen in clinical practice are shown in [Figure 19.1](#). The pituitary gland, a pea-sized structure situated at the base of the brain, plays a key role in the control and feedback mechanisms of the endocrine system and has been termed the 'conductor of the endocrine orchestra'.

Clinical presentation of endocrine disease

History

Hormones produce widespread effects in the body, and states of hormonal deficiency or excess typically present with symptoms that are generalized, diffuse and nonspecific. Symptoms of tiredness, weakness or lack of energy or drive and changes in appetite or thirst are common presentations. Other typical 'hormonal' symptoms include changes in body size and shape, problems with libido and potency, periods or sexual development, and changes in the skin (dry, greasy, acne, bruising, thinning or thickening) and hair (loss or

excess). The differential diagnosis is often wide but endocrine disorders should be always considered when assessing a patient with any of these common complaints.

The past, family and social history is essential for making the diagnosis, planning appropriate management and interpreting results of borderline hormonal blood tests.

- The past history should include previous surgery or radiation involving endocrine glands, menstrual history, pregnancy and growth and development in childhood.
- A full drug history will exclude common iatrogenic endocrine problems ([Table 19.1](#)).
- A family history of autoimmune disease, endocrine disease including tumours, diabetes and cardiovascular disease is frequently relevant, and knowledge of family members' height, weight, body habitus, hair growth and age of sexual development may aid interpretation of the patient's own symptoms.

Examination

A full general examination is essential to endocrine assessment because endocrine disorders affect all organ systems. Weight, height, body mass index (BMI), blood pressure and general habitus should all be documented, together with presence or absence of specific signs of deficiency or excess of individual hormone axes (signs of hyper- or hypothyroidism, acromegaly, Cushing's).

In people with suspected pituitary disease, visual fields and adjacent cranial nerves should be assessed clinically. In thyroid disease, presence of goitre or thyroid eye disease

Figure 19.1 The major endocrine organs and common endocrine problems.

Table 19.1 Drugs and endocrine disease	
Drug ^a	Effect
Drugs inducing endocrine disease	
Traditional antipsychotics (chlorpromazine, haloperidol, risperidone, etc.) Dopamine-antagonist antiemetics (metoclopramide, domperidone, prochlorperazine) Oestrogens	Increase prolactin, causing galactorrhoea and oligo-/amenorrhoea
Iodine Amiodarone Immune-modulating drugs	Hyperthyroidism
Lithium Amiodarone	Hypothyroidism
Ketoconazole Metyrapone Aminoglutethimide	Hypoadrenalism
Chemotherapy	Ovarian and testicular failure
Drugs simulating endocrine disease	
Sympathomimetics Amfetamines	Mimic thyrotoxicosis or phaeochromocytoma
Liquorice	Increase mineralocorticoid activity; mimic aldosteronism
Purgatives	Hypokalaemia
Diuretics	Secondary aldosteronism
ACE inhibitors	Hypoaldosteronism
Drugs affecting hormone-binding proteins	
Oestrogens (e.g. contraceptive pills)	Raise CBG – increase total cortisol
Exogenous hormones or stimulating agents	
Use, abuse or misuse, by patient or doctor, of the following: Steroids	Cushing's syndrome Diabetes
Anabolic steroids (androgens)	Suppression of gonadal axis
Levothyroxine	Thyrotoxicosis factitia
Vitamin D preparations Milk and alkali preparations	Hypercalcaemia
Insulin Sulfonylureas	Hypoglycaemia
^a Drugs causing gynaecomastia are listed in Table 19.23. Amiodarone may cause both hypo- or hyperthyroidism. CBG, cortisol-binding globulin.	

should be documented. Skin changes may give clinical clues, including pigmentation (Addison's and Nelson's), vitiligo (autoimmune endocrinopathies), acanthosis nigricans (polycystic ovary syndrome (PCOS) and diabetes), skin thinning (Cushing's, hypogonadism) or thickening (acromegaly, PCOS) and bruising and striae (Cushing's). Hirsutism is a key sign in women and signs of hair loss from the head (following a change in thyroid function, androgen excess in women or normal virilization in men) or from the body, axillary and pubic areas (hypogonadism) may occur in both sexes.

In children, height and pubertal status are an essential part of the clinical examination.

Specific clinical signs associated with particular endocrine diseases are discussed in detail in the appropriate sections.

Common endocrine conditions

The most common endocrine disorders, excluding obesity (Ch. 5) and diabetes mellitus (Ch. 20), are:

- Thyroid disorders: hypothyroidism, hyperthyroidism, goitre
- Menstrual disorders
- Hirsutism, usually due to polycystic ovary syndrome
- Subfertility
- Osteoporosis and metabolic bone disease
- Disorders of growth or puberty.

While most other endocrine conditions are uncommon, they often affect young people and are usually curable or completely controllable with appropriate therapy.

Aetiology of endocrine disease

Aetiological mechanisms common to many endocrine disorders include:

Autoimmune disease

Organ-specific autoimmune diseases can affect every major endocrine organ (Table 19.2). They are characterized by the

presence of specific antibodies in the serum, often present years before clinical symptoms are evident, are usually more common in women and have a strong genetic component, often with an identical-twin concordance rate of 50% and with HLA associations (see individual diseases). Several of the autoantigens have been identified.

Endocrine tumours

Most endocrine tumours are benign, although a cytological or histological diagnosis may be needed if there is clinical or radiological suspicion of malignancy. Clinical presentation depends on whether the tumour is functional or non-functional, the latter presenting only as a mass clinically or on imaging. Palpable thyroid nodules are common, and mass effects are a frequent presentation of pituitary adenomas, but the increased use of high-resolution ultrasound and detailed cross-sectional imaging has revealed a very high prevalence of asymptomatic, incidentally-discovered thyroid, adrenal and pituitary lesions, commonly termed 'incidentalomas' (see p. 989).

Functional tumours cause their effects via excess secretion of the relevant hormone. While often considered to be 'autonomous', i.e. independent of the physiological control mechanisms, many functional tumours do show evidence of feedback occurring at a higher 'set-point' than normal (e.g. ACTH secretion from a pituitary basophil adenoma). This is relevant in the dynamic assessment of endocrine diseases such as in the differential diagnosis of Cushing's syndrome.

Endocrine adenomas typically present in a single gland, although rarer multiple endocrine neoplasia (MEN) syndromes exist due to very specific mutations of a single gene, such as the mutations of the *RET* proto-oncogene in MEN 2 or the *MEN1* gene mutation in MEN 1 (see p. 997).

Enzyme defects

The biosynthesis of most hormones involves many stages. Deficient or abnormal enzymes can lead to absent or reduced production of the secreted hormone. In general, severe deficiencies present early in life with obvious signs; partial

Table 19.2 Types of autoimmune disease affecting endocrine organs

Organ and frequency if known	Antibody	Antigen if known	Clinical syndrome
Stimulating			
Thyroid (1 in 100)	Thyroid-stimulating immunoglobulin (TSI, TSAb)	TSH receptor	Graves' disease, neonatal thyrotoxicosis
Destructive			
Thyroid (1 in 100)	Thyroid microsomal Thyroglobulin	Thyroid peroxidase enzyme (TPO) Thyroglobulin	Primary hypothyroidism (myxoedema)
Adrenal (1 in 20 000)	Adrenal cortex	21-Hydroxylase enzyme	Primary hypoadrenalism (Addison's disease)
Pancreas (1 in 500)	Islet cell	GAD (see p. 1005)	Type 1 diabetes
Stomach	Gastric parietal cell Intrinsic factor	Gastric parietal cell Intrinsic factor	Pernicious anaemia
Skin	Melanocyte	Melanocyte	Vitiligo
Ovary (1 in 500)	Ovary		Primary ovarian failure
Testis	Testis		Primary testicular failure
Parathyroid	Parathyroid chief cell	Parathyroid chief cell	Primary hypoparathyroidism
Pituitary	Pituitary-specific cells		Autoimmune hypophysitis Selective hypopituitarism (e.g. GH deficiency, diabetes insipidus)
Frequencies are approximate and refer to the population in Northern Europe. GAD, glutamic acid dehydrogenase; GH, growth hormone. Note: Other related diseases include myasthenia gravis and autoimmune liver diseases.			

deficiencies usually present later with mild signs or are only evident under stress. An example of an enzyme deficiency is congenital adrenal hyperplasia (CAH), where the molecular basis has also been identified as mutations or deletions of the gene encoding the relevant enzymes (see p. 987).

Receptor abnormalities

There are rare conditions in which hormone secretion and control are normal but the receptors are defective; thus, if androgen receptors are defective, normal levels of androgen will not produce masculinization (e.g. testicular feminization). There are also a number of rare syndromes of diabetes and insulin resistance from receptor abnormalities (see p. 1006); other examples include nephrogenic diabetes insipidus, pseudohypoparathyroidism and thyroid hormone resistance which can cause an unusual pattern of thyroid blood results.

HORMONAL ACTIVITY

Synthesis, storage and release of hormones

Hormones may be of several chemical structures: polypeptide, glycoprotein, steroid or amine. Hormone release is the end-product of a long cascade of intracellular events. In the case of polypeptide hormones, neural or endocrine stimulation of the cell leads to increased transcription from DNA to a specific mRNA, which is in turn translated to the peptide product. This is often in the form of a precursor molecule that may itself be biologically inactive. This 'prohormone' is then further processed before being packaged into granules, in the Golgi apparatus. These granules are then transported to the plasma membrane before release, which is itself regulated by a complex combination of intracellular regulators. Hormone release may be in a brief spurt caused by the sudden stimulation of granules, often induced by an intracellular Ca^{2+} -dependent process, or it is 'constitutive' (immediate and continuous secretion).

Plasma transport

Most classical hormones are secreted into the systemic circulation. In contrast, hypothalamic releasing hormones are released into the pituitary portal system so that much higher concentrations of the releasing hormones reach the pituitary than occur in the systemic circulation.

Many hormones are bound to proteins within the circulation. In most cases, only the free (unbound) hormone is available to the tissues and thus biologically active. This binding serves to buffer against very rapid changes in plasma levels of the hormone, and some binding protein interactions are also involved in the active regulation of hormone action. Many tests of endocrine function measure total rather than free hormone, which can give rise to difficulties in interpretation when binding proteins are altered in disease states or by drugs.

Binding proteins comprise both specific, high-affinity proteins of limited capacity, such as thyroxine-binding globulin (TBG), cortisol-binding globulin (CBG), sex-hormone-binding globulin (SHBG) and IGF-binding proteins (e.g. IGF-BP3) and other less specific, low-affinity ones, such as prealbumin and albumin.

Hormone action and receptors

Hormones act by binding to specific receptors in the target cell. Most hormone receptors are proteins with complex

tertiary structures. The structure of the hormone-binding domain of the receptor complements the tertiary structure of the hormone, while changes in other parts of the receptor in response to hormone binding are responsible for the effects of the activated receptor within the cell. The structure of common hormones and their receptors is described under individual hormone axes.

Hormone receptors are broadly divided into:

- **Cell surface or membrane receptors:** typically transmembrane receptors which contain hydrophobic sections spanning the lipid-rich plasma membrane and which trigger internal cellular messengers (see also p. 18)
- **Nuclear receptors** which typically bind hormones and translocate them to the nucleus where they bind hormone response elements of nuclear DNA via characteristic amino-acid sequences (e.g. so-called 'zinc fingers', see p. 27).

Abnormal receptors are an occasional cause of endocrine disease (see p. 43).

Mechanisms of hormone-receptor action

Common structural mechanisms of hormone-receptor action are illustrated in Figure 2.9 (p. 25) and include:

G-protein coupled receptors (7-transmembrane or serpentine receptors). These bind hormones on their extracellular domain and activate the membrane G-protein complex with their intracellular domain. The activated complex may then:

- stimulate cyclic AMP (cAMP) generation by adenylate cyclase – activating further intracellular kinases and leading to phosphorylation
- activate phospholipase C (PLC) leading to generation of inositol 1,4,5-triphosphate (IP_3) and release of intracellular calcium – in turn leading to calmodulin-dependent kinase activity and phosphorylation
- lead to diacylglycerol (DAG) activation of C-kinase and subsequent protein phosphorylation.

Most peptide hormones act via G-protein coupled receptors.

Dimeric transmembrane receptors, from several receptor superfamilies, bind hormone in their extracellular components (sometimes causing the dimerization of the receptor monomer) and directly phosphorylate intracellular messengers via their intracellular components, leading to a variety of intracellular activation cascades. Growth hormone, prolactin and insulin-like growth factor-1 (IGF-1) act via this type of receptor.

Lipid-soluble molecules pass through the cell membrane and typically bind with their **nuclear receptors** in the cell cytoplasm before translocation of the activated hormone-receptor complex to the nucleus where it binds to nuclear DNA, often in combination with a multi-component complex of promoters, inhibitors and transcription factors. This interaction usually leads to increased transcription of the relevant gene product. Steroid and thyroid hormones act via this type of receptor.

Hormone release and binding to receptors. The activation of intracellular kinases, phosphorylation, release of intracellular calcium and other 'second messenger' pathways and the direct stimulation of DNA transcription results in some or all of the following:

- Stimulation or release of pre-formed hormone from storage granules
- Stimulation or synthesis of hormone and other cellular components

- Opening or closing of ion or water channels in the cell membrane (e.g. calcium channels or aquaporin water channels)
- Activation or deactivation of other DNA binding proteins leading to stimulation or inhibition of DNA transcription.

In each case, binding of the hormone to its receptor is the first step in a complex cascade of interrelated intracellular events which eventually lead to the overall effects of that hormone on cellular function.

The sensitivity and/or number of receptors for a hormone are often decreased after prolonged exposure to a high hormone concentration, the receptors thus becoming less sensitive ('downregulation', e.g. angiotensin II receptors, β -adrenoceptors). The reverse is true when stimulation is absent or minimal, the receptors showing increased numbers or sensitivity ('upregulation').

Control and feedback

Most hormone systems are under tight regulatory control (typically by the hypothalamo-pituitary (HP) axis) by a system known as negative feedback. An example of the negative feedback system in the hypothalamo-pituitary-thyroid axis is demonstrated in Figure 19.2 and described here:

- TRH (thyrotrophin-releasing hormone) is secreted in the hypothalamus and travels via the portal system to the pituitary where it stimulates the thyrotrophs to produce thyroid-stimulating hormone (TSH).
- TSH is secreted into the systemic circulation where it stimulates increased thyroidal iodine uptake by the thyroid and the synthesis and release of thyroxine (T_4) and triiodothyronine (T_3).
- Serum levels of T_3 and T_4 are increased by TSH; in addition, the conversion of T_4 to T_3 (the more

active hormone) in peripheral tissues is stimulated by TSH.

- T_3 and T_4 then enter cells where they bind to nuclear receptors and promote increased metabolic and cellular activity.
- Levels of T_3 , from the blood and from local conversion of T_4 , are sensed by receptors in the pituitary and the hypothalamus. If they rise above normal, TRH and TSH production is suppressed, leading to reduced T_3 and T_4 secretion.
- Peripheral T_3 and T_4 levels fall to normal.
- If, however, T_3 and T_4 levels are low, for example after thyroidectomy, increased amounts of TRH and TSH are secreted, stimulating the remaining thyroid to produce more T_3 and T_4 ; blood levels of T_3 and T_4 may be restored to normal, at the expense of increased TSH drive, reflected by a high TSH level, 'compensated euthyroidism'.
- Conversely, in thyrotoxicosis when factors other than TSH itself are maintaining high T_3 and T_4 levels, the same mechanisms lead to suppression of TSH secretion.

Primary and secondary gland failure

It is useful in clinical endocrinology to distinguish between 'primary' disease of the end-organ gland (e.g. due to autoimmune destruction, atrophic change, infiltration or surgical removal of the gland), and 'secondary' disorders of the same axis caused by disease of the pituitary gland. An understanding of the negative feedback system is key to interpreting endocrine blood results and diagnosing the site of the disease process in clinical practice. In general terms:

- **'Primary' hormone deficiency** due to a disease process in the endocrine end-organ (thyroid, adrenal or gonad) will lead to a loss of negative feedback and subsequent elevation in the corresponding anterior pituitary hormone. Conversely, an abnormal hormone excess due to a disease process in the primary endocrine gland, or excess amount of exogenous hormone, will lead to increased negative feedback and suppression of the corresponding pituitary hormones.
- In **'secondary gland failure'** there are low or 'inappropriately normal' levels of the pituitary trophic hormone in the face of a low end-organ hormone level. For example, if a patient has low circulating free T_3 (fT_3) and T_4 levels in the context of a low TSH, pituitary disease should be suspected. Equally, the presence of a non-suppressed plasma ACTH in the context of Cushing's syndrome implies that the pituitary rather than the adrenal itself is the cause.

Hormone resistance

In certain situations, receptor abnormalities can give rise to abnormal negative feedback due to hormone resistance, which can lead to an unusual pattern of blood results. For example, thyroid hormone resistance, due to mutations in the thyroid hormone receptor, is characterized by an elevation in thyroid hormones with a non-suppressed TSH. With this pattern of thyroid results, the clinician should also consider the rare diagnosis of a TSH secreting pituitary tumour.

Figure 19.2 The hypothalamic-pituitary-thyroid axis. Pituitary TSH is secreted in response to hypothalamic TRH and stimulates secretion of T_4 and T_3 from the thyroid. T_4 and T_3 have actions in peripheral tissues and exert negative feedback on pituitary and hypothalamus.

Measurement of hormones

Hormones are measured in routine clinical practice by biochemical assays in the laboratory. It is possible to measure pituitary trophic hormones and the hormones produced by the end-organ glands, but hypothalamic hormones are not routinely measured in practice because of their low concentration and local action within the hypothalamo-pituitary axis. Circulating levels of most hormones are very low (10^{-9} – 10^{-12} mol/L) and cannot be measured by simple chemical techniques. Hormones are therefore usually measured by immunoassays, which rely on highly specific polyclonal or monoclonal antibodies, which bind to the hormone being measured during the assay incubation. This hormone-antibody interaction is measured by use of labelled hormone after separation of bound and free fractions (Fig. 19.3).

Immunoassays are sensitive but have limitations. In particular, the immunological activity of a hormone, as used in developing the antibody, may not necessarily correspond to biological activity and there may be false positive and negative results. The patient's blood may also contain heterophile antibodies which interact with the animal antibodies used in the assay, and result in falsely low or high values. When there is a discrepancy between endocrine blood results and the clinical presentation, the clinician must question the validity of an endocrine result, and a close relationship with the relevant laboratory is essential. It may be necessary for the sample to be measured in a different laboratory using an alternative antibody, or to measure hormones in ways other than by immunoassay. Examples of alternative techniques to accurately quantify and characterize hormone levels include equilibrium dialysis, high-pressure liquid chromatography (HPLC) and, increasingly, mass spectroscopy.

Figure 19.3 Principles of measurement of hormone levels in plasma by immunoassay (precise details vary with different assays and manufacturers). Immunoassays use two antibodies specific to the hormone being measured – one typically attached to a solid phase and one labelled antibody in the liquid phase. **(a)** High hormone levels in plasma: large amount of hormone binds to antibody on solid phase – large amount of labelled antibody linked to solid phase via molecules of the hormone. **(b)** Low hormone levels in plasma: less hormone, and therefore less labelled antibody, is linked to the solid phase. Label (radioactive, chemiluminescent, enzymatic or fluorescent) can be measured in either solid or liquid phase after separation of phases; levels of label will be proportional to the amount of hormone in the sample.

Hormone binding proteins

Many hormones are transported in the bloodstream from the primary gland to their distant target organ attached to a specific binding protein (p. 940). It is more helpful to measure the free hormone rather than total bound hormone level, as this is the part that is biologically active. Some modern assays attempt to measure the free hormone level directly (e.g. free T_4) and are therefore a more accurate reflection of biological activity, although there are often technical problems with this approach and many assays still measure total hormone level.

Cortisol, which is bound to cortisol binding globulin (CBG), and testosterone, which is bound to sex hormone binding globulin (SHBG), are still usually measured in their total form and can be affected by alterations in binding protein levels. In women who are pregnant or on the combined oral contraceptive pill, high oestrogen levels may lead to an elevation in CBG which can overestimate cortisol and give the false impression of hypercortisolaemia. In people with diabetes mellitus or other insulin-resistant states which may lower SHBG levels, low total testosterone levels may give the false impression of androgen deficiency. Conversely, hyperthyroidism or oestrogen excess can cause an elevation in SHBG, leading to apparently high total testosterone levels. As with all endocrine results, the data need to be interpreted in the clinical context.

Patterns of hormonal secretion

Hormone secretion can be continuous or intermittent, for example:

- **Continuous secretion** is shown by the thyroid hormones, with a half-life of 7–10 days for T_4 and 6–10 hours for T_3 , and with little variation in levels over the day, month and year
- **Pulsatile secretion** is the normal pattern for the gonadotrophins, LH and FSH, with major pulses released every 1–2 hours depending on the phase of the menstrual cycle. Growth hormone is also secreted in a pulsatile fashion, with undetectable levels in between pulses. A single measurement is therefore not helpful to diagnose GH deficiency or excess.

Biological rhythms

Circadian means changes over the 24 hours of the day–night cycle and is best shown for the pituitary–adrenal axis. Figure 19.4 shows plasma cortisol levels measured over 24 hours – levels are highest in the early morning and lowest overnight. Additionally, cortisol release is pulsatile, following the pulsatility of pituitary ACTH. Thus ‘normal’ cortisol levels vary during the day and great variations can be seen in samples taken only 30 minutes apart.

The menstrual cycle is an example of a longer and more complex (28-day) biological rhythm (see p. 972).

Other regulatory factors

- **Stress.** Physiological ‘stress’ and acute illness produce rapid increases in ACTH and cortisol, growth hormone (GH), prolactin, adrenaline (epinephrine) and noradrenaline (norepinephrine). These can occur within seconds or minutes.
- **Sleep.** Secretion of GH and prolactin is increased during sleep, especially the rapid eye movement (REM) phase.
- **Feeding and fasting.** Many hormones regulate the body's control of energy intake and expenditure and are

Figure 19.4 Plasma cortisol levels during a 24-hour period. Note both the pulsatility and the shifting baseline. Normal ranges for 09:00 hours (180–700 nmol/L) and 24:00 hours (<100 nmol/L; must be taken when asleep) are shown in the orange boxes. Purple shading shows sleep.

therefore profoundly influenced by feeding and fasting. Secretion of insulin is increased and growth hormone decreased after ingestion of food, and secretion of a number of hormones is altered during prolonged food deprivation.

TESTING ENDOCRINE FUNCTION

Endocrine function is assessed by measurement of hormone levels in blood (or more precisely in plasma or serum) and sometimes in other body fluids on samples obtained basally and in response to stimulation and suppression tests.

Basal blood levels

Assays for all clinically relevant pituitary and end-organ hormones are available.

The time, day and condition of measurement make great differences to hormone levels, and the method and timing of samples therefore depends upon the characteristics of the endocrine system involved. There are also sex, developmental and age differences.

Basal levels are especially useful for systems with long half-lives (e.g. T_4 and T_3 , IGF-1, androstenedione, SHBG). These vary little over the short term and random samples are therefore satisfactory.

Basal samples for many hormones need to be interpreted with respect to normal ranges for the time of day/month, diet or posture concerned. Hormones with a marked circadian rhythm (testosterone in men, cortisol, ACTH, 17α OH-progesterone) must be measured at appropriate time of day (typically at 08:00 to 10:00 but, e.g. at 24:00 to demonstrate normal low levels of cortisol at this time). LH/FSH, oestrogen and progesterone vary with time of menstrual cycle and renin/aldosterone vary with sodium intake, posture and age. For these hormones, all relevant details must be recorded or the results may prove uninterpretable.

Stress-related hormones

Measurement of stress-related hormones may be problematic either because the patient is stressed by hospital attendance or venepuncture, leading to falsely high levels (e.g. catecholamines, prolactin where sampling via an indwelling needle some time after initial venepuncture may be required) or because low levels in a non-stressed individual are unable

Box 19.1 Short ACTH (tetracosactide) stimulation test

Indication

- Diagnosis of Addison's disease
- Screening test for ACTH deficiency

Procedure

- Intravenous cannula for sampling
- Any time of day, but best at 09:00 hours; non-fasting
- Tetracosactide 250 μ g, i.v. or i.m. at time 0
- Measure serum cortisol at time 0 and time +30 min

Normal response

- 30 min cortisol >600 nmol/L^a
 - (400–600 nmol/L borderline and may indicate deficiency)

^aPrecise cortisol normal ranges are variable between laboratories and assays – appropriate local reference ranges must be used.

to confirm an adequate reserve required for normal physiological stress (cortisol and GH).

Urine collections

Collections over 24 hours have the advantage of providing an 'integrated mean' of a day's secretion but in practice are often incomplete or wrongly timed. They also vary with sex and body size or age. Written instructions should be provided for the patient to ensure accurate collection. Examples of hormones measured in this way are catecholamines and urinary free cortisol levels.

Saliva

Saliva is sometimes used for steroid estimations, especially in children or for samples taken at home. Midnight salivary cortisol levels are increasingly used for the diagnosis of Cushing's syndrome due to the practical difficulties in obtaining a midnight blood sample.

Stimulation and suppression tests

These tests are used when basal levels give equivocal information. In general, stimulation tests are used to confirm suspected deficiency, and suppression tests to confirm suspected excess of hormone secretion. These tests are valuable in many instances.

For example, where the secretory capacity of a gland is damaged, maximal stimulation by the trophic hormone will give a diminished output. Thus, in the short ACTH stimulation test for adrenal reserve (Box 19.1, Fig. 19.5a), the healthy subject shows a normal response while the subject with primary hypoadrenalism (Addison's disease) demonstrates an impaired cortisol response to tetracosactide (an ACTH analogue).

A patient with a hormone-producing tumour usually fails to show normal negative feedback. A patient with Cushing's disease (excess pituitary ACTH) will thus fail to suppress ACTH and cortisol production when given a dose of synthetic steroid, in contrast to normal subjects. Figure 19.5b shows the response of a normal subject given dexamethasone 1 mg at midnight; cortisol is suppressed the following morning. The subject with Cushing's disease shows inadequate suppression.

The detailed protocol for each test must be followed exactly, since differences in technique will produce variations in results.

Figure 19.5 Short ACTH stimulation and dexamethasone tests. (a) This test shows a normal response in a healthy subject and a decreased response in a patient with Addison's disease. **(b)** Dexamethasone suppression tests in a normal subject and in a patient with Cushing's disease showing inadequate suppression.

THE PITUITARY GLAND AND HYPOTHALAMUS

Anatomy

Most peripheral hormone systems are controlled by the hypothalamus and pituitary. The hypothalamus is sited at the base of the brain around the third ventricle and above the pituitary stalk, which leads down to the pituitary itself, carrying the hypophyseal-pituitary portal blood supply.

The anatomical relations of the hypothalamus and pituitary (Fig. 19.6) include the optic chiasm just above the pituitary fossa; any expanding lesion from the pituitary or hypothalamus can thus produce visual field defects by pressure on the chiasm. Such upward expansion of the gland through the diaphragma sellae is termed 'suprasellar extension'. Lateral extension of pituitary lesions may involve the vascular and nervous structures in the cavernous sinus and may rarely reach the temporal lobe of the brain. The pituitary is itself encased in a bony box, therefore any lateral, anterior or posterior expansion must cause bony erosion.

Embryologically, the anterior pituitary is formed from an upgrowth of Rathke's pouch (ectodermal) which meets an outpouching of the third ventricular floor which becomes the posterior pituitary. This unique combination of primitive gut and neural tissue provides an essential link between the rapidly responsive central nervous system and the longer-acting endocrine system. Several transcription factors

Figure 19.6 MR image of a sagittal section of the brain, showing the pituitary fossa and adjacent structures.

(By kind permission of Dr Martin Jeffree.)

– LHX3, HESX1, PROP1, POU1F1 – are responsible for the differentiation and development of the pituitary cells. Mutation of these produces pituitary disease.

Physiology

Hypothalamus

This contains many vital centres for such functions as appetite, thirst, thermal regulation and sleeping/waking. It acts as an integrator of many neural and endocrine inputs to control the release of pituitary hormone-releasing factors. It plays a role in the circadian rhythm, menstrual cyclicity, and responses to stress, exercise and mood.

Hypothalamic neurones secrete pituitary hormone-releasing and -inhibiting factors and hormones (Table 19.3) into the portal system which run down the stalk to the pituitary. As well as the classical hormones illustrated in Figure 19.7, the hypothalamus also contains large amounts of other neuropeptides and neurotransmitters such as neuropeptide Y, vasoactive intestinal peptide (VIP) and nitric oxide that can also alter pituitary hormone secretion.

Synthetic hypothalamic hormones and their antagonists are available for the testing of many aspects of endocrine function and for treatment.

Anterior pituitary

The majority of anterior pituitary hormones are under predominantly positive control by the hypothalamic releasing hormones apart from prolactin, which is under tonic inhibition by dopamine. Pathological conditions interrupt the flow of hormones between the hypothalamus and pituitary gland and therefore cause deficiency of most hormones but oversecretion of prolactin. There are five major anterior pituitary axes: the gonadotrophin axis, the growth axis, prolactin, the thyroid axis and the adrenal axis.

Posterior pituitary

The posterior pituitary is neuro-anatomically connected to specific hypothalamic nuclei, and acts merely as a storage organ. Antidiuretic hormone (ADH, also called vasopressin) and oxytocin, both nonapeptides, are synthesized in the supraoptic and paraventricular nuclei in the anterior hypothalamus. They are then transported along the axon and stored in the posterior pituitary (Fig. 19.7). This means that damage

Table 19.3 Hormones and receptors of the hypothalamic–pituitary axis

Hormone	Source	Site of action	Hormone structure	Receptor	Post-receptor activity
Pituitary growth axis					
Growth hormone-releasing hormone (GHRH)	Hypothalamus	Pituitary	Peptide – 44 AA	Membrane – 7TM	G-proteins cAMP
Somatostatin (inhibitory GHRH)	Hypothalamus	Pituitary	Cyclic peptide – 14 or 28 AA	Membrane – 7TM SST2 + SST5	G-proteins Inhibit cAMP
Growth hormone	Pituitary	Liver and other tissues	Peptide – 191 AA	Transmembrane Dimerized GHR	JAK2 STAT
Insulin-like growth factor 1 (IGF-1)	Liver + locally elsewhere	Many tissues	Peptide – 70 AA 3 S=S bridges	Transmembrane – IGFR 2 α + 2 β subunits	Receptor tyrosine kinase
Pituitary-thyroid axis					
Thyrotrophin-releasing hormone (TRH)	Hypothalamus	Pituitary	Peptide – 3 AA	Membrane – 7TM TRHR	G-proteins PLC/IP ₃
Thyroid-stimulating hormone (TSH)	Pituitary	Thyroid	Glycoprotein: α and β subunits	Membrane – 7TM TSHR	G-proteins cAMP/PLC/IP ₃
Thyroxine and triiodothyronine (T ₄ and T ₃)	Thyroid	All tissues	Thyronines – 4/3 iodine atoms	Nuclear TR- α and β	Transcription TRE/RXR
Pituitary-gonadal axis					
Gonadotrophin-releasing hormone (GnRH; LHRH)	Hypothalamus	Pituitary	Peptide – 10 AA	Membrane – 7TM GnRH-R1	G-proteins PLC / IP ₃
Luteinizing hormone (LH)	Pituitary	Gonad	Glycoprotein: α and β subunits	Membrane – 7TM LHhCGR	G-proteins cAMP
Follicle-stimulating hormone (FSH)	Pituitary	Gonad	Glycoprotein: α and β subunits	Membrane – 7TM FSHR	G-proteins cAMP
Oestradiol	Ovary	Uterus, breast bone, vascular	Steroid ring	Nuclear ER α and β (ESR1/ESR2)	Homo-/hetero-dimer ERE Transcription
Testosterone	Testis	Many tissues	Steroid ring	Nuclear AR (NR3C4)	Dimer ARE Transcription
Inhibin and activin	Gonad	Pituitary – hypothalamus	Peptide dimers α and β subunits	Transmembrane dimerized	Phosphorylation by receptor
Prolactin axis					
Dopamine	Hypothalamus	Pituitary	Amine	Membrane – 7TM D2 receptor	G-proteins Inhibit cAMP
Prolactin	Pituitary	Breast Other tissues	Peptide – 199 AA	Transmembrane PRLR Class 1 cytokine	JAK2 and other pathways
Pituitary-adrenal axis					
Corticotrophin releasing hormone (CRH)	Hypothalamus	Pituitary	Peptide – 41 AA	Membrane – 7TM CRF1	G-proteins cAMP
Adrenocorticotrophic hormone (ACTH)	Pituitary	Adrenal	Peptide – 39 AA	Membrane – 7TM ACTHR (MCR2)	G-proteins cAMP
Cortisol	Adrenal	All tissues	Steroid ring	Nuclear GR α	Transcription GRE
Posterior pituitary axes					
Vasopressin (antidiuretic hormone, ADH)	Hypothalamus → pituitary	Kidney	Peptide – 9 AA	Membrane – 7TM AVPR2	G-proteins cAMP Aquaporin-2
	Hypothalamus → pituitary	Vascular	Peptide – 9 AA	Membrane – 7TM AVPR1A	G-proteins PLC/IP ₃
	Hypothalamus → portal veins	Pituitary (ACTH secretion)	Peptide – 9 AA	Membrane – 7TM AVPR1B	G-proteins PLC/IP ₃
Oxytocin	Hypothalamus → pituitary	Uterus and breast	Peptide – 9 AA	Membrane – 7TM OXTR	G-proteins

7TM, 7 transmembrane (G-protein coupled receptor); AA, amino acids; ARE, androgen response element; cAMP, adenylate cyclase → cyclic AMP; ERE, oestrogen response element; GRE, glucocorticoid response element; JAK, Janus kinase; MCR, melanocortin receptor; PLC/IP₃, phospholipase C/inositol triphosphate; STAT, signal transducers and activators of transcriptions; GHRH, growth hormone releasing inhibitory hormone; SST, somatostatin receptor subtypes; TRE/RXR, thyroid hormone response element/response silencing region; LHhCGR, luteinizing hormone human chorionic gonadotrophin receptor; AVPR, arginine vasopressin receptor; OXTR, oxytocin receptor.

Figure 19.7 Hypothalamic releasing hormones and the pituitary trophic hormones. See the text for an explanation.

to the stalk or pituitary alone does not prevent synthesis and release of ADH and oxytocin. ADH is discussed on [page 991](#); oxytocin produces milk ejection and uterine myometrial contraction.

PRESENTATIONS OF PITUITARY AND HYPOTHALAMIC DISEASE

Diseases of the pituitary can cause under- or overactivity of each of the hypothalamo-pituitary-end-organ axes which are under the control of this gland. The clinical features of the syndromes associated with such altered pituitary function, e.g. Cushing's syndrome, can be the presenting symptom of pituitary disease or of end-organ disease and are discussed later. First, however, we look at clinical features of pituitary disease which are common to all hormonal axes.

Pituitary space-occupying lesions and tumours

Pituitary tumours ([Table 19.4](#)) are the most common cause of pituitary disease, and the great majority of these are benign pituitary adenomas, usually monoclonal in origin. Problems are caused by:

- local effects of a tumour
- excess hormone secretion
- the result of inadequate production of hormone by the remaining normal pituitary, i.e. hypopituitarism.

Investigations (of a possible or proven mass)

Is there a tumour?

If there is, how big is it and what *local anatomical effects* is it exerting? Pituitary and hypothalamic space-occupying lesions, hormonally active or not, can cause symptoms by pressure on, or infiltration of:

- the visual pathways, with field defects and visual loss (most common)

- the cavernous sinus, with III, IV and VI cranial nerve lesions
- bony structures and the meninges surrounding the fossa, causing headache
- hypothalamic centres: altered appetite, obesity, thirst, somnolence/wakefulness or precocious puberty
- the ventricles, causing interruption of cerebrospinal fluid (CSF) flow leading to hydrocephalus
- the sphenoid sinus with invasion causing CSF rhinorrhoea.

Investigations

- **MRI of the pituitary.** MRI is superior to CT scanning ([Fig. 19.8](#)) and will readily show any significant pituitary mass. Small lesions within the pituitary fossa on MRI consistent with small pituitary microadenomas are very common (10% of normal individuals in some studies). Such small lesions are sometimes detected during MRI scanning of the head for other reasons – so-called 'pituitary incidentalomas'.
- **Visual fields.** These should be plotted formally by automated computer perimetry or Goldmann perimetry, but clinical assessment by confrontation using a small red pin as target is also sensitive and valuable. Common defects are upper temporal quadrantanopia and bitemporal hemianopia (see [p. 1073](#)).

Is there a hormonal excess?

There are three major conditions usually caused by secretion from pituitary adenomas which will show positive immunostaining for the relevant hormone:

- Prolactin excess (**prolactinoma or hyperprolactinaemia**): histologically, prolactinomas are 'chromophobe' adenomas (a description of their appearance on classical histological staining)
- GH excess (**acromegaly or gigantism**): somatotroph adenomas, usually 'acidophil', and sometimes due to specific G-protein mutations (see [p. 945](#))

Table 19.4 Characteristics of common pituitary and related tumours		
Tumour or condition	Usual size	Most common clinical presentation
Prolactinoma	Most <10 mm (microprolactinoma)	Galactorrhoea, amenorrhoea, hypogonadism, erectile dysfunction
	Some >10 mm (macroprolactinoma)	As above plus headaches, visual field defects and hypopituitarism
Acromegaly	Few mm to several cm	Change in appearance, visual field defects and hypopituitarism
Cushing's disease	Most small: few mm (some cases are hyperplasia)	Central obesity, cushingoid appearance (local symptoms rare)
Nelson's syndrome	Often large: >10 mm	Post-adrenalectomy, pigmentation, sometimes local symptoms
Non-functioning tumours	Usually large: >10 mm	Visual field defects; hypopituitarism (microadenomas may be incidental finding)
Craniopharyngioma	Often very large and cystic (skull X-ray abnormal in >50%; calcification common)	Headaches, visual field defects, growth failure (50% occur below age 20; about 15% arise from within sella)

Figure 19.8 (a) Coronal MRI of pituitary, showing a left-sided lucent intrasellar microadenoma (arrowed). The pituitary stalk is deviated slightly to the right. (b) Coronal MRI of pituitary, showing macroadenoma with moderate suprasellar extension, and lateral extension compressing left cavernous sinus. The top of the adenoma is compressing the optic chiasm (arrowed). (c) Sagittal MRI of head, showing a pituitary macroadenoma with massive suprasellar extension (arrows).

- excess ACTH secretion (**Cushing's disease and Nelson's syndrome**): corticotroph adenomas, usually 'basophil'.

Many tumours are able to synthesize several pituitary hormones, and occasionally more than one hormone is secreted in clinically significant excess (e.g. both GH and prolactin).

The clinical features of acromegaly, Cushing's disease or hyperprolactinaemia are usually (but not always) obvious, and are discussed on pages 953, and 957. Hyperprolactinaemia may be clinically 'silent'. Tumours producing LH, FSH or TSH are well described but very rare.

Some common pituitary tumours, usually 'chromophobe' adenomas, cause no clinically apparent hormone excess and are referred to as 'non-functioning' tumours. Laboratory studies such as immunocytochemistry or in situ hybridization show that these tumours may often produce small amounts of LH and FSH or the α -subunit of LH, FSH and TSH, and occasionally ACTH.

Is there a deficiency of any hormone?

Clinical examination may give clues; thus, short stature in a child with a pituitary tumour is likely to be due to GH deficiency. A slow, lethargic adult with pale skin is likely to be deficient in TSH and/or ACTH. Milder deficiencies may not be obvious, and require specific testing (see Table 19.7).

Treatment

Treatment depends on the type and size of tumour (Table 19.5). In general, therapy has three aims:

Removal/control of tumour

- **Surgery** via the trans-sphenoidal route is usually the treatment of choice. Very large tumours are occasionally removed via the open transcranial (usually transfrontal) route.
- **Radiotherapy** – by conventional linear accelerator or newer stereotactic techniques – is usually employed when surgery is impracticable or incomplete, as it controls but rarely abolishes tumour mass. The conventional regimen involves a dose of 45 Gy, given as 20–25 fractions via three fields. Stereotactic techniques use either a linear accelerator or multiple cobalt sources ('gamma-knife').
- **Medical therapy** with somatostatin analogues and/or dopamine agonists sometimes causes shrinkage of specific types of tumour (see p. 954) and if successful can be used as primary therapy.

Reduction of excess hormone secretion

Reduction is usually obtained by surgical removal but sometimes by medical treatment. Useful control can be achieved

Table 19.5 Comparisons of primary treatments for pituitary tumours

Treatment method	Advantages	Disadvantages
Surgical		
Trans-sphenoidal adenectomy or hypophysectomy	Relatively minor procedure Potentially curative for microadenomas and smaller macroadenomas	Some extrasellar extensions may not be accessible Risk of CSF leakage and meningitis
Transcranial (usually transfrontal)	Good access to suprasellar region	Major procedure; danger of frontal lobe damage High chance of subsequent hypopituitarism
Radiotherapy		
External (40–50 Gy)	Non-invasive Reduces recurrence rate after surgery	Slow action, often over many years Not always effective Possible late risk of tumour induction
Stereotactic	Precise administration of high dose to lesion	Long-term follow-up data limited
Medical		
Dopamine agonist therapy (e.g. bromocriptine, cabergoline)	Non-invasive; reversible	Usually not curative; significant side-effects in minority Concerns about fibrotic reactions
Somatostatin analogue therapy (octreotide, lanreotide)	Non-invasive; reversible	Usually not curative; gallstones; expensive
Growth hormone receptor antagonist (pegvisomant)	Highly selective	Usually not curative; very expensive

with dopamine agonists for prolactinomas or somatostatin analogues for acromegaly, but ACTH secretion usually cannot be controlled by medical means. Growth hormone antagonists are also available for acromegaly (p. 955).

Replacement of hormone deficiencies

Replacement of hormone deficiencies, i.e. hypopituitarism, is discussed below (see Table 19.8).

Small tumours producing no significant symptoms, pressure or endocrine effects may be observed with appropriate clinical, visual field, imaging and endocrine assessments.

Differential diagnosis of pituitary or hypothalamic masses

Although pituitary adenomas are the most common mass lesion of the pituitary (90%), a variety of other conditions may also present as a pituitary or hypothalamic mass and form part of the differential diagnosis.

Other tumours

- **Craniopharyngioma** (1–2%), a usually cystic hypothalamic tumour, often calcified, arising from Rathke's pouch, often mimics an intrinsic pituitary lesion. It is the most common pituitary tumour in children but may present at any age.
- **Uncommon tumours** include meningiomas, gliomas, chondromas, germinomas and pinealomas. Primary pituitary carcinomas are very rare, but occasionally prolactin and ACTH secreting tumours can present in an aggressive manner which may require chemotherapy in addition to conventional treatment. Secondary deposits occasionally present as apparent pituitary tumours, typically presenting with headache and diabetes insipidus.

Hypophysitis and other inflammatory masses

A variety of inflammatory masses occur in the pituitary or hypothalamus. These include rare pituitary-specific conditions (e.g. autoimmune [lymphocytic] hypophysitis, giant cell

hypophysitis, postpartum hypophysitis) or pituitary manifestations of more generalized disease processes (sarcoidosis, Langerhans' cell histiocytosis, Wegener's granulomatosis). These lesions may be associated with diabetes insipidus and/or an unusual pattern of hypopituitarism.

Other lesions

Carotid artery aneurysms may masquerade as pituitary tumours and must be diagnosed before surgery. Cystic lesions may also present as a pituitary mass, including arachnoid and Rathke cleft cysts.

Hypopituitarism

Pathophysiology

Deficiency of hypothalamic releasing hormones or of pituitary trophic hormones can be selective or multiple. Thus isolated deficiencies of GH, LH/FSH, ACTH, TSH and vasopressin (ADH) are all seen, some cases of which are genetic and congenital and others sporadic and autoimmune or idiopathic in nature.

Multiple deficiencies usually result from tumour growth or other destructive lesions. There is generally a progressive loss of anterior pituitary function. GH and gonadotrophins are usually first affected. Hyperprolactinaemia, rather than prolactin deficiency, occurs relatively early because of loss of tonic inhibitory control by dopamine. TSH and ACTH are usually last to be affected.

Panhypopituitarism refers to deficiency of all anterior pituitary hormones; it is most commonly caused by pituitary tumours, surgery or radiotherapy. Vasopressin (ADH) and oxytocin secretion will be significantly affected only if the hypothalamus is involved by a hypothalamic tumour or major suprasellar extension of a pituitary lesion, or if there is an infiltrative/inflammatory process. Posterior pituitary deficiency is rare in an uncomplicated pituitary adenoma.

Genetics of hypopituitarism

Specific genes are responsible for the development of the anterior pituitary involving interaction between signalling

Meningioma involving pituitary fossa showing typical 'dural tail'.

Table 19.6 Causes of hypopituitarism

Congenital	Traumatic
Isolated deficiency of pituitary hormones (e.g. Kallmann's syndrome) POU1F1 (PIT-1), PROP1, HESX1 mutations	Skull fracture through base Surgery, especially transfrontal Perinatal trauma
Infective	Infiltrations
Basal meningitis (e.g. tuberculosis) Encephalitis Syphilis	Sarcoidosis Langerhans' cell histiocytosis Hereditary haemochromatosis Hypophysitis Postpartum Giant cell
Vascular	Others
Pituitary apoplexy Sheehan's syndrome (postpartum necrosis) Carotid artery aneurysms	Radiation damage Fibrosis Chemotherapy Empty sella syndrome
Immunological	'Functional'
Autoimmune (lymphocytic) hypophysitis Pituitary antibodies	Anorexia nervosa Starvation Emotional deprivation
Neoplastic	
Pituitary or hypothalamic tumours Craniopharyngioma Meningiomas Gliomas Pinealoma Secondary deposits, especially breast Lymphoma	

molecules and transcription factors. For example, mutations in PROP1 and POU1F1 (previously PIT-1) prevent the differentiation of anterior pituitary cells (precursors to somatotroph, lactotroph, thyrotroph and gonadotroph cells), leading to deficiencies of GH, prolactin, TSH and GnRH. In addition, novel mutations within GH and GHRH receptor genes have been identified which may explain the pathogenesis of isolated GH deficiency in children. Despite these advances, most cases of hypopituitarism do not have specific identifiable genetic causes.

Causes

Disorders causing hypopituitarism are listed in Table 19.6. Pituitary and hypothalamic tumours, and surgical or radiotherapy treatment, are the most common.

Clinical features

Symptoms and signs depend upon the extent of hypothalamic and/or pituitary deficiencies, and mild deficiencies may not lead to any complaint by the patient. In general, symptoms of deficiency of a pituitary-stimulating hormone are the same as primary deficiency of the peripheral endocrine gland (e.g. TSH deficiency and primary hypothyroidism cause similar symptoms due to lack of thyroid hormone secretion).

- **Secondary hypothyroidism** and **adrenal failure** both lead to tiredness and general malaise.
- **Hypothyroidism** causes weight gain, slowness of thought and action, dry skin and cold intolerance.
- **Hypoadrenalism** causes mild hypotension, hyponatraemia and ultimately cardiovascular collapse during severe intercurrent stressful illness.

- **Gonadotrophin** and thus **gonadal deficiencies** lead to loss of libido, loss of secondary sexual hair, amenorrhoea and erectile dysfunction.
 - **Hyperprolactinaemia** may cause galactorrhoea and hypogonadism.
 - **GH deficiency** causes growth failure in children and impaired wellbeing in some adults.
 - **Weight may increase** (due to hypothyroidism, see above) or decrease in severe combined deficiency (pituitary cachexia).
 - Longstanding **panhypopituitarism** gives the classic picture of pallor with hairlessness ('alabaster skin').
- Particular syndromes related to hypopituitarism are:

Kallmann's syndrome. This syndrome is isolated gonadotrophin (GnRH) deficiency (p. 976). This syndrome arises due to mutations in the *KAL1* gene which is located on the short (p) arm of the X chromosome. Kallmann's is classically characterized by anosmia because the *KAL1* gene provides instructions to make anosmin, which has a role in development of both the olfactory system as well as migration of GnRH secreting neurones.

Septo-optic dysplasia. This is a rare congenital syndrome (associated with mutations in the *HESX1* gene) presenting in childhood with a clinical triad of midline forebrain abnormalities, optic nerve hypoplasia and hypopituitarism.

Sheehan's syndrome is due to pituitary infarction following postpartum haemorrhage and is rare in developed countries.

Pituitary apoplexy. A pituitary tumour occasionally enlarges rapidly owing to infarction or haemorrhage. This may produce severe headache, double vision and sudden severe visual loss, sometimes followed by acute life-threatening hypopituitarism. Often pituitary apoplexy can be managed conservatively with replacement of hormones and close monitoring of vision, although if there is a rapid deterioration in visual acuity and fields, surgical decompression of the optic chiasm may be necessary.

The 'empty sella' syndrome. An 'empty sella' is sometimes reported on pituitary imaging. This is sometimes due to a defect in the diaphragma and extension of the subarachnoid space (cisternal herniation) or may follow spontaneous infarction or regression of a pituitary tumour. All or most of the sella turcica is devoid of apparent pituitary tissue, but, despite this, pituitary function is usually normal, the pituitary being eccentrically placed and flattened against the floor or roof of the fossa.

Investigations

Each axis of the hypothalamic-pituitary system requires separate investigation. However, the presence of normal gonadal function (ovulation/menstruation or normal libido/erections) suggests that multiple defects of anterior pituitary function are unlikely.

Tests range from the simple basal levels (e.g. free T_4 for the thyroid axis), to stimulatory tests for the pituitary, and tests of feedback for the hypothalamus (Table 19.7). Assessment of the hypothalamic-pituitary-adrenal axis is complex: basal 09:00 hours cortisol levels above 400 nmol/L usually indicate an adequate reserve, while levels below 100 nmol/L predict an inadequate stress response. In many cases basal levels are equivocal and a dynamic test is essential: the insulin tolerance test (Box 19.2) is widely regarded as the 'gold standard' but the short ACTH stimulation test (Box 19.1), though an indirect measure, is used by many as a routine test of hypothalamic-pituitary-adrenal status. Occasionally, the difference between ACTH deficiency and normal

Pituitary apoplexy, showing a bright area of haemorrhage at the top of a pituitary adenoma. (a) Sagittal, (b) coronal.

Table 19.7 Tests for hypothalamic-pituitary (HP) function

All hormone levels are measured in plasma unless otherwise stated.				
Tests shown in bold are those normally measured on a single basal 09:00 hours sample in the initial assessment of pituitary function.				
Axis	Basal investigations			
	Pituitary hormone	End-organ product/function	Common dynamic tests	Other tests
Anterior pituitary				
HP-ovarian	LH FSH	Oestradiol Progesterone (day 21 of cycle)		Ovarian ultrasound LHRH test ^a
HP-testicular	LH FSH	Testosterone		Sperm count LHRH test ^a
Growth	GH	IGF-1 IGF-BP3	Insulin tolerance test Glucagon test	GH response to sleep, exercise or arginine infusion GHRH test ^a
Prolactin	Prolactin	Prolactin	–	–
HP-thyroid	TSH	Free T₄, T₃		TRH test ^a
HP-adrenal	ACTH	Cortisol	Insulin tolerance test Short ACTH (tetracosactide) stimulation test	Glucagon test CRH test ^a Metyrapone test
Posterior pituitary				
Thirst and osmoregulation		Plasma/urine osmolality	Water deprivation test	Hypertonic saline infusion

^aReleasing hormone tests were a traditional part of pituitary function testing, but have been largely replaced by the advent of more reliable assays for basal hormones. They test only the 'readily releasable pool' of pituitary hormones and normal responses may be seen in hypopituitarism.

**Box 19.2 Insulin tolerance test****Indication**

- Diagnosis or exclusion of ACTH and growth hormone deficiency

Procedure

- Test explained to patient and consent obtained
- Should only be performed in experienced, specialist units
- Exclude cardiovascular disease (ECG), epilepsy or unexplained blackouts; exclude severe untreated hypopituitarism (basal cortisol must be >100 nmol/L; normal free T₄)
- Intravenous hydrocortisone and glucose available for emergency
- Overnight fast, begin at 08:00–09:00 hours
- Soluble insulin, 0.15 U/kg, i.v. at time 0
- Glucose, cortisol and GH levels at 0, 30, 45, 60, 90, 120 min

Normal response

- Cortisol rises above 550 nmol/L^a
- GH rises above 7 ng/L (severe deficiency = <3 ng/L (<9 mU/L))
- Glucose must be <2.2 mmol/L to achieve adequate stress response

^aPrecise cortisol normal ranges are variable between laboratories and assays – appropriate local reference ranges must be used.

HPA axis can be subtle, and the assessment of adrenal reserve is best left to an experienced endocrinologist.

Treatment

- Steroid and thyroid hormones are essential for life. Both are given as oral replacement drugs, as in primary thyroid and adrenal deficiency, aiming to restore the patient to clinical and biochemical normality (Table 19.8) and levels are monitored by routine hormone assays.
- Note:** Thyroid replacement should not commence until

Table 19.8 Replacement therapy for hypopituitarism

Axis	Usual replacement therapies
Adrenal	Hydrocortisone 15–40 mg daily (starting dose 10 mg on rising/5 mg lunchtime/5 mg evening) (Normally no need for mineralocorticoid replacement)
Thyroid	Levothyroxine 100–150 µg daily
Gonadal	
Male	Testosterone intramuscularly, orally, transdermally or implant
Female	Cyclical oestrogen/progestogen orally or as patch
Fertility	HCG plus FSH (purified or recombinant) or pulsatile GnRH to produce testicular development, spermatogenesis or ovulation
Growth	Recombinant human GH used routinely to achieve normal growth in children Also advocated for replacement therapy in adults where GH has effects on muscle mass and wellbeing
Thirst	Desmopressin 10–20 µg one to three times daily by nasal spray or orally 100–200 µg three times daily Carbamazepine, thiazides and chlorpropamide are very occasionally used in mild diabetes insipidus
Breast (prolactin inhibition)	Dopamine agonist (e.g. cabergoline, 500 µg weekly)

normal glucocorticoid function has been demonstrated or replacement steroid therapy initiated, as an adrenal 'crisis' may otherwise be precipitated.

- Sex hormones are replaced with androgens and oestrogens, both for symptomatic control and to prevent long-term problems related to deficiency (e.g. osteoporosis).

- When fertility is desired, gonadal function is stimulated directly by human chorionic gonadotrophin (HCG, mainly acting as LH), purified or biosynthetic gonadotrophins, or indirectly by pulsatile gonadotrophin-releasing hormone (GnRH – also known as luteinizing hormone-releasing hormone, LHRH); all are expensive and time-consuming and should be restricted to specialist units.
- GH therapy is given in the growing child, under the care of a paediatric endocrinologist. In adult GH deficiency, GH therapy also produces improvements in body composition, work capacity and psychological wellbeing, together with reversal of lipid abnormalities associated with a high cardiovascular risk, and often results in significant symptomatic benefit in some cases. NICE recommends GH replacement for people with severe GH deficiency and significant quality of life impairment. It is expensive and in the UK costs £2500–6000 per annum.
- Glucocorticoid deficiency may mask impaired urine concentrating ability, diabetes insipidus only becoming apparent after steroid replacement because steroids are required for excretion of free water.

GROWTH AND ABNORMAL STATURE

Physiology and control of growth hormone (GH) (Fig. 19.9)

GH is the pituitary factor responsible for stimulation of body growth in humans. Its secretion is stimulated by GHRH, released into the portal system from the hypothalamus; it is also under inhibitory control by somatostatin. A separate GH stimulating system involves a distinct receptor (GH

secretagogue receptor), which interacts with ghrelin (see p. 259). It is not known how these two systems interact but because ghrelin is synthesized in the stomach, it suggests a nutritional role for GH.

- **GH** acts by binding to a specific (single transmembrane) receptor located mainly in the liver (Table 19.3). This induces an intracellular phosphorylation cascade involving the JAK/STAT (Janus kinase/signal transducing activators of transcription) pathway (p. 32). STAT proteins are translocated from the cytoplasm into the cell nucleus and cause GH-specific effects by binding to nuclear DNA.
- **IGF-1 (insulin-like growth factor-1)**, a somatomedin stimulates growth and its hepatic secretion is stimulated by a tissue-specific effect of GH on the liver. There are multiple IGF-binding proteins (IGF-BP) in plasma – IGF-BP3 can be measured clinically to improve assessment of GH status, particularly in children. The metabolic actions of the system are:

- Increasing collagen and protein synthesis
- Promoting retention of calcium, phosphorus and nitrogen, necessary substrates for anabolism
- Opposing the action of insulin (a 'counter-regulatory' hormone effect).

GH release is intermittent and mainly nocturnal, especially during REM sleep. The frequency and size of GH pulses increase during the growth spurt of adolescence and decline thereafter. Acute stress and exercise both stimulate GH release while, in the normal subject, hyperglycaemia suppresses it.

IGF-1 may, in addition, play a major role in maintaining neoplastic growth. A relationship has been shown between circulating IGF-1 concentrations and breast cancer in premenopausal women and prostate cancer in men.

Figure 19.9 The control of growth hormone (GH) and insulin-like growth factor-1 (IGF-1). Pituitary GH is secreted under dual control of growth hormone-releasing hormone (GHRH) and somatostatin and stimulates release of IGF-1 in liver and elsewhere. IGF-1 has peripheral actions including bone growth and exerts negative feedback to hypothalamus and pituitary.

Normal growth

There are factors other than GH involved in linear growth in the human.

- **Genetic factors.** Children of two short parents will probably be short and vice-versa.
- **Nutritional factors.** Adequate nutrients must be available. Impaired growth can result from inadequate dietary intake or small bowel disease (e.g. coeliac disease).
- **General health.** Any serious systemic disease in childhood is likely to reduce growth (e.g. chronic kidney disease or chronic infection).
- **Intrauterine growth retardation.** These infants often grow poorly in the long term, while infants with simple prematurity usually catch up. There is some evidence that low birthweight may predispose to hypertension, diabetes and other health problems in later adult life (p. 195).
- **Emotional deprivation and psychological factors.** These can impair growth by complex, poorly understood mechanisms, probably involving temporarily decreased GH secretion.

In general, there are three overlapping phases of growth: infantile (0–2 years), which appears largely substrate (food) dependent; childhood (age 2 years to puberty), which is largely GH dependent; and the adolescent 'growth spurt', dependent on GH and sex hormones.

Box 19.3 Assessment of problems of growth and development

History

- Pregnancy records
- Rate of growth (home/school records, e.g. heights on kitchen door)
- Comparison with peers at school and siblings
- Change in appearance (re: old photographs)
- Change in shoe/glove/hat size or frequency of 'growing out'
- Age of appearance of pubic hair, breasts, menarche

Physical signs

- Evidence of systemic disease
- Body habitus, size, relative weight, proportions (span versus height)
- Skin thickness, interdental separation
- Facial features
- Spade hands/feet
- Grading of secondary sexual characteristics

The relevant aspects of history and examination in the assessment of problems are shown in Box 19.3.

Assessment of growth

Charts showing normal centiles of height and weight are essential to monitor growth; they are available for normal British children (Fig. 19.10) and many other national and ethnic groups. Height must be measured, ideally at the same time of day on the same instrument by the same observer.

Height velocity is more helpful than current height. It requires at least two measurements some months apart and, ideally, multiple serial measurements. Height velocity is the rate of current growth (cm per year), while the current attained height is largely dependent upon previous growth. Standard deviation scores (SDS) based on the degree of deviation from age-sex norms are widely used. Computer programs also allow calculation of many of these indices.

The approximate future height of a child ('mid-parental height') can be simply predicted from the parental heights. For a boy, this is:

$$(\text{Maternal height} + 14 \text{ cm (5.5 inches)} + \text{Paternal height})/2$$

and for a girl:

$$(\text{Paternal height} - 14 \text{ cm (5.5 inches)} + \text{Maternal height})/2$$

Thus, with a father of 180 cm and mother of 154 cm, the predicted heights are 174 cm for a son and 160 cm for a daughter.

Growth failure: short stature

When children or their parents complain of short stature, particular attention should focus on:

- Intrauterine growth retardation, weight and gestation at birth
- Possible systemic disorders – any system, but especially small bowel disease
- Evidence of skeletal, chromosomal or other congenital abnormalities
- Endocrine status – particularly thyroid
- Dietary intake and use of drugs, especially steroids for asthma
- Emotional, psychological, family and school problems.

School, general practitioner, clinic and home records of height and weight should be obtained if possible to allow

Figure 19.10 A height chart for boys. **Child A** illustrates the course of a child with hypopituitarism, initially treated with cortisol and thyroxine, but showing growth only after growth hormone treatment. **Child B** shows the course of a child with constitutional growth delay without treatment.

growth-velocity calculation. If unavailable, such data must be obtained prospectively.

A child with normal growth velocity is unlikely to have significant endocrine disease and the commonest cause of short stature in this situation is pubertal or 'constitutional' delay. However, low growth velocity without apparent systemic cause requires further investigation. Sudden cessation of growth suggests major physical disease; if no gastrointestinal, respiratory, renal or skeletal abnormality is apparent, then a cerebral tumour or hypothyroidism is likeliest.

Consistently slow-growing children require full endocrine assessment. Features of the more common causes of growth failure are given in Table 19.9.

Around the time of puberty, where constitutional delay is clearly shown and symptoms require intervention, then very-low-dose sex steroids in 3- to 6-month courses will usually induce acceleration of growth.

Investigations

Systemic disease having been excluded, perform:

- **Thyroid function tests:** serum TSH and free T_4 to exclude hypothyroidism
- **GH status.** Basal levels are of little value. Dynamic tests include the GH response to insulin (the 'gold standard'; Box 19.2), glucagon, arginine, exercise and clonidine. Tests should only be performed in centres experienced in their use and interpretation. Normal responses depend on test and GH assay used

Table 19.9 Clinical features of common causes of short stature

Cause	Family history	Growth pattern, clinical features and puberty	Bone age	Remarks
Constitutional delay	Often present	Slow from birth, immature but appropriate with late but spontaneous puberty	Moderate delay	Often difficult to differentiate from GH deficiency Growth velocity measurement vital
Familial short stature	Positive	Slow from birth, clinically normal with normal puberty	Normal	Need heights of family members Growth velocity normal
GH insufficiency	Rare	Slow growth, immature, often overweight, delayed puberty	Moderate delay, increasing with time	Early investigation and treatment vital Increased suspicion if child is plump
Primary hypothyroidism	Rare	Slow growth, immature and delayed puberty	Marked delay	Measure TSH, T ₄ in all cases of short stature Clear clinical signs not obvious
Small bowel disease	Sometimes	Slow, immature, usually thin for height, delayed puberty	Delayed	Diarrhoea and/or macrocytosis/anaemia Occasionally no GI symptoms

- **Blood levels of IGF-1 (insulin-like growth factor-1) and IGF-BP3 (binding protein 3)** may provide evidence of GH undersecretion
- **Assessment of bone age.** Non-dominant hand and wrist X-rays allow assessment of bone age by comparison with standard charts
- **Karyotyping in females.** Turner's syndrome (p. 978) is associated with short stature. It is thought that this is due to a defect in the short stature homeobox (*SHOX*) gene which has a role in non-GH mediated growth.

Treatment

Systemic illness should be treated and primary hypothyroidism treated with levothyroxine.

For GH insufficiency, recombinant GH (somatropin) is given as nightly injections in doses of 0.17–0.35 mg/kg per week, with dose adjustments made according to clinical response and IGF-1 levels. Treatment is expensive and should be supervised in expert centres.

GH treatment in so-called 'short normal' children has not been shown to produce any worthwhile increase in final height. In Turner's syndrome (see p. 983) large doses of GH are effective in increasing final height, especially in combination with appropriate very-low-dose oestrogen replacement. Familial cases of resistance to GH owing to an abnormal GH receptor (Laron-type dwarfism) are well described. They are very rare but may respond to therapy with synthetic IGF-1 (mecasermin).

Tall stature

The most common causes are hereditary (two tall parents!), idiopathic (constitutional) or early development. It can occasionally be due to hyperthyroidism. Other causes include chromosomal abnormalities (e.g. Klinefelter's syndrome, Marfan's syndrome) or metabolic abnormalities. GH excess is a very rare cause and is usually clinically obvious.

PITUITARY HYPERSECRETION SYNDROMES

Acromegaly and gigantism

Growth hormone stimulates skeletal and soft tissue growth. GH excess therefore produces gigantism in children (if

acquired before epiphyseal fusion) and acromegaly in adults. Both are due to a GH secreting pituitary tumour (somatotroph adenoma) in almost all cases. Hyperplasia due to ectopic GHRH excess is very rare. Overall incidence is approximately 3–4/million per year and the prevalence is 50–80/million worldwide. Acromegaly usually occurs sporadically, although gene mutations can rarely give rise to familial acromegaly, typically the AIP gene in familial isolated pituitary adenoma.

Clinical features

Symptoms and signs of acromegaly are shown in Figure 19.11. One-third of patients present with changes in appearance, one-quarter with visual field defects or headaches; in the remainder the diagnosis is made by an alert observer in another clinic, e.g. GP, diabetic, hypertension, dental, dermatology. Sleep apnoea is common and requires investigation and treatment if there are suggestive symptoms (see p. 818). Sweating, headaches and soft tissue swelling are particularly useful symptoms of persistent growth hormone secretion. Headache is very common in acromegaly and may be severe even with small tumours; it is often improved after surgical cure or with somatostatin analogues.

Investigations

- **GH levels** may exclude acromegaly if undetectable but a detectable value is non-diagnostic taken alone. Normal adult levels are <0.5 µg/L for most of the day except during stress or a 'GH pulse'.
- **A glucose tolerance test** is diagnostic if there is no suppression of GH. Acromegalics fail to suppress GH below 0.3 µg/L and some show a paradoxical rise; about 25% of acromegalics have a positive diabetic glucose tolerance test.
- **IGF-1 levels** are almost always raised in acromegaly – a single plasma level of IGF-1 reflects mean 24-hour GH levels and is useful in diagnosis. A normal IGF-1 together with random growth hormone <1 µg/L may be taken to exclude acromegaly if the diagnosis is clinically unlikely.
- **Visual field examination:** defects are common, e.g. bitemporal hemianopia.
- **MRI scan** of pituitary if above tests abnormal. This will almost always reveal the pituitary adenoma.
- **Pituitary function:** partial or complete anterior hypopituitarism is common.

Figure 19.11 Acromegaly: symptoms and signs. Bold type indicates signs of greater discriminant value.

- **Prolactin:** mild to moderate hyperprolactinaemia occurs in 30% of patients (see Fig. 19.13). In some, the adenoma secretes both GH and prolactin.

Management and treatment

Untreated acromegaly results in markedly reduced survival. Most deaths occur from heart failure, coronary artery disease and hypertension-related causes. In addition, there is an increase in deaths due to neoplasia, particularly large bowel tumours (some specialist centres advocate regular colonoscopy to detect and remove colonic polyps to reduce the risk of colonic cancer). Treatment is therefore indicated in all except the elderly or those with minimal abnormalities. The aim of therapy is to achieve a mean growth hormone level below 2.5 µg/L; this is not always 'normal' but has been shown to reduce mortality to normal levels and is therefore considered a 'safe' GH level. A normal IGF-1 is also a goal of therapy. Occasionally there can be discordance between GH and IGF-1 levels, which can create management dilemmas.

When present, hypopituitarism should be corrected (see p. 950) and concurrent diabetes and/or hypertension should be treated conventionally; both usually improve with treatment of the acromegaly.

The general advantages and disadvantages of surgery, radiotherapy and medical treatment are discussed on page 947. Progress can be assessed by monitoring GH and IGF-1 levels.

- **Surgery.** Trans-sphenoidal surgery is the appropriate first-line therapy. It will result in clinical remission in a majority of cases (60–90%) with pituitary microadenoma, but in only 50% of those with macroadenoma. Very high preoperative GH and IGF-1 levels are also poor prognostic markers of surgical cure. Surgical success rates are variable and highly dependent upon experience, and a specialist pituitary surgeon is essential. Transfrontal surgery is rarely required except for massive macroadenomas. There is approximately a 10% recurrence rate.

- **Pituitary radiotherapy.** External radiotherapy is normally used after pituitary surgery fails to normalize GH levels rather than as primary therapy. It is often combined with medium-term treatment with a somatostatin analogue, dopamine agonist or GH antagonist because of the slow biochemical response to radiotherapy, which may take 10 years or more and is often associated with hypopituitarism which makes it unattractive in patients of reproductive age. Stereotactic radiotherapy is used in some centres.

- **Medical therapy.** There are three receptor targets for the treatment of acromegaly: pituitary somatostatin receptors and dopamine (D₂) receptors and growth hormone receptors in the periphery.
 - **Somatostatin receptor agonists.** *Octreotide* and *lanreotide* are synthetic analogues of somatostatin (p. 951) that selectively act on somatostatin receptor subtypes (SST2 and SST5), which are highly expressed in growth-hormone-secreting tumours. These drugs were used as a short-term treatment whilst other modalities become effective, but now are sometimes used as primary therapy. They reduce GH and IGF levels in most patients but not all achieve treatment targets. Both drugs are typically administered as monthly depot injections and are generally well tolerated but are associated with an increased incidence of gallstones and are expensive.
 - **Dopamine agonists.** Dopamine agonists act on D₂ receptors (p. 878) and can be given to shrink tumours prior to definitive therapy or to control symptoms and persisting GH secretion; they are probably most effective in mixed growth-hormone-producing (somatotroph) and prolactin-producing (mammotroph) tumours. Typical doses are bromocriptine 10–60 mg daily or cabergoline 0.5 mg daily (higher than for prolactinomas). Given alone they reduce GH to 'safe' levels in only a minority of cases – but they are useful for mild residual disease or in combination with somatostatin analogues. Drugs with combined

somatostatin and dopamine receptor activity are under development.

- **Growth hormone antagonists.** Pegvisomant (a genetically modified analogue of GH) is a GH receptor antagonist which has its effect by binding to and preventing dimerization of the GH receptor. It does not lower growth hormone levels or reduce tumour size but has been shown to normalize IGF-1 levels in 90% of patients. It is given by a daily injection and its main role at the present time is treatment of patients in whom GH and IGF levels cannot be reduced to safe levels with somatostatin analogues alone, surgery or radiotherapy.

Hyperprolactinaemia

The hypothalamic-pituitary control of prolactin secretion is illustrated in [Figure 19.12](#). Prolactin is a large peptide secreted in the pituitary and acts via a transmembrane receptor stimulating JAK2 and other pathways ([Table 19.3](#)).

Prolactin is under tonic dopamine inhibition: factors known to increase prolactin secretion (e.g. TRH) are probably of less relevance. Prolactin stimulates milk secretion (but not breast tissue development) but also inhibits gonadal activity. It decreases GnRH pulsatility at the hypothalamic level and, to a lesser extent, blocks the action of LH on the ovary or testis, producing hypogonadism even when the pituitary gonadal axis itself is intact.

The role of prolactin outside pregnancy and lactation is not well defined, although there is some epidemiological evidence of a link between high prolactin levels and breast cancer which has led to an interest in the development of prolactin receptor antagonists.

Physiological hyperprolactinaemia occurs in pregnancy, lactation and severe stress, as well as during sleep and

coitus. The range of serum prolactin seen in common causes of hyperprolactinaemia is illustrated in [Figure 19.13](#). Mildly increased prolactin levels (400–600 mU/L) may be physiological and asymptomatic but higher levels require a diagnosis. Levels above 5000 mU/L always imply a prolactin-secreting pituitary tumour.

Causes

Hyperprolactinaemia has many causes. Common pathological causes include prolactinoma, co-secretion of prolactin in tumours causing acromegaly, stalk compression due to pituitary adenomas and other pituitary masses, polycystic ovary syndrome, primary hypothyroidism and 'idiopathic' hyperprolactinaemia. Rarer causes are oestrogen therapy (e.g. the 'pill'), renal failure, liver failure, post-ictal state and chest wall injury. Dopamine antagonist drugs (metoclopramide, domperidone, most antipsychotics) are a common iatrogenic cause, as well as most other antiemetics (except cyclizine) and opiates.

Clinical features

Hyperprolactinaemia stimulates milk production in the breast and inhibits GnRH and gonadotrophin secretion per se. It usually presents with:

- Galactorrhoea, spontaneous or expressible (60% of cases)
- Oligomenorrhoea or amenorrhoea
- Decreased libido in both sexes
- Decreased potency in men
- Subfertility
- Symptoms or signs of oestrogen or androgen deficiency – in the long term osteoporosis may result, especially in women
- Delayed or arrested puberty in the peripubertal patient
- Mild gynaecomastia is often seen in men due to the associated hypogonadism rather than a direct effect of prolactin.

Additionally, headaches and/or visual field defects occur if there is a pituitary tumour (more common in men). Note that many people with galactorrhoea do not have

Figure 19.12 The control and actions of prolactin.

Prolactin is mainly controlled by tonic inhibition by hypothalamic dopamine. Prolactin stimulates lactation but also inhibits both hypothalamic GnRH secretion and the gonadal actions of LH.

Figure 19.13 Range of serum prolactin seen in common causes of hyperprolactinaemia.

hyperprolactinaemia – ‘normoprolactinaemic galactorrhoea’ – and the causes are poorly understood.

Investigations

Hyperprolactinaemia should be confirmed by repeat measurement. If there are no clinical features of hyperprolactinaemia, the possibility of *macroprolactinaemia* should be considered. This is a higher molecular weight complex of prolactin bound to IgG, which is physiologically inactive but occurs in a small proportion of normal people and can therefore lead to unnecessary treatment. Macroprolactinaemia can be diagnosed in the laboratory by precipitation of IgG with polyethylene glycol, after which prolactin levels will be normal on testing; most laboratories will do this routinely.

Further tests are appropriate after physiological and drug causes have been excluded:

- **Visual fields** should be checked.
- **Primary hypothyroidism** must be excluded since this is a cause of hyperprolactinaemia.
- **Anterior pituitary function** should be assessed if there is any clinical evidence of hypopituitarism or radiological evidence of a pituitary tumour (Table 19.7; Box 19.1, Box 19.2).
- **MRI of the pituitary** is necessary if there are any clinical features suggestive of a pituitary tumour, and desirable in all cases when prolactin is significantly elevated (above 1000 mU/L).

In the presence of a pituitary mass on MRI, the level of prolactin helps determine whether the mass is a prolactinoma or a non-functioning pituitary tumour causing stalk-disconnection hyperprolactinaemia: levels of above 5000 mU/L in the presence of a macroadenoma, or above 2000 mU/L in the presence of a microadenoma (or with no radiological abnormality), strongly suggest a prolactinoma (see p. 946). Macroprolactinoma refers to tumours above 10 mm diameter, microprolactinoma to smaller ones.

Occasionally, very large prolactinomas can be associated with such high serum prolactin levels that some assays give an artefactual falsely low result (known as the ‘hook effect’). If suspected, this can be excluded by serial dilutions of the serum sample.

Treatment

Hyperprolactinaemia is usually treated to avoid the long-term effects of oestrogen deficiency (even if the patient would otherwise welcome the lack of periods!) or testosterone deficiency in the male. Exceptions include minor elevations

(400–1000 mU/L) with preservation of normal regular menstruation (or normal male testosterone levels) and postmenopausal people with microprolactinomas who are not taking oestrogen replacement.

Medical treatment. Hyperprolactinaemia is controlled with a dopamine agonist.

- **Cabergoline** (500 µg once or twice a week judged on clinical response and prolactin levels) is the best tolerated and longest-acting drug and is the first drug of choice.
- **Bromocriptine** is the longest-established therapy and therefore preferred if pregnancy is planned: initial doses should be small (e.g. 1 mg), taken with food and gradually increased to 2.5 mg two or three times daily. Side-effects, which prevent effective therapy in a minority of cases, include nausea and vomiting, dizziness and syncope, constipation and cold peripheries.
- **Quinagolide** (75–150 µg once daily) is an alternative.

Complications seen, when cabergoline is used in higher doses in Parkinson’s disease, include pulmonary, retroperitoneal and pericardial fibrotic reactions and cardiac valve lesions. Patients need monitoring, although such adverse effects appear to be very rare in patients on lower, ‘endocrine’ doses.

In most cases a dopamine agonist will be the first and only therapy and can be used in the long term. Prolactinomas usually shrink in size on a dopamine agonist, and in macroadenomas any pituitary mass effects commonly resolve (Fig. 19.14). Microprolactinomas may not recur after several years of dopamine agonist therapy in a minority of cases, but in the majority hyperprolactinaemia will recur if treatment is stopped.

Trans-sphenoidal surgery may restore normoprolactinaemia in people with microadenoma, but is rarely completely successful with macroadenomas and risks damage to normal pituitary function. Therefore most patients and physicians elect to continue medical therapy rather than proceed to surgery. Prolactin should therefore always be measured before surgery on any mass in the pituitary region. Some surgeons believe that long-term bromocriptine increases the hardness of the adenoma and makes resection more difficult, but others dissent from this view.

Radiotherapy usually controls adenoma growth and is slowly effective in lowering prolactin but causes progressive hypopituitarism. It may be advocated after medical tumour shrinkage or after surgery in larger tumours, especially where

Figure 19.14 Macroprolactinoma before (a) and after (b) 2 years treatment with the dopamine agonist cabergoline showing marked adenoma shrinkage.

families are complete or if the drug treatment is poorly tolerated, but most workers simply advocate continuation of dopamine agonist therapy in responsive cases.

In patients planning *pregnancy*, it is useful to know the size of the pituitary lesion before starting dopamine agonist therapy. Rarely, tumours enlarge during pregnancy to produce headaches and visual field defects. Dopamine agonists, which are traditionally stopped after conception, can be restarted if there are any signs of tumour growth during pregnancy.

Cushing's syndrome

Cushing's syndrome is the term used to describe the clinical state of increased free circulating glucocorticoid. It occurs most often following the therapeutic administration of synthetic steroids or ACTH (see below).

Pathophysiology and causes

Spontaneous Cushing's syndrome is rare, with an incidence of <5/million per year.

Causes of Cushing's syndrome are usually subdivided into two groups (Table 19.10):

1. Increased circulating ACTH from the pituitary (65% of cases), known as Cushing's disease, or from an

'ectopic', non-pituitary, ACTH-producing tumour elsewhere in the body (10%) with consequent glucocorticoid excess ('ACTH dependent' Cushing's)

2. A primary excess of endogenous cortisol secretion (25%) by an adrenal tumour or nodular hyperplasia, with subsequent (physiological) suppression of ACTH ('non-ACTH-dependent' Cushing's). Rare cases are due to aberrant expression of receptors for other hormones (e.g. glucose-dependent insulinotropic peptide (GIP), LH or catecholamines) in adrenal cortical cells.

Clinical features

The clinical features of Cushing's syndrome are those of glucocorticoid excess and are illustrated in Figure 19.15.

- **Pigmentation** occurs only with ACTH-dependent causes.
- **A cushingoid appearance** can be caused by excess alcohol consumption (pseudo-Cushing's syndrome) – the pathophysiology is poorly understood.
- **Impaired glucose tolerance** or frank diabetes is common, especially in the ectopic ACTH syndrome.
- **Hypokalaemia** due to the mineralocorticoid activity of cortisol is common with ectopic ACTH secretion.
- **Hypertension** is common in all causes of Cushing's syndrome.

Diagnosis

There are two phases to the investigation.

1. Confirmation

Most obese, hirsute, hypertensive patients do not have Cushing's syndrome, and some cases of genuine Cushing's have relatively subtle clinical signs. Confirmation rests on demonstrating inappropriate cortisol secretion, not suppressed by exogenous glucocorticoids: difficulties occur with obesity and depression where cortisol dynamics are often abnormal. Random cortisol measurements are of no value.

Table 19.11 Dexamethasone suppression test in the diagnosis of Cushing's syndrome

Test and protocol	Measure	Normal test result or positive suppression	Use and explanation
Dexamethasone (for Cushing's)			
Overnight			
Take 1 mg on going to bed at 23:00 hours	Plasma cortisol at 09:00 hours next morning	Plasma cortisol <100 nmol/L	Outpatient screening test Some 'false positives'
'Low-dose'			
0.5 mg 6-hourly Eight doses from 09:00 hours on day 0	Plasma cortisol at 09:00 hours on days 0 and +2	Plasma cortisol <50 nmol/L on second sample	For diagnosis of Cushing's syndrome
'High-dose' used in differential diagnosis			
2 mg 6-hourly Eight doses from 09:00 hours on day 0	Plasma cortisol at 09:00 hours on days 0 and +2	Plasma cortisol on day +2 less than 50% of that on day 0 suggests pituitary-dependent disease	Differential diagnosis of Cushing's syndrome Pituitary-dependent disease suppresses in about 90% of cases
Plasma cortisol values are very dependent upon the assay used – local reference ranges must be consulted.			

Occasional patients are seen with so-called 'cyclical Cushing's' where the abnormalities come and go.

Investigations to confirm the diagnosis include:

- **48-hour low-dose dexamethasone test** (see Table 19.11). Normal individuals suppress plasma cortisol to <50 nmol/L. People with Cushing's syndrome fail to show complete suppression of plasma cortisol levels (although levels may fall substantially in a few cases). This test is highly sensitive (>97%). The overnight dexamethasone test is slightly simpler, but has a higher false-positive rate.
- **24-hour urinary free cortisol measurements.** This is simple, but less reliable – repeatedly normal values render the diagnosis most unlikely, but some people with Cushing's syndrome have normal values on some collections (approximately 10%).
- **Circadian rhythm.** After 48 hours in hospital, cortisol samples are taken at 09:00 hours and 24:00 hours (without warning the patient). Normal subjects show a pronounced circadian variation (see Fig. 19.4, p. 942); those with Cushing's syndrome have high midnight cortisol levels (>100 nmol/L), though the 09:00 hours value may be normal. Midnight salivary cortisol collected at home gives the same information more simply where the assay is available.
- **Other tests.** There are frequent exceptions to the classic responses to diagnostic tests in Cushing's syndrome. If any clinical suspicion of Cushing's remains after preliminary tests then specialist investigations are still indicated. These may include insulin stress test, desmopressin stimulation test (p. 993) and CRH tests.

2. Differential diagnosis of the cause

This can be extremely difficult since all causes can result in clinically identical Cushing's syndrome. The classical ectopic ACTH syndrome is distinguished by a short history, pigmentation and weight loss, unprovoked hypokalaemia, clinical or chemical diabetes and plasma ACTH levels above 200 ng/L, but many ectopic tumours are benign and mimic pituitary disease closely, both clinically and biochemically. Severe hirsutism/virilization suggests an adrenal tumour.

Biochemical and radiological procedures for diagnosis include:

- **Plasma ACTH levels.** Low or undetectable ACTH levels (<10 ng/L) on two or more occasions are a reliable indicator of non-ACTH-dependent disease.
- **Adrenal CT or MRI scan.** Adrenal adenomas and carcinomas causing Cushing's syndrome are relatively large and always detectable by CT scan. Carcinomas are distinguished by large size, irregular outline and signs of infiltration or metastases. Bilateral adrenal hyperplasia may be seen in ACTH-dependent causes or in ACTH-independent nodular hyperplasia.
- **Pituitary MRI.** A pituitary adenoma may be seen but the adenoma is often small and not visible in a significant proportion of cases.
- **Plasma potassium levels.** Hypokalaemia is common with ectopic ACTH secretion. (All diuretics must be stopped.)
- **High-dose dexamethasone test** (Table 19.11). Failure of significant plasma cortisol suppression suggests an ectopic source of ACTH or an adrenal tumour.
- **CRH test.** An exaggerated ACTH and cortisol response to exogenous CRH suggests pituitary-dependent Cushing's disease, as ectopic sources rarely respond.
- **Chest X-ray** to look for a carcinoma of the bronchus or a bronchial carcinoid. Carcinoid lesions may be very small; if ectopic ACTH is suspected, whole-lung, mediastinal and abdominal **CT scanning** should be performed.

Further investigations may involve selective catheterization of the inferior petrosal sinus to measure ACTH for pituitary lesions, or blood samples taken throughout the body in a search for ectopic sources. Radiolabelled octreotide (¹¹¹In octreotide) is occasionally helpful in locating ectopic ACTH sites.

Treatment

Successful treatment of Cushing's syndrome with a normal biochemical profile should lead to reversal of the presenting clinical features. However, untreated Cushing's syndrome has a very bad prognosis, with death from hypertension, myocardial infarction, infection and heart failure. Whatever the underlying cause, cortisol hypersecretion should be controlled prior to surgery or radiotherapy. Considerable morbidity and mortality is otherwise associated with operating on unprepared patients, especially when abdominal surgery is required.

The usual drug is metyrapone, an 11 β -hydroxylase blocker, which is given in doses of 750 mg to 4 g daily in 3–4 divided doses. Ketoconazole (200 mg three times daily) is also used and is synergistic with metyrapone. Plasma cortisol should be monitored, aiming to reduce the mean level during the day to 150–300 nmol/L, equivalent to normal production rates. Aminoglutethimide and trilostane (which reversibly inhibits 3-hydroxysteroid dehydrogenase/5–5,4 isomers) are occasionally used.

Choice of further treatment depends upon the cause.

Cushing's disease (pituitary-dependent hyperadrenalism)

- **Trans-sphenoidal removal of the tumour** is the treatment of choice. Selective adenomectomy nearly always leaves the patient ACTH deficient immediately postoperatively, and this is a good prognostic sign. Overall, pituitary surgery results in remission in 75–80% of cases, but results vary considerably and an experienced surgeon is essential.
- **External pituitary irradiation** alone is slow acting, only effective in 50–60% even after prolonged follow-up and mainly used after failed pituitary surgery. Children, however, respond much better to radiotherapy, 80% being cured. Stereotactic radiotherapy can be useful in selected cases.
- **Medical therapy** to reduce ACTH (e.g. bromocriptine, cabergoline, cyproheptadine, somatostatin analogues such as pasireotide) is rarely effective. There is some evidence that aggressive corticotroph adenomas may respond to temozolomide chemotherapy.
- **Bilateral adrenalectomy** is an effective last resort if other measures fail to control the disease (see Nelson's syndrome). This can be performed laparoscopically.

Cushing's syndrome due to other causes

Adrenal adenomas should be resected after achievement of clinical remission with metyrapone or ketoconazole. Contralateral adrenal suppression may last for a year or more.

Adrenal carcinomas are highly aggressive and the prognosis is poor. In general, if there are no widespread metastases, tumour bulk should be reduced surgically. The adrenolytic drug mitotane may inhibit growth of the tumour and prolong survival, though it can cause nausea and ataxia. Some would also give radiotherapy to the tumour bed after surgery.

Tumours secreting ACTH ectopically should be removed if possible. Otherwise chemotherapy/radiotherapy may be used, depending on the tumour. Control of the Cushing's syndrome with metyrapone or ketoconazole is beneficial for symptoms, and bilateral adrenalectomy may be appropriate to give complete control of Cushing's syndrome if prognosis from the tumour itself is reasonable.

If the source of ACTH is not clear, cortisol hypersecretion should be controlled with medical therapy until a diagnosis can be made.

Nelson's syndrome

Nelson's syndrome is increased pigmentation (because of high levels of ACTH) associated with an enlarging pituitary tumour, which occurs in about 20% of cases after bilateral adrenalectomy for Cushing's disease. The syndrome is rare now that adrenalectomy is an uncommon primary treatment, and its incidence may be reduced by pituitary radiotherapy soon after adrenalectomy. The Nelson's adenoma may be treated by pituitary surgery and/or radiotherapy (unless given previously).

Hypersecretion of other pituitary hormones

Pituitary tumours may rarely secrete TSH (and cause thyrotoxicosis). Such 'TSHomas' lead to the unusual biochemical pattern of elevated fT_4 levels with normal or high circulating TSH levels. FSH and LH secreting pituitary tumours may cause elevated sex steroids but are extremely uncommon.

THE THYROID AXIS

The metabolism of virtually all nucleated cells of many tissues is controlled by the thyroid hormones. Overactivity or underactivity of the gland are the most common of all endocrine problems.

Anatomy

The thyroid gland consists of two lateral lobes connected by an isthmus. It is closely attached to the thyroid cartilage and to the upper end of the trachea, and thus moves on swallowing. It is often palpable in normal women.

Embryologically it originates from the base of the tongue and descends to the middle of the neck. Remnants of thyroid tissue can sometimes be found at the base of the tongue (lingual thyroid) and along the line of descent. The gland has a rich blood supply from superior and inferior thyroid arteries.

The thyroid gland consists of follicles lined by cuboidal epithelioid cells. Inside is the colloid (the iodinated glycoprotein thyroglobulin) which is synthesized by the follicular cells. Each follicle is surrounded by basement membrane, between which are parafollicular cells containing calcitonin-secreting C cells.

Physiology

Synthesis. The thyroid synthesizes two hormones:

- Triiodothyronine (T_3), which acts at the cellular level
- L-thyroxine (T_4), which is the prohormone.

Inorganic iodide is trapped by the gland by an enzyme dependent system, oxidized and incorporated into the glycoprotein thyroglobulin to form mono- and diiodotyrosine and then T_4 and T_3 (Fig. 19.16).

More T_4 than T_3 is produced, but T_4 is converted in some peripheral tissues (liver, kidney and muscle) to the more active T_3 by 5'-monodeiodination; an alternative 3'-monodeiodination yields the inactive reverse T_3 (rT_3). The latter step occurs particularly in severe non-thyroidal illness (see below).

In plasma, more than 99% of all T_4 and T_3 is bound to hormone-binding proteins (thyroxine-binding globulin, TBG; thyroid-binding prealbumin, TBPA; and albumin). Only free hormone is available for action in the target tissues, where T_3 binds to specific nuclear receptors within target cells. Many drugs and other factors affect TBG; all may result in confusing total T_4 levels in blood, and most laboratories therefore now measure free T_4 levels.

Control of the hypothalamic-pituitary-thyroid axis.

Thyrotrophin-releasing hormone (TRH), a peptide produced in the hypothalamus, stimulates the pituitary to secrete thyroid-stimulating hormone (TSH) (see Fig. 19.2). TSH in turn stimulates growth and activity of the thyroid follicular cells via the G-protein coupled TSH membrane receptor (see Table 19.3). The T_3 and T_4 subsequently secreted into the circulation by follicular cells exert negative feedback on the hypothalamus, as described on page 941.

Figure 19.16 Synthesis and metabolism of the thyroid hormones. Tg, thyroglobulin.

SIGNIFICANT WEBSITE

International Council for the Control of Iodine Deficiency Disorders: <http://www.icidd.org>

Circulating T₄ is peripherally deiodinated to T₃ which binds to the thyroid hormone nuclear receptor (TR) on target organ cells to cause modified gene transcription. There are two TR receptors (TR-α and TR-β) and the tissue-specific effects of T₃ are dependent upon the local expression of these TR receptors. TR-α knockout mice show poor growth, bradycardia and hypothermia, whilst TR-β knockout mice show thyroid hyperplasia and high T₄ levels in the presence of inappropriately normal circulating TSH, suggesting a role for the latter receptors in thyroid hormone resistance (see p. 967).

Physiological effects of thyroid hormones. The physiological effects of thyroid hormones are summarized in Table 19.12.

Dietary iodine requirement. Globally, dietary iodine deficiency is a major cause of thyroid disease, as iodine is an essential requirement for thyroid hormone synthesis. The recommended daily intake of iodine should be at least 140 μg, and dietary supplementation of salt and bread has reduced the number of areas where 'endemic goitre' still occurs (see below).

Thyroid function tests

Immunoassays for free T₄, free T₃ and TSH are widely available. There are only minor circadian rhythms, and measurements may be made at any time. Particular uses of the tests are summarized in Table 19.13, with typical findings in common disorders.

TSH measurement

In most circumstances, TSH levels can discriminate between hyperthyroidism, hypothyroidism and euthyroidism (normal

Table 19.12 Physiological effects of thyroid hormone

Target	Effect
Cardiovascular system	Increases heart rate and cardiac output
Bone	Increases bone turnover and resorption
Respiratory system	Maintains normal hypoxic and hypercapnic drive in respiratory centre
Gastrointestinal system	Increases gut motility
Blood	Increases red blood cell 2,3-BPG ^a facilitating oxygen release to tissues
Neuromuscular function	Increases speed of muscle contraction and relaxation and muscle protein turnover
Carbohydrate metabolism	Increases hepatic gluconeogenesis/glycolysis and intestinal glucose absorption
Lipid metabolism	Increases lipolysis and cholesterol synthesis and degradation
Sympathetic nervous system	Increases catecholamine sensitivity and β-adrenergic receptor numbers in heart, skeletal muscle, adipose cells and lymphocytes Decreases cardiac α-adrenergic receptors

^a2,3-BPG, 2,3-bisphosphoglyceric acid.

thyroid gland function). Exceptions are hypopituitarism, and the 'sick euthyroid' syndrome where low levels (which normally imply hyperthyroidism) occur in the presence of low or normal T₄ and T₃ levels. As a single test of thyroid function TSH is the most sensitive in most circumstances, but

Table 19.13 Characteristics of thyroid function tests in common thyroid disorders (the clinically most informative tests in each situation are shown in bold)

	TSH (0.3–3.5 mU/L)	Free T₄ (10–25 pmol/L)	Free T₃ (3.5–7.5 pmol/L)
Thyrotoxicosis	Suppressed (<0.05 mU/L)	Increased	Increased
Primary hypothyroidism	Increased (>10 mU/L)	Low/low-normal	Normal or low
TSH deficiency	Low-normal or subnormal	Low/low-normal	Normal or low
T₃ toxicosis	Suppressed (<0.05 mU/L)	Normal	Increased
Compensated euthyroidism	Slightly increased (5–10 mU/L)	Normal	Normal

accurate diagnosis requires at least two tests, e.g. TSH plus free T₄ or free T₃ where hyperthyroidism is suspected, TSH plus serum free T₄ where hypothyroidism is likely.

TRH test

This has been rendered almost obsolete by modern sensitive TSH assays except for investigation of hypothalamic-pituitary dysfunction. TRH (protirelin) is occasionally used to differentiate between thyroid hormone resistance and TSHoma in the context of raised fT₄ and TSH levels. Typically, after TRH administration there is a rise in TSH in thyroid hormone resistance, whilst in TSHoma there is a flat response due to continued autonomous TSH secretion which does not respond to TRH.

Problems in interpretation of thyroid function tests

There are three major areas of difficulty.

1. Serious acute or chronic illness

Thyroid function is affected in several ways:

- Reduced concentration and affinity of binding proteins
- Decreased peripheral conversion of T₄ to T₃ with more rT₃
- Reduced hypothalamic-pituitary TSH production.

Systemically ill patients can therefore have an apparently low total and free T₄ and T₃ with a normal or low basal TSH (the 'sick euthyroid' syndrome). Levels are usually only mildly below normal and are thought to be mediated by interleukins IL-1 and IL-6; the tests should be repeated after resolution of the underlying illness.

2. Pregnancy and oral contraceptives

These lead to greatly increased TBG levels and thus to high or high-normal total T₄. Free T₄ is usually normal. Normal ranges for free T₄ and TSH alter with the normal physiological changes during pregnancy and TSH is often slightly suppressed in the first trimester, but this rarely causes clinical problems.

3. Drugs

Amiodarone decreases T₄ to T₃ conversion and free T₄ levels may therefore be above normal in a euthyroid patient; conversely amiodarone may induce both hyper- and hypothyroidism – the TSH level is usually reliable.

Many drugs affect thyroid function tests by interfering with protein binding but this now rarely causes a problem with free T₄ assays.

Antithyroid antibodies

Serum antibodies to the thyroid are common and may be either destructive or stimulating; both occasionally co-exist in the same patient.

Table 19.14 Causes of hypothyroidism

Primary disease of thyroid	
Congenital	Infective
Agnesis	Post-subacute thyroiditis
Ectopic thyroid remnants	Post-surgery
Defects of hormone synthesis	Post-irradiation
Iodine deficiency	Radioactive iodine therapy
Dyshormonogenesis	External neck irradiation
Antithyroid drugs	Infiltration
Other drugs (e.g. lithium, amiodarone, interferon)	Tumour
Autoimmune	Secondary (to hypothalamic-pituitary disease)
Atrophic thyroiditis	Hypopituitarism
Hashimoto's thyroiditis	Isolated TSH deficiency
Postpartum thyroiditis	Peripheral resistance to thyroid hormone

Destructive antibodies are directed against the microsome or against thyroglobulin; the antigen for thyroid microsomal antibodies is the thyroid peroxidase (TPO) enzyme. TPO antibodies are found in up to 20% of the normal population, especially older women, but only 10–20% of these develop overt hypothyroidism.

TSH receptor IgG antibodies (TRAb) typically stimulate, but occasionally block, the receptor; they can be measured in two ways:

- By the inhibition of binding of TSH to its receptors (TSH-binding inhibitory immunoglobulin, TBII)
- By demonstrating that they stimulate the release of cyclic AMP (thyroid-stimulating immunoglobulin/antibody TSI, TSAb).

Hypothyroidism

Pathophysiology

Underactivity of the thyroid is usually primary, from disease of the thyroid, but may be secondary to hypothalamic-pituitary disease (reduced TSH drive) (Table 19.14). Primary hypothyroidism is one of the most common endocrine conditions with an overall UK prevalence of over 2% in women, but under 0.1% in men; lifetime prevalence for an individual is higher – perhaps as high as 9% for women and 1% for men with mean age at diagnosis around 60 years. The worldwide prevalence of subclinical hypothyroidism varies from 1% to 10%.

Causes of primary hypothyroidism (Table 19.14)

Autoimmune

Atrophic (autoimmune) hypothyroidism. This is the most common cause of hypothyroidism and is associated with

Symptoms		Signs
Tiredness/malaise		Mental slowness
Weight gain		Psychosis/dementia
Anorexia		Ataxia
Cold intolerance		Poverty of movement
Poor memory		Deafness
Change in appearance		
Depression		'Peaches and cream' complexion
Poor libido		Dry thin hair
Goitre		Loss of eyebrows
Puffy eyes		
Dry, brittle unmanageable hair		Hypertension
Dry, coarse skin		Hypothermia
Arthralgia		Heart failure
Myalgia		Bradycardia
Muscle weakness/Stiffness		Pericardial effusion
Constipation		
Menorrhagia or oligomenorrhoea in women		Cold peripheries
Psychosis		Carpal tunnel syndrome
Coma		Oedema
Deafness		

Figure 19.17 Hypothyroidism: symptoms and signs. Bold type indicates symptoms or signs of greater discriminant value. A history from a relative is often revealing. Symptoms of other autoimmune disease may be present.

FURTHER READING

Zimmermann MB, Jooste PL, Pandar CS. Iodine deficiency disorders. *Lancet* 2008; 372:1251–1262.

antithyroid autoantibodies leading to lymphoid infiltration of the gland and eventual atrophy and fibrosis. It is six times more common in females and the incidence increases with age. The condition is associated with other autoimmune disease such as pernicious anaemia, vitiligo and other endocrine deficiencies (p. 939). Occasionally intermittent hypothyroidism occurs with subsequent recovery; antibodies which block the TSH receptor may sometimes be involved in the aetiology.

Hashimoto's thyroiditis. This form of autoimmune thyroiditis, again more common in women and most common in late middle age, produces atrophic changes with regeneration, leading to goitre formation. The gland is usually firm and rubbery but may range from soft to hard. TPO antibodies are present, often in very high titres (>1000 IU/L). Patients may be hypothyroid or euthyroid, though they may go through an initial toxic phase, 'Hashi-toxicity'. Levothyroxine therapy may shrink the goitre even when the patient is not hypothyroid.

Postpartum thyroiditis. This is usually a transient phenomenon observed following pregnancy. It may cause hyperthyroidism, hypothyroidism or the two sequentially. It is believed to result from the modifications to the immune system necessary in pregnancy, and histologically is a lymphocytic thyroiditis. The process is normally self-limiting, but when conventional antibodies are found there is a high chance of this proceeding to permanent hypothyroidism. Postpartum thyroiditis may be misdiagnosed as postnatal depression, emphasizing the need for thyroid function tests in this situation.

Defects of hormone synthesis

Iodine deficiency. Dietary iodine deficiency still exists (p. 213) in some areas as 'endemic goitre' where goitre, occasionally massive, is common. The patients may be euthyroid or hypothyroid depending on the severity of iodine deficiency. The mechanism is thought to be borderline hypothyroidism leading to TSH stimulation and thyroid enlargement in the face of continuing iodine deficiency. Iodine deficiency is still a problem in the Netherlands, Western Pacific, India, South East Asia, Russia and parts of Africa. Efforts to prevent deficiency by providing iodine in salt continue worldwide but

often with incomplete success. Even in the late 20th century of the 500 million with iodine deficiency in India, about 2 million had cretinism (see below).

Dyshormonogenesis. This rare condition is due to genetic defects in the synthesis of thyroid hormones; patients develop hypothyroidism with a goitre. One particular familial form is associated with sensorineural deafness due to a deletion mutation in chromosome 7, causing a defect of the transporter pendrin (Pendred's syndrome) (see Fig. 19.16).

Clinical features (Fig. 19.17)

Hypothyroidism produces many symptoms. The alternative term 'myxoedema' refers to the accumulation of mucopolysaccharide in subcutaneous tissues. The classic picture of the slow, dry-haired, thick-skinned, deep-voiced patient with weight gain, cold intolerance, bradycardia and constipation makes the diagnosis easy. Milder symptoms are, however, more common and hard to distinguish from other causes of nonspecific tiredness. Many cases are detected on biochemical screening.

Special difficulties in diagnosis may arise in certain circumstances:

- **Children with hypothyroidism** may not show classic features but often have a slow growth velocity, poor school performance and sometimes arrest of pubertal development.
- **Young women with hypothyroidism** may not show obvious signs. Hypothyroidism should be excluded in all people with oligomenorrhoea/amenorrhoea, menorrhagia, infertility or hyperprolactinaemia.
- **The elderly** show many clinical features that are difficult to differentiate from normal ageing.

Investigation of primary hypothyroidism

Serum TSH is the investigation of choice; a high TSH level confirms primary hypothyroidism. A low free T_4 level confirms the hypothyroid state (and is also essential to exclude TSH deficiency if clinical hypothyroidism is strongly suspected and TSH is normal or low).

Thyroid and other organ-specific antibodies may be present. Other abnormalities include the following:

- **Anaemia**, which is usually normochromic and normocytic in type but may be macrocytic (sometimes this is due to associated pernicious anaemia) or microcytic (in women, due to menorrhagia)
- **Increased serum aspartate transferase levels**, from muscle and/or liver
- **Increased serum creatine kinase levels**, with associated myopathy
- **Hypercholesterolaemia** and hypertriglyceridaemia
- **Hyponatraemia** due to an increase in ADH and impaired free water clearance.

Treatment

Replacement therapy with levothyroxine (thyroxine, i.e. T_4) is given for life. The starting dose will depend upon the severity of the deficiency and on the age and fitness of the patient, especially their cardiac performance: 100 µg daily for the young and fit, 50 µg (increasing to 100 µg after 2–4 weeks) for the small, old or frail. People with ischaemic heart disease require even lower initial doses, especially if the hypothyroidism is severe and longstanding. Most physicians would then begin with 25 µg daily and perform serial ECGs, increasing the dose at 3- to 4-week intervals if angina does not occur or worsen and the ECG does not deteriorate. Occasional patients develop 'thyrotoxic' (hyperthyroid) symptoms despite normal fT_4 levels if dose is increased too rapidly.

Monitoring. The aim is to restore T_4 and TSH to well within the normal range. Adequacy of replacement is assessed clinically and by thyroid function tests after at least 6 weeks on a steady dose. If serum TSH remains high, the dose of T_4 should be increased in increments of 25–50 µg with the tests repeated at 6–8 weeks intervals until TSH becomes normal. Complete suppression of TSH should be avoided because of the risk of atrial fibrillation and osteoporosis. The usual maintenance dose is 100–150 µg given as a single daily dose. An annual thyroid function test is recommended – this is usually performed in the primary care setting, often assisted and prompted by district 'thyroid registers'.

Clinical improvement on T_4 may not begin for 2 weeks or more, and full resolution of symptoms may take 6 months. The necessity of lifelong therapy must be emphasized and the possibility of other autoimmune endocrine disease developing, especially Addison's disease or pernicious anaemia, should be considered. During pregnancy, an increase in T_4 dosage of about 25–50 µg is often needed to maintain normal TSH levels, and the necessity of optimal replacement during pregnancy is emphasized by the finding of reductions in cognitive function in children of mothers with elevated TSH during pregnancy.

A few people with primary hypothyroidism complain of incomplete symptomatic response to T_4 replacement. Combination T_4 and T_3 replacement has been advocated in this context, but randomized clinical trials show no consistent benefit in quality of life symptoms.

Borderline hypothyroidism or 'compensated euthyroidism'

Patients are frequently seen with low-normal serum T_4 levels and slightly raised TSH levels. Sometimes this follows surgery or radioactive iodine therapy when it can reasonably be seen as 'compensatory'. Treatment with levothyroxine is normally recommended where the TSH is consistently above 10 mU/L, or when possible symptoms, high-titre thyroid antibodies, or lipid abnormalities are present. Where the TSH is only marginally raised, the tests should be repeated 3–6 months later.

Conversion to overt hypothyroidism is more common in men or when TPO antibodies are present. In practice, vague symptoms in people with marginally elevated TSH (below 10 mU/L) rarely respond to treatment, but a 'therapeutic trial' of replacement may be needed to confirm that symptoms are unrelated to the thyroid. It is also considered best to normalize TSH during (and ideally before) pregnancy to avoid fetal adverse effects.

Myxoedema coma

Severe hypothyroidism, especially in the elderly, may present with confusion or even coma. Myxoedema coma is very rare: hypothermia is often present and the patient may have severe cardiac failure, pericardial effusions, hypoventilation, hypoglycaemia and hyponatraemia. The mortality was previously at least 50% and patients require full intensive care. Optimal treatment is controversial and data lacking; most physicians would advise T_3 orally or intravenously in doses of 2.5–5 µg every 8 hours, then increasing as above. Large intravenous doses should not be used. Additional measures, though unproven, should include:

- Oxygen (by ventilation if necessary)
- Monitoring of cardiac output and pressures
- Gradual rewarming
- Hydrocortisone 100 mg i.v. 8-hourly
- Glucose infusion to prevent hypoglycaemia.

Myxoedema madness. Depression is common in hypothyroidism. Rarely, with severe hypothyroidism in the elderly, the patient may become frankly demented or psychotic, sometimes with striking delusions. This may occur shortly after starting T_4 replacement.

Screening for hypothyroidism

- The incidence of *congenital* hypothyroidism is approximately 1 in 3500 births. Untreated, severe hypothyroidism produces permanent neurological and intellectual damage ('cretinism'). Routine screening of the newborn using a blood spot, as in the Guthrie test, to detect a high TSH level as an indicator of primary hypothyroidism is efficient and cost-effective; cretinism is prevented if T_4 is started within the first few months of life.
- Screening of *elderly* patients for thyroid dysfunction has a low pick-up rate and is controversial and not currently recommended. However, patients who have undergone thyroid surgery or received radioiodine should have regular thyroid function tests, as should those receiving lithium or amiodarone therapy.

Hyperthyroidism

Hyperthyroidism (thyroid overactivity, thyrotoxicosis) is common, affecting perhaps 2–5% of all females at some time and with a sex ratio of 5:1, most often between the ages of 20 and 40 years. Nearly all cases (>99%) are caused by intrinsic thyroid disease; a pituitary cause is extremely rare (Table 19.15).

Graves' disease

This is the most common cause of hyperthyroidism and is due to an autoimmune process. Serum IgG antibodies bind to TSH receptors in the thyroid, stimulating thyroid hormone production, i.e. they behave like TSH. These TSH receptor antibodies (TSHR-Ab) are specific for Graves' disease.

Table 19.15 Causes of hyperthyroidism

Common
Graves' disease (autoimmune)
Toxic multinodular goitre
Solitary toxic nodule/adenoma
Uncommon
Acute thyroiditis
Viral (e.g. de Quervain's)
Autoimmune
Post-irradiation
Postpartum
Gestational thyrotoxicosis (HCG stimulated)
Neonatal thyrotoxicosis (maternal thyroid antibodies)
Exogenous iodine
Drugs – amiodarone
Thyrotoxicosis factitia (secret T ₄ consumption)
Rare
TSH-secreting pituitary tumours
Metastatic differentiated thyroid carcinoma
HCG-producing tumours
Hyperfunctioning ovarian teratoma (struma ovarii)

Persistent high levels predict a relapse when drug treatment is stopped. There is an association with HLA-B8, DR3 and DR2 and a 40% concordance rate amongst monozygotic twins with a 5% concordance rate in dizygotic twins. There is a weak association with cytotoxic T lymphocyte-associated antigen 4 (CTLA-4), HLA-DRB*08 and DRB3*0202 on chromosome 6.

Yersinia enterocolitica, *Escherichia coli* and other Gram-negative organisms contain TSH binding sites. This raises the possibility that the initiating event in the pathogenesis may be an infection with possible 'molecular mimicry' in a genetically susceptible individual, but the precise initiating mechanisms remain unproven in most cases.

Thyroid eye disease accompanies the hyperthyroidism in many cases (see below) but other components of Graves' disease, e.g. Graves' dermopathy, are very rare. Rarely lymphadenopathy and splenomegaly may occur. Graves' disease is also associated with other autoimmune disorders such as pernicious anaemia, vitiligo and myasthenia gravis.

The natural history is one of fluctuation, many patients showing a pattern of alternating relapse and remission; perhaps only 40% of subjects have a single episode. Many patients eventually become hypothyroid.

Other causes of hyperthyroidism/thyrotoxicosis

Solitary toxic adenoma/nodule

This is the cause of about 5% of cases of hyperthyroidism. It does not usually remit after a course of antithyroid drugs.

Toxic multinodular goitre

This commonly occurs in older women. Again, antithyroid drugs are rarely successful in inducing a remission, although they can control the hyperthyroidism.

de Quervain's thyroiditis

This is transient hyperthyroidism from an acute inflammatory process, probably viral in origin. Apart from the toxicosis, there is usually fever, malaise and pain in the neck with tachycardia and local thyroid tenderness. Thyroid function tests show initial hyperthyroidism, the erythrocyte sedimentation rate (ESR) and plasma viscosity are raised, and thyroid uptake scans show suppression of uptake in the acute phase.

Hypothyroidism, usually transient, may then follow after a few weeks. Treatment of the acute phase is with aspirin, using short-term prednisolone in severely symptomatic cases.

Postpartum thyroiditis

This is described on page 967.

Amiodarone-induced thyrotoxicosis

Amiodarone, a class III antiarrhythmic drug (see p. 699), causes two types of hyperthyroidism.

Type I amiodarone-induced thyrotoxicosis (AIT) is associated with pre-existing Graves' disease or multinodular goitre. In this situation hyperthyroidism is probably triggered by the high iodine content of amiodarone.

Type II AIT is not associated with previous thyroid disease and is thought to be due to a direct effect of the drug on thyroid follicular cells leading to a destructive thyroiditis with release of T₄ and T₃. Type II AIT may be associated with a hypothyroid phase several months after presentation. Because amiodarone inhibits the deiodination of T₄ to T₃, biochemical presentation of both types of AIT may be associated with higher T₄:T₃ ratios than usual.

Clinical features of hyperthyroidism

The symptoms and signs of hyperthyroidism affect many systems (Fig. 19.18).

Symptomatology and signs vary with age and with the underlying aetiology.

- **The eye signs, of lid lag and 'stare'** may occur with hyperthyroidism of any cause but other features of thyroid eye disease (see below) occur only in Graves' disease.
- **Graves' dermopathy** is rare: **pretibial myxoedema** is an infiltration of the skin on the shin. **Thyroid acropachy** is very rare and consists of clubbing, swollen fingers and periosteal new bone formation.
- **In the elderly**, a frequent presentation is with atrial fibrillation, other tachycardias and/or heart failure, often with few other signs. Thyroid function tests are mandatory in any patient with atrial fibrillation.
- **Children** frequently present with excessive height or excessive growth rate, or with behavioural problems such as hyperactivity. They may also show weight gain rather than loss.
- **So-called 'apathetic thyrotoxicosis'** in some elderly patients presents with a clinical picture more like hypothyroidism. There may be very few signs and a high degree of clinical suspicion is essential.

Differential diagnosis

Hyperthyroidism is often clinically obvious but treatment should never be instituted without biochemical confirmation.

Differentiation of the mild case from anxiety states may be difficult; useful positive clinical markers are eye signs, a diffuse goitre, proximal myopathy and wasting. Weight loss, despite a normal or increased appetite, is a very useful clinical symptom of hyperthyroidism. The hyperdynamic circulation with warm peripheries seen with hyperthyroidism can be contrasted with the clammy hands of anxiety.

Investigations

- Serum TSH is suppressed in hyperthyroidism (<0.05 mU/L), except for the very rare instances of TSH hypersecretion.

Table 19.16 Drugs used in the treatment of hyperthyroidism			
Drug	Usual starting dose	Side-effects	Remarks
Antithyroid drugs			
Carbimazole	20–40 mg daily, 8-hourly, or in single dose	Rash, nausea, vomiting, arthralgia, agranulocytosis (0.1%), jaundice	Active metabolite is thiamazole (methimazole) Mild immunosuppressive activity
Propylthiouracil	100–200 mg 8-hourly	Rash, nausea, vomiting, agranulocytosis	Additionally blocks conversion of T_4 to T_3
Beta-blocker for symptomatic control			
May need higher doses than normal			
Propranolol	40–80 mg every 6–8 h	Avoid in asthma	Use agents without intrinsic sympathomimetic activity as receptors highly sensitive

- A raised free T_4 or T_3 confirms the diagnosis; T_4 is almost always raised but T_3 is more sensitive as there are occasional cases of isolated ' T_3 toxicosis'.
 - Thyroid peroxidase (TPO) and thyroglobulin antibodies are present in most cases of Graves' disease.
- TSHR-Ab are not measured routinely, but are commonly present: thyroid-stimulating immunoglobulin (TSI) 80% positive, TSH-binding inhibitory immunoglobulin (TBII) 60–90% in Graves' disease (see p. 961).

Treatment

Three possibilities are available: antithyroid drugs, radioiodine and surgery. Practices and beliefs differ widely within and between countries.

Antithyroid drugs

Carbimazole is most often used in the UK, and propylthiouracil (PTU) is also used. **Thiamazole** (methimazole), the active

metabolite of carbimazole, is used in the USA. These drugs inhibit the formation of thyroid hormones and also have other minor actions; carbimazole/thiamazole is also an immunosuppressive agent. Initial doses and side-effects are detailed in Table 19.16.

Although thyroid hormone synthesis is reduced very quickly, the long half-life of T_4 (7 days) means that clinical benefit is not apparent for 10–20 days. As many of the manifestations of hyperthyroidism are mediated via the sympathetic system, beta-blockers are used to provide rapid partial symptomatic control; they also decrease peripheral conversion of T_4 to T_3 . Drugs preferred are those without intrinsic sympathomimetic activity, e.g. propranolol (Table 19.16). They should not be used alone for hyperthyroidism except when the condition is self-limiting, as in subacute thyroiditis.

Subsequent management is either by gradual dose titration or a 'block and replace' regimen. Neither regimen has been shown to be unequivocally superior. TSH often remains suppressed for many months after clinical improvement and normalization of T_4 and T_3 .

Dosage regimen**Gradual dose titration.**

1. Start carbimazole 20–40 mg daily.
2. Review after 4–6 weeks and reduce the dose of carbimazole, depending on clinical state and fT_4/fT_3 levels. TSH levels may remain suppressed for several months and are unhelpful at this stage.
3. When clinically and biochemically euthyroid, stop beta-blockers.
4. Review thyroid function regularly during the planned course of treatment (typically 18 months – but some use courses between 6 and 24 months).
5. Reduce carbimazole if fT_4 falls below or TSH rises above normal – and when approaching the end of the planned course.
6. Increase carbimazole if fT_4 or fT_3 are above normal (and consider if TSH remains suppressed after several months with a normal fT_4).
7. Stop treatment at end of course if the patient is euthyroid on 5 mg daily carbimazole.

PTU is used in similar fashion (Table 19.16).

'Block and replace' regimen. With this policy, full doses of antithyroid drugs, usually carbimazole 40 mg daily, are given to suppress the thyroid completely while replacing thyroid activity with 100 µg of levothyroxine daily once euthyroidism has been achieved. This is continued usually for 18 months, the claimed advantages being the avoidance of over- or undertreatment and the better use of the immunosuppressive action of carbimazole. This regimen is contraindicated in pregnancy as T_4 crosses the placenta less well than carbimazole.

Relapse

About 50% of patients will relapse after a course of carbimazole or PTU, mostly within the following 2 years but occasionally much later. Long-term antithyroid therapy is then used or surgery or radiotherapy is considered (see below). Most patients (90%) with hyperthyroidism have a diffuse goitre but those with large single or multinodular goitres are unlikely to remit after a course of antithyroid drugs and will usually require definitive treatment. Severe biochemical hyperthyroidism is also less likely to remain in remission.

Toxicity

The major side-effect of drug therapy is agranulocytosis that occurs in approximately 1 in 1000 patients, usually within 3 months of treatment. All patients must be warned to seek immediate medical attention for a white blood cell count if they develop unexplained fever or sore throat – written information is essential. Rashes are more frequent and usually require a change of drug. If toxicity occurs on carbimazole, PTU may be used and vice-versa; side-effects are only occasionally repeated on the other drug.

Radioactive iodine

Radioactive iodine (RAI) is given to patients of all ages, although it is contraindicated in pregnancy and while breastfeeding. RAI is the most common treatment modality in the USA whereas antithyroid drugs tend to be favoured in Europe.

^{131}I is given in an empirical dose (usually 200–550 MBq) because of variable uptake and radiosensitivity of the gland. It accumulates in the thyroid and destroys the gland by local radiation although it takes several months to be fully effective.

Patients must be rendered euthyroid before treatment. They should stop antithyroid drugs at least 4 days before

radioiodine, and not recommence until 3 days after radioiodine. Patients on PTU should stop antithyroid medication earlier than those on carbimazole before RAI because it has a radioprotective action. Many patients do not need to restart antithyroid medication after treatment.

Early discomfort in the neck and immediate worsening of hyperthyroidism are sometimes seen; if worsening occurs, the patient should receive propranolol (Table 19.16); if necessary carbimazole can be restarted. Euthyroidism normally returns in 2–3 months. People with dysthyroid eye disease are more likely to show worsening of eye problems after radioiodine than after antithyroid drugs; this represents a partial contraindication to RAI, although worsening can usually be prevented by steroid administration.

Long-term surveillance. Hypothyroidism affects the majority of subjects over the following 20 years. Some 75% of patients are rendered euthyroid in the short term but a small proportion remain hyperthyroid and may require a second dose of radioiodine. Long-term surveillance of thyroid function is necessary with frequent tests in the first year after therapy, and at least annually thereafter.

Risk of carcinogenesis has been long debated, but the overwhelming evidence suggests that overall cancer incidence and mortality are not increased after radioactive iodine (and indeed are significantly reduced in some studies).

Surgery

Thyroidectomy should be performed only in patients who have previously been rendered euthyroid. Conventional practice is to stop the antithyroid drug 10–14 days before operation and to give potassium iodide (60 mg three times daily), which reduces the vascularity of the gland.

The operation should be performed only by experienced surgeons to reduce the chance of complications:

- Early postoperative bleeding causing tracheal compression and asphyxia is a rare emergency requiring immediate removal of all clips/sutures to allow escape of the blood/haematoma.
- Laryngeal nerve palsy occurs in 1%. Vocal cord movement should be checked preoperatively. Mild hoarseness is more common and thyroidectomy is best avoided in professional singers!
- Transient hypocalcaemia occurs in up to 10% but with permanent hypoparathyroidism in fewer than 1%.
- Ongoing thyroid function depends on the operation performed. With a single toxic nodule excision of the lesion is curative. With Graves' disease or multinodular goitre the traditional 'subtotal' thyroidectomy, aiming for euthyroidism on no treatment, results in recurrent hyperthyroidism in 1–3% within 1 year, then 1% per year and hypothyroidism in about 10% of patients within 1 year, and then increasing with time. 'Near-total' thyroidectomy is therefore now preferred with inevitable hypothyroidism but a much reduced risk of recurrence.

Indications for either surgery or radioiodine are given in Box 19.4.

Special situations in hyperthyroidism**Thyroid crisis or 'thyroid storm'**

This rare condition, with a mortality of 10%, is a rapid deterioration of hyperthyroidism with hyperpyrexia, severe tachycardia, extreme restlessness, cardiac failure and liver dysfunction. It is usually precipitated by stress, infection or surgery in an unprepared patient, or radioiodine therapy. With careful management it should no longer occur and most

Box 19.4 Choice of surgery or radioiodine therapy for hyperthyroidism

Indications for surgery or radioiodine

- Patient choice
- Persistent drug side-effects
- Poor compliance with drug therapy
- Recurrent hyperthyroidism after drugs

Indication for surgery

- A large goitre, which is unlikely to remit after antithyroid medication

cases referred as 'crisis' are simply severe but uncomplicated thyrotoxicosis.

Treatment is urgent. Propranolol in full doses is started immediately together with potassium iodide, antithyroid drugs, corticosteroids (which suppress many of the manifestations of hyperthyroidism) and full supportive measures. Control of cardiac failure and tachycardia is also necessary.

Occasionally, hyperthyroidism can lead to a thyrotoxic cardiomyopathy which causes ischaemic changes on a 12-lead ECG which reverse after reversion to euthyroidism.

Hyperthyroidism in pregnancy and neonatal life

Since hyperthyroidism typically affects young women, pregnancies, both planned and unplanned, inevitably occur during antithyroid treatment. PTU is usually the preferred antithyroid drug during pregnancy or in any woman planning pregnancy, due to rare reports of congenital abnormalities with carbimazole which have not been described with PTU.

The high level of HCG found in normal pregnancy is a weak stimulator of the TSH receptor, commonly causing suppressed TSH with slightly elevated fT_4/fT_3 in the first trimester which may be associated with hyperemesis gravidarum. True maternal hyperthyroidism occurring *de novo* during pregnancy is however uncommon and usually mild. Diagnosis can be difficult because of the overlap with symptoms of normal pregnancy and misleading thyroid function tests, although TSH is largely reliable. The pathogenesis is almost always Graves' disease.

Thyroid-stimulating immunoglobulin (TSI) crosses the placenta to stimulate the fetal thyroid. Carbimazole and PTU (see below) also cross the placenta, but T_4 does so poorly, so a 'block-and-replace' regimen is contraindicated. The smallest dose necessary of PTU (see above) is used and the fetus must be monitored. If necessary (high doses needed, poor patient compliance or drug side-effects), surgery can be performed, preferably in the second trimester. Radioactive iodine is absolutely contraindicated.

The fetus and maternal Graves' disease

Any mother with a history of Graves' disease may have circulating TSI. Even if she is euthyroid after surgery or RAI, the immunoglobulin may still be present to stimulate the fetal thyroid, and the fetus can thus become hyperthyroid.

Any such patient should therefore be monitored during pregnancy. Fetal heart rate provides a direct biological assay of fetal thyroid status, and monitoring should be performed at least monthly. Rates above 160/minute are strongly suggestive of fetal hyperthyroidism, and maternal treatment with PTU and/or propranolol is used. Direct measurement of TSHR-Ab may be helpful to predict neonatal thyrotoxicosis in this situation. To prevent a euthyroid mother becoming hypothyroid, T_4 may be given as this does not easily cross

the placenta. Sympathomimetics, used to prevent premature labour, are contraindicated as they may provoke fatal tachycardia in the fetus. The paediatrician should be informed and the infant checked immediately after birth – overtreatment with PTU or carbimazole can cause fetal goitre. Breast-feeding while on usual doses of carbimazole or PTU appears to be safe.

Hyperthyroidism may also develop in the neonatal period as TSI has a half-life of approximately 3 weeks. Manifestations in the newborn include irritability, failure to thrive and persisting weight loss, diarrhoea and eye signs. Thyroid function tests are difficult to interpret as neonatal normal ranges vary with age.

Untreated neonatal hyperthyroidism is probably associated with hyperactivity in later childhood.

Thyroid hormone resistance

Thyroid hormone resistance is an inherited condition caused by an abnormality of the thyroid hormone receptor. Mutations to the receptor (TR β) result in the need for higher levels of thyroid hormones to achieve the same intracellular effect. As a result, the normal feedback control mechanisms (see Fig. 19.2, p. 941) result in high blood levels of T_4 with a normal TSH in order to maintain a euthyroid state. This has two consequences:

1. Thyroid function tests appear abnormal even when the patient is euthyroid and requires no treatment. Specialist review is required to differentiate from hyperthyroidism due to inappropriate TSH secretion.
2. Different tissues contain different thyroid hormone receptors and, in some families, receptors in certain tissues may have normal activity. In this case the level of thyroid hormones to maintain euthyroidism at pituitary and hypothalamic levels (which controls secretion of TSH) may be higher than that required in other tissues such as heart and bone, so that these tissues may exhibit 'thyrotoxic' effects in spite of a normal serum TSH. This 'partial thyroid hormone resistance' can be very difficult to manage effectively.

Long-term consequences of hyperthyroidism

Long-term follow-up studies of hyperthyroidism show a slight increase in overall mortality, which affects all age groups, is not fully explained and tends to occur in the first year after diagnosis. Thereafter, the only long-term risk of adequately treated hyperthyroidism appears to be an increased risk of osteoporosis. People with persistently suppressed TSH levels have an increased likelihood of developing atrial fibrillation which may predispose to thromboembolic disease.

Thyroid eye disease

This is also known as dysthyroid eye disease or ophthalmic Graves' disease.

Pathophysiology

The ophthalmopathy of Graves' disease is due to a specific immune response that causes retro-orbital inflammation (Fig. 19.19). Swelling and oedema of the extraocular muscles lead to limitation of movement and to proptosis which is usually bilateral but can sometimes be unilateral. Ultimately increased pressure on the optic nerve may cause optic atrophy. Histology of the extraocular muscles shows focal oedema and glycosaminoglycan deposition followed by fibrosis. The precise autoantigen which leads to the immune response remains to be identified, but it appears to be an antigen in

Thyrotoxic cardiomyopathy: ECG showing marked lateral T-wave inversion.

Figure 19.19 Model of the Initiation of Thyrotrophin-Receptor Autoimmunity in Graves' Ophthalmopathy and Its Consequences. Thyrotrophin receptor is internalized and degraded by antigen-presenting cells that present thyrotrophin-receptor peptides, in association with major histocompatibility complex (MHC) class II antigens, to helper T cells. These cells become activated, interact with autoreactive B cells through CD154-CD40 bridges, and secrete interleukin-2 and interferon- γ . These cytokines induce the differentiation of B cells into plasma cells that secrete anti-thyrotrophin-receptor antibodies. Anti-thyrotrophin-receptor antibodies recognize the thyrotrophin receptor on orbital fibroblasts and, in conjunction with the secreted type 1 helper T cytokines interferon- γ and tumour necrosis factor (TNF), initiate the tissue changes characteristic of Graves' ophthalmopathy. These antibodies stimulate the thyrotrophin receptor on thyroid follicular epithelial cells, leading to hyperplasia and increased production of the thyroid hormones triiodothyronine (T_3) and thyroxine (T_4). IL, interleukin; IFN, interferon. (Adapted from Bahn RS 2010 Graves' ophthalmology. *N Engl J Med* 362:726–738.)

FURTHER READING

Bahn RS. Graves ophthalmopathy. *N Engl J Med* 2010; 362:726–738.

retro-orbital tissue with similar immunoreactivity to the TSH receptor.

Eye disease is a manifestation of Graves' disease and can occur in patients who may be hyperthyroid, euthyroid or hypothyroid. Thyroid dysfunction and ophthalmopathy usually occur within two years of each other although sometimes a gap of many years is seen. TSH receptor antibodies are almost invariably found in the serum but their role in the pathogenesis is becoming clearer (Fig. 19.19). Ophthalmopathy is more common and more severe in smokers.

Clinical features

The clinical appearances are characteristic (Fig. 19.18) but thyroid eye disease demonstrates a wide range of severity. A high proportion of people with Graves' disease notice some soreness, painful watering or prominence of the eyes, and the 'stare' of lid retraction is relatively common. More severe proptosis occurs in a minority of cases, and limitation and discomfort of eye movement and visual impairment due to optic nerve compression are relatively uncommon. Proptosis and lid retraction may limit the ability to close the eyes completely so that corneal damage may occur. There is peri-orbital oedema and conjunctival oedema and inflammation.

Eye manifestations do not parallel the degree of biochemical thyrotoxicosis, or the need for antithyroid therapy, but exacerbation of eye disease is more common after radio-iodine treatment (15% versus 3% on antithyroid drugs). Sight is threatened in only 5–10% of cases, but the discomfort and cosmetic problems cause great patient anxiety.

Investigations

Few investigations are necessary if the appearances are characteristic and bilateral. TSH, fT_3 and fT_4 are measured.

There are a variety of grading systems but none is universally accepted. It is essential to clearly document eye movements and the degree of oedema and inflammation. The exophthalmos should be measured to allow progress to be monitored. MRI or CT of the orbits will exclude retro-orbital space-occupying lesions, show enlarged muscles and oedema, and may show a taut optic nerve due to raised intra-orbital pressure.

Treatment

If the patient is thyrotoxic this should be treated, but this will not directly result in an improvement of the ophthalmopathy, and hypothyroidism must be avoided as it may exacerbate the eye problem. Smoking should be stopped. Treatment of the eyes may be either local or systemic, and always requires close liaison between specialist endocrinologist and ophthalmologist:

- **Methylcellulose or hypromellose eyedrops** are given to aid lubrication and improve comfort.
- **Some patients gain relief by sleeping upright.**
- **The eyelids can be taped to ensure closure at night.**
- **Systemic steroids** (prednisolone 30–120 mg daily) usually reduce inflammation if more severe symptoms are present. Pulse intravenous methylprednisolone may be used initially and is more rapidly effective in severe cases.
- **Surgical decompression of the orbit(s)** may be required, particularly if pressure of orbital contents on the optic nerve threatens vision, and at a later, stable stage for cosmetic reasons.
- **Lid surgery** will protect the cornea if lids cannot be closed, and can be useful later for cosmetic reasons.
- **Corrective eye muscle surgery** may improve diplopia due to muscle changes, but should be deferred until the situation has been stable for 6 months and should follow any orbital decompression.
- **Irradiation of the orbits** (20 Gy in divided doses) is used in some centres. This improves inflammation and ocular motility but has little effect on proptosis and its precise role is debated.
- **Immunomodulatory agents** may produce a response in some patients when conventional treatments fail, although clinical trial evidence is inconsistent.

Goitre (thyroid enlargement)

Goitre is more common in women than in men and may be either physiological or pathological.

FURTHER READING

Bartalena L et al. Consensus statement of the European Group on Graves' Orbitopathy (EUGOGO) on management of Graves' orbitopathy. *Thyroid* 2008; 18:333–346.

Clinical features

Goitres are present on examination in up to 9% of the population. Most commonly a goitre is noticed as a cosmetic defect by the patient or by friends or relatives. The majority are painless, but pain or discomfort can occur in acute varieties. Large goitres can produce dysphagia and difficulty in breathing, implying oesophageal or tracheal compression.

A small goitre may be more easily visible (on swallowing) than palpable. Clinical examination should record the size, shape, consistency and mobility of the gland as well as whether its lower margin can be demarcated (thus implying the absence of retrosternal extension). A bruit may be present. Associated lymph nodes should be sought and the tracheal position determined if possible. Examination should never omit an assessment of the patient's clinical thyroid status.

Specific enquiry should be made about any medication, especially iodine-containing preparations, and possible exposure to radiation.

Particular points of note are:

- Puberty and pregnancy may produce a diffuse increase in size of the thyroid.
- Pain in a goitre may be caused by thyroiditis, bleeding into a cyst or (rarely) a thyroid tumour.
- Excessive doses of carbimazole or PTU will induce goitre.
- Iodine deficiency and dysmorphogenesis (see above) can also cause goitre.

Assessment

There are two major aspects of any goitre: its pathological nature and the patient's thyroid status.

The nature can often be judged clinically. Goitres (Table 19.17) are usually separable into diffuse and nodular types, the causes of which differ.

Diffuse goitre

Simple goitre

In this instance, no clear cause is found for enlargement of the thyroid, which is usually smooth and soft. It may be associated with thyroid growth-stimulating antibodies.

Autoimmune thyroid disease

Hashimoto's thyroiditis and thyrotoxicosis are both associated with firm diffuse goitre of variable size. A bruit is often present in thyrotoxicosis.

Thyroiditis

Acute tenderness in a diffuse swelling, sometimes with severe pain, is suggestive of an acute viral thyroiditis (de

Quervain's). It may produce transient clinical hyperthyroidism with an increase in serum T_4 (see p. 964).

Nodular goitres

Multinodular goitre

Most common is the multinodular goitre, especially in older patients. The patient is usually euthyroid but may be hyperthyroid or borderline with suppressed TSH levels but normal free T_4 and T_3 . Multinodular goitre is the most common cause of tracheal and/or oesophageal compression and can cause laryngeal nerve palsy. It may also extend retrosternally.

The classical 'multinodular goitre' is usually readily apparent clinically, but it should be noted that modern, high-resolution ultrasound frequently reports multiple small nodules in glands which are clinically diffusely enlarged and associated with autoimmune thyroid disease. These nodules are also found in up to 40% of the normal population.

Solitary nodular goitre

Such a goitre presents a difficult problem of diagnosis. Malignancy should be of concern in any solitary nodule – however, the majority of such nodules are cystic or benign and, indeed, may simply be the largest nodule of a multinodular goitre. The diagnostic challenge is to identify the small minority of malignant nodules, which require surgery, from the majority of benign nodules, which do not. Sometimes a history of rapid enlargement, associated lymph nodes or pain may suggest an aggressive malignancy, but most thyroid cancers are painless and slow-growing so that investigations are paramount. Risk factors for malignancy include previous irradiation, longstanding iodine deficiency and occasional familial cases.

Solitary toxic nodules are quite uncommon and may be associated with T_3 toxicosis.

Fibrotic goitre (Riedel's thyroiditis)

Fibrotic goitre is a rare condition, usually producing a 'woody' gland. It is associated with other midline fibrosis and is often difficult to distinguish from carcinoma, being irregular and hard. Clinical clues include systemic symptoms of inflammation and elevation in inflammatory markers; it has been shown to be an IgG₄-related disease.

Malignancy

In addition to thyroid carcinomas (see below), the thyroid is rarely the site of a metastatic deposit or the site of origin of a lymphoma.

Investigations

Clinical findings will dictate appropriate initial tests:

- **Thyroid function tests:** TSH plus free T_4 or T_3 (see Table 19.7).
- **Thyroid antibodies:** to exclude autoimmune aetiology.
- **Ultrasound.** Ultrasound with high resolution is a sensitive method for delineating nodules and can demonstrate whether they are cystic or solid. In addition, a multinodular goitre may be demonstrated when only a single nodule is palpable. Unfortunately, even cystic lesions can be malignant and thyroid tumours may arise within a multinodular goitre; therefore fine-needle aspiration (see below) is often required and performed under ultrasound control at the same time as the scan.
- **Chest and thoracic inlet X-rays or CT scan** to detect tracheal compression and large retrosternal extensions in people with very large goitre or clinical symptoms.

Tc scan showing multinodular goitre, with predominant involvement of the left lobe of the thyroid (anterior view with arrowed anatomical marker at the sternal notch).

Retrosternal goitre showing deviation and compression of trachea on a CT scan.

Table 19.17 Goitre: causes and types

Diffuse	Nodular
Simple Physiological (puberty, pregnancy)	Multinodular goitre Solitary nodular Fibrotic (Reidel's thyroiditis)
Autoimmune Graves' disease Hashimoto's disease	Cysts
Thyroiditis Acute (de Quervain's thyroiditis)	Tumours Adenomas Carcinoma Lymphomas
Iodine deficiency (endemic goitre)	Miscellaneous Sarcoidosis Tuberculosis
Dyshormonogenesis Goitrogens (e.g. sulfonylureas)	

- **Fine-needle aspiration (FNA).** In people with a solitary nodule or a dominant nodule in a multinodular goitre, there is a 5% chance of malignancy; in view of this, FNA should be performed in the outpatient clinic or during ultrasound. Cytology in expert hands can usually differentiate the suspicious or definitely malignant nodule.

FNA reduces the necessity for surgery, but there is a 5% false-negative rate, which must be borne in mind (and the patient appropriately counselled). Continued observation is required when an isolated thyroid nodule is assumed to be benign without excision.

- **Thyroid scan** (^{99m}Tc , ^{125}I or ^{131}I) can be useful to distinguish between functioning (hot) or non-functioning (cold) nodules. A hot nodule is only rarely malignant; however, a cold nodule is malignant in only 10% of cases and FNA has largely replaced isotope scans in the diagnosis of thyroid nodules.

Treatment

Euthyroid goitre

Many goitres are small, cause no symptoms and can be observed (including self-monitoring by the patient in the long term). In particular, during puberty and pregnancy a goitre associated with euthyroidism rarely requires intervention and the patient can be reassured that spontaneous resolution is likely. Indications for surgical intervention are:

- **The possibility of malignancy.** A positive or suspicious FNA makes surgery mandatory and surgery may be necessary if doubt persists even in the presence of a negative FNA (especially if the patient is concerned by the false-negative rate).
- **Pressure symptoms on the trachea or, more rarely, oesophagus.** The possibility of retrosternal extension should be excluded.
- **Cosmetic reasons.** A large goitre is often a considerable anxiety to the patient even though functionally and anatomically benign.

Radioactive iodine has also been advocated for the treatment of euthyroid goitre, particularly when surgery is an unattractive option.

Toxic nodule

This is initially with antithyroid drugs but surgery or radioiodine is often required.

Thyroid carcinoma

Types of thyroid carcinoma, their characteristics and treatment are listed in Table 19.18. While not common, these tumours are responsible for 400 deaths annually in the UK and an annual incidence of 30 000 cases in the USA. Over 75% occur in women. In 90% of cases they present as

thyroid nodules (see above), but occasionally with cervical lymphadenopathy (about 5%), or with lung, cerebral, hepatic or bone metastases.

Carcinomas derived from thyroid epithelium may be papillary or follicular (differentiated) or anaplastic (undifferentiated). Medullary carcinomas (about 5% of all thyroid cancers) arise from the calcitonin-producing C cells. The pathogenesis of thyroid epithelial carcinomas is not understood except for occasional familial papillary carcinoma and those cases related to previous head and neck irradiation or ingestion of radioactive iodine (e.g. post-Chernobyl). These tumours are minimally active hormonally and are extremely rarely associated with hyperthyroidism; over 90%, however, secrete thyroglobulin, which can therefore act as a tumour marker after thyroid ablation.

Papillary and follicular carcinomas

The primary treatment is surgical, normally total or near-total thyroidectomy for local disease. Regional or more extensive neck dissection is needed where there is local nodal spread or involvement of local structures.

Most tumours will take up iodine, and UK and other guidelines currently recommend radioactive iodine (RAI) ablation of residual thyroid tissue postoperatively for most people with differentiated thyroid cancer. After ablation of normal thyroid in this way, RAI may be used to localize residual disease (scanning using low doses) or to treat it (using high doses: 5.5–7.5 GBq). When recurrence does occur, local invasion and lymph node involvement is most common, and lungs and bone are the most common sites of distant metastases.

To minimize risk of recurrence patients are treated with suppressive doses of levothyroxine (sufficient to suppress TSH levels below the normal range). Patient progress is monitored both clinically and biochemically using serum thyroglobulin levels as a tumour marker. The measurement of thyroglobulin is most sensitive when TSH is high but this requires the withdrawal of levothyroxine therapy. Recombinant TSH (thyrotropin alfa, rhTSH) 900 μg (2 doses over 48 hours) is used to stimulate thyroglobulin without stopping thyroxine therapy. Detectable thyroglobulin suggests recurrence, in which case whole body ^{131}I scanning is required. Unfortunately the presence of anti-thyroglobulin antibodies can make the assay unreliable.

The prognosis is extremely good when differentiated thyroid cancer is excised while confined to the thyroid gland, and the specific therapies available lead to a relatively good prognosis even in the presence of metastases at diagnosis. Accepted markers of high risk include greater age (>40 years), larger primary tumour size (>4 cm) and macroscopic invasion of capsule and surrounding tissues.

Anaplastic carcinomas and lymphoma

These do not respond to radioactive iodine, and external radiotherapy produces only a brief respite.

Table 19.18 Types of thyroid malignancy

Cell type	Frequency	Behaviour	Spread	Prognosis
Papillary	70%	Occurs in young people	Local, sometimes lung/bone secondaries	Good, especially in young
Follicular	20%	More common in females	Metastases to lung/bone	Good if resectable
Anaplastic	<5%	Aggressive	Locally invasive	Very poor
Lymphoma	2%	Variable		Sometimes responsive to radiotherapy
Medullary cell	5%	Often familial	Local and metastases	Poor, but indolent course

Medullary carcinoma

Medullary carcinoma (MTC) is a neuroendocrine tumour of the calcitonin-producing C cells of the thyroid. This condition is often associated with multiple endocrine neoplasia type 2 (MEN 2, see p. 998) – approximately 25% of patients diagnosed with MTC have a mutation of the *RET* proto-oncogene, although the other manifestations of MEN 2 may be absent, hence the importance of genetic counselling and family screening. People with MEN2 mutations are advised to have a prophylactic thyroidectomy as early as 5 years of age to prevent the development of MTC.

Total thyroidectomy and wide lymph node clearance is usually indicated in MTC. Local invasion or metastasis is frequent, and the tumour responds poorly to treatment, although progression is often slow.

REPRODUCTION AND SEX

Terminology in reproductive medicine is shown in Box 19.5.

Embryology

Up to 8 weeks of gestation the sexes share a common development, with a primitive genital tract including the Wolffian and Müllerian ducts. There are additionally a primitive perineum and primitive gonads.

- In the presence of a Y chromosome, the potential testis develops while the ovary regresses.
- In the absence of a Y chromosome, the potential ovary develops and related ducts form a uterus and the upper vagina.

Production of Müllerian inhibitory factor from the early 'testis' produces atrophy of the Müllerian duct, while, under the influence of testosterone and dihydrotestosterone, the Wolffian duct differentiates into an epididymis, vas deferens, seminal vesicles and prostate. Androgens induce transformation of the perineum to include a penis, penile urethra and

scrotum containing the testes, which descend in response to androgenic stimulation. At birth, testicular volume is 0.5–1 mL.

Physiology

The male

An outline of the hypothalamic-pituitary-gonadal axis is shown in Figure 19.20.

1. Pulses of gonadotrophin-releasing hormone (GnRH) are released from the hypothalamus and stimulate LH

Box 19.5 Definitions in reproductive medicine

Erectile dysfunction	Inability of the male to achieve or sustain an erection adequate for satisfactory intercourse
Azoospermia	Absence of sperm in the ejaculate
Oligospermia	Reduced numbers of sperm in the ejaculate
Libido	Sexual interest or desire; often difficult to assess and is greatly affected by stress, tiredness and psychological factors
Menarche	Age at first period
Primary amenorrhoea	Failure to begin spontaneous menstruation by age 16
Secondary amenorrhoea	Absence of menstruation for 3 months in a woman who has previously had cycles
Oligomenorrhoea	Irregular long cycles; often used for any length of cycle above 32 days
Dyspareunia	Pain or discomfort in the female during intercourse
Menstruation	Onset of spontaneous (usually regular) uterine bleeding in the female
Virilization	Occurrence of male secondary sexual characteristics in the female

Reproduction and sex

a Male

b Female

Figure 19.20 Male and female hypothalamic-pituitary-gonadal axes. LH and FSH are secreted in pulses in response to hypothalamic GnRH and have differential effects on the gonads (see text). Testosterone and oestrogens have multiple peripheral effects and exert negative feedback on LH secretion. Inhibin exerts negative feedback on FSH secretion.

and FSH release from the pituitary. LH and FSH are composed of two glycoprotein chains (α and β subunits). The α subunits are identical and are shared with TSH, whilst the β subunit confers specific biological activity.

2. LH stimulates testosterone production from Leydig cells of the testis.
3. Testosterone acts via nuclear androgen receptors which interact with coregulatory proteins to produce the appropriate tissue responses: male secondary sexual characteristics, anabolism and the maintenance of libido. It also acts locally within the testis to aid spermatogenesis. Testosterone circulates largely bound to sex hormone-binding globulin (SHBG) (see p. 942). Testosterone feeds back on the hypothalamus/pituitary to inhibit GnRH secretion.
4. FSH stimulates the Sertoli cells in the seminiferous tubules to produce mature sperm and the inhibins A and B.
5. Inhibin feeds back to the pituitary to decrease FSH secretion. Activin, a related peptide, counteracts inhibin.

The secondary sexual characteristics of the male. for which testosterone is necessary are the growth of pubic, axillary and facial hair, enlargement of the external genitalia, deepening of the voice, sebum secretion, muscle growth and frontal balding.

The female

Female physiology is more complex (Figs 19.20, 19.21).

1. In the adult female, higher brain centres impose a menstrual cycle of 28 days upon the activity of hypothalamic GnRH.
2. Pulses of GnRH, at about 2-hour intervals, stimulate release of pituitary LH and FSH.
3. LH stimulates ovarian androgen production by the ovarian theca cells.
4. FSH stimulates follicular development and aromatase activity (an enzyme required to convert ovarian androgens to oestrogens) in the ovarian granulosa cells. FSH also stimulates release of inhibin from ovarian stromal cells, which inhibits FSH release. Activin counteracts inhibin (Fig. 19.20).

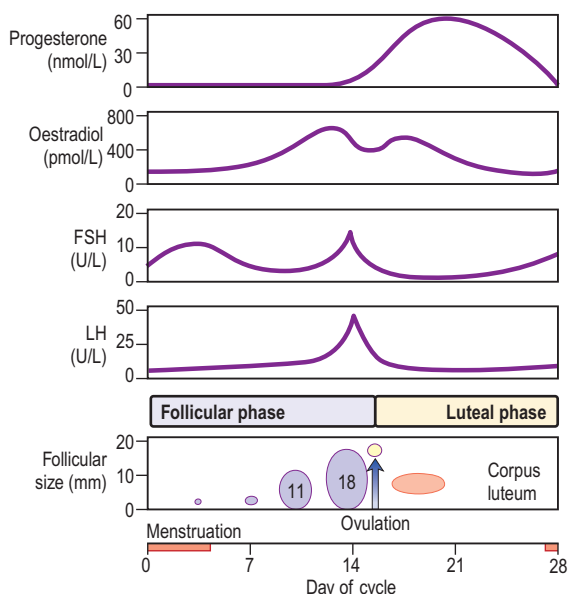

Figure 19.21 Hormonal and follicular changes during the normal menstrual cycle.

5. Although many follicles are 'recruited' for development in early folliculogenesis, by day 8–10 a 'leading' (or 'dominant') follicle is selected for development into a mature Graafian follicle.
6. Oestrogens have a double feedback action on the pituitary (Fig. 19.20). Initially they inhibit gonadotrophin secretion (negative feedback), but later high-level exposure results in increased GnRH secretion and increased LH sensitivity to GnRH (positive feedback), which leads to the mid-cycle LH surge inducing ovulation from the leading follicle (Fig. 19.21).
7. The follicle then differentiates into a corpus luteum, which secretes both progesterone and oestradiol during the second half of the cycle (luteal phase).
8. Oestrogen initially and then progesterone cause uterine endometrial proliferation in preparation for possible implantation; if implantation does not occur, the corpus luteum regresses and progesterone secretion and inhibin levels fall so that the endometrium is shed (menstruation) allowing increased GnRH and FSH secretion.
9. If implantation and pregnancy follow, human chorionic gonadotrophin (HCG) production from the trophoblast maintains corpus luteum function until 10–12 weeks of gestation, by which time the placenta will be making sufficient oestrogen and progesterone to support itself.

Secondary sexual characteristics of the female. These are induced by oestrogens, especially development of the breast and nipples, vaginal and vulval growth and pubic hair development. Oestrogens also induce growth and maturation of the uterus and fallopian tubes. They circulate largely bound to SHBG.

Puberty

The mechanisms initiating puberty are poorly understood but are thought to result from withdrawal of central inhibition of GnRH release. Environmental and physical factors are involved in the timing of puberty (including body fat changes, physical exercise) as well as genetic factors (e.g. a G protein-coupled receptor gene, *GPR54*) required for pubertal maturation. Kisspeptin is the endogenous ligand for kisspeptin receptor KISSIR formerly known as *GPR54* and this peptide is believed to play a crucial role in the regulation of GnRH production and the timing of puberty.

LH and FSH are both low in the prepubertal child. In early puberty, FSH begins to rise first, initially in nocturnal pulses; this is followed by a rise in LH with a subsequent increase in testosterone/oestrogen levels. The milestones of puberty in the two sexes are shown in Figure 19.22.

In boys, pubertal changes begin at between 10 and 14 years and are complete at between 15 and 17 years. The genitalia develop, testes enlarge and the area of pubic hair increases. Peak height velocity is reached between ages 12 and 17 years during stage 4 of testicular development. Full spermatogenesis occurs comparatively late.

In girls, events start a year earlier. Breast bud enlargement begins at age 9–13 years and continues to 12–18 years. Pubic hair growth commences at ages 9–14 years and is completed at 12–16 years. Menarche occurs relatively late (age 11–15 years) but peak height velocity is reached earlier (at age 10–13 years), and growth is completed much earlier than in boys.

Carel JC, Léger J. Precocious puberty. *N Engl J Med* 2008; 358:2366–2377.

Figure 19.22 The age of development of features of puberty. Stages and testicular size show mean ages, and all vary considerably between individuals. The same is true of height spurt, shown here in relation to other data. Numbers 2–5 indicate stages of development.

Precocious puberty

Development of secondary sexual characteristics, or menarche in girls, at or before the age of 9 years is premature. All cases require assessment by a paediatric endocrinologist.

Idiopathic (true) precocity is most common in girls and very rare in boys. This is a diagnosis of exclusion. With no apparent cause for premature breast or pubic hair development, and an early growth spurt, it may be normal and may run in families. Treatment with long-acting GnRH analogues (given by nasal spray, by subcutaneous injection or by implant) causes suppression of gonadotrophin release via downregulation of the receptor – and therefore reduced sex hormone production – and is moderately effective; cyproterone acetate, an antiandrogen with progestational activity, is also used.

Other forms of precocity include:

- **Cerebral precocity.** Many causes of hypothalamic disease, especially tumours, present in this way. In boys this must be rigorously excluded. MRI scan is almost always indicated to exclude this diagnosis.
- **McCune–Albright syndrome.** This usually occurs in girls, with precocity, polyostotic fibrous dysplasia and skin pigmentation (café-au-lait). See also page 998.
- **Premature thelarche.** This is early breast development alone, usually transient, at age 2–4 years. It may regress or persist until puberty. There is no evidence of follicular development.
- **Premature adrenarche.** This is early development of pubic hair without significant other changes, usually after the age of 5 years and more commonly in girls. It is also more common in obese children due to reduced SHBG levels leading to higher free circulating androgens. In boys with precocious adrenarche, the rare possibility of an androgen-secreting testicular tumour should be looked for if serum androgens are high and LH is suppressed.

Delayed puberty

Over 95% of children show signs of pubertal development by the age of 14 years. In its absence, investigation should begin by the age of 15 years. Causes of hypogonadism (see below) are clearly relevant but most cases represent constitutional delay.

In constitutional delay, pubertal development, bone age and stature are in parallel. A family history may confirm that other family members experienced the same delayed development, which is common in boys but very rare in girls.

In boys, a testicular volume >5 mL indicates the onset of puberty. A rising serum testosterone is an earlier clue.

In girls, the breast bud is the first sign. Ultrasound allows accurate assessment of ovarian and uterine development.

Elevated LH/FSH levels will identify a primary gonadal defect, and in other cases, GnRH (LHRH) tests can indicate the stage of early puberty.

If any progression into puberty is evident clinically, investigations are not required. When delay is great and problems are serious (e.g. severe teasing at school), low-dose short-term sex hormone therapy is used to induce puberty.

The menopause

The menopause, or cessation of periods, naturally occurs at about the age of 45–55 years. During the late 40s, FSH initially, and then LH concentrations begin to rise, probably as follicle supply diminishes. Oestrogen levels fall and the cycle becomes disrupted. Most women notice irregular scanty periods coming on over a variable period, though in some sudden amenorrhoea or menorrhagia occurs. Eventually the menopausal pattern of low oestradiol levels with grossly elevated LH and FSH levels (usually >50 and >25 U/L, respectively) is established. Premature menopause may also occur surgically, with radiotherapy to the ovaries and with ovarian disease.

Clinical features and treatment

Features of oestrogen deficiency are hot flushes (which occur in most women and can be disabling), vaginal dryness and atrophy of the breasts. There may also be symptoms of loss of libido, loss of self-esteem, nonspecific aches and pains, sleep disturbance, irritability, depression, loss of concentration and weight gain.

Women show a rapid loss of bone density in the 10 years following the menopause (osteoporosis, see p. 552) and the premenopausal protection from ischaemic heart disease disappears.

Hormone replacement therapy (HRT). Symptomatic patients should usually be treated but the previous widespread use of HRT has been thrown into doubt by a number of large prospective studies which have reported in recent years. Although scientific debate continues, the overall benefits and risks are summarized as in Box 19.6.

Absolute risks and benefits for individual women clearly depend on their background risk of that disease, and there is as yet no evidence on the relative risks of different hormone preparations or routes of administration (oral, transdermal or implant). Overall, the WHI study estimated that, over 5 years of treatment, an extra one woman in every 100 would develop an illness that would not have occurred had she not been taking HRT. However, the decision about whether or not a woman takes HRT is now very much an individual decision based on:

- the severity of the woman's menopausal symptoms
- her personal risk of conditions which may be prevented or made more likely by HRT
- individual patient choice.

Box 19.6 Risks and benefits of hormone replacement therapy^a

Potential benefits

- *Symptomatic improvement in most menopausal symptoms* for the majority of women. Oestrogen-deficient symptoms respond well to oestrogen replacement, the vaguer general symptoms may or may not improve. Vaginal symptoms also respond to local oestrogen preparations.
- *Protection against fractures of wrist, spine and hip, secondary to osteoporosis* (~24–33%) (see p. 552), owing to protection of predominantly trabecular bone (p. 549). However, this is not a recommended indication for therapy.
- Significant reduction in the risk of large bowel cancer (~33%).
- *Possible increase in general wellbeing*, although hopes for a reduction in the incidence of Alzheimer's disease have not been confirmed.

Potential risks

- *Significant increase in the risk of breast cancer* (+26%), but no change in breast cancer mortality. This is primarily a risk of combined oestrogen-progesterone HRT. Some studies suggest that breast cancers diagnosed on HRT are easier to treat effectively.
- *Significant increase in the risk of endometrial cancer* when unopposed oestrogens are given to women with a uterus.
- Significant increase in the risk of ischaemic heart disease (+29%) and stroke (+41%).
- Inconvenience of withdrawal bleeds, unless a hysterectomy has been performed or regimens used which include continuous oestrogen and progesterone.

^aPercentages are from the Women's Health Initiative (WHI) study of 16600 women.

Box 19.7 Sexual and menstrual disorders

History

- Menstruation – timing of bleeding and cycle
- Relationship of symptoms to cycle
- Breasts (tenderness/galactorrhoea)
- Hirsutism and acne
- Libido and potency
- Problems with intercourse
- Past fertility and future plans

Physical signs

- Evidence of systemic disease
- Secondary sexual characteristics
- Extent/distribution of hair
- Genital size (testes, ovaries, uterus)
- Clitoromegaly
- Breast development, gynaecomastia
- Galactorrhoea

The ageing male

In the male, there is no sudden 'change of life'. However, there is a progressive loss in sexual function with reduction in morning erections and frequency of intercourse.

The age of onset varies widely. Typically, overall testicular volume diminishes and sex hormone-binding globulin (SHBG) and gonadotrophin levels gradually rise, but other men present with low or borderline testosterone without elevation of LH/FSH. Low testosterone certainly increases the risk of osteoporosis and in some studies is associated with increased cardiovascular risk, but it remains unclear to what extent general symptoms of lack of energy, drive, muscle strength and general wellbeing may relate to these hormonal changes. Loss of libido and erectile dysfunction are common symptoms even when hormones are normal, and long-term outcome studies of testosterone replacement are still awaited. Therefore, the decision to offer testosterone replacement to an ageing male is currently based on full clinical and biochemical assessment and full discussion of potential risks (including prostate disease) as well as benefits. If testosterone is unequivocally low (<7 pmol/L) most authorities would recommend replacement. However, few would treat if testosterone is >12 pmol/L with normal LH/FSH. Clinically, a large proportion of cases are in the borderline range (7–12 pmol/L), which can lead to difficulties in reaching a firm diagnosis.

Clinical features of disorders of sex and reproduction

A detailed history and examination of all systems is required (Box 19.7). A man having regular satisfactory intercourse or a woman with regular ovulatory periods is most unlikely to have significant endocrine disease, assuming the history is accurate.

Tests of gonadal function

Much can be deduced from basal measurements of the gonadotrophins, oestrogens/testosterone and prolactin:

- Low testosterone or oestradiol with high gonadotrophins indicates primary gonadal disease.
- Low levels of testosterone/oestradiol with low or normal LH/FSH imply hypothalamic-pituitary disease.
- Demonstration of ovulation (by measurement of luteal phase serum progesterone and/or by serial ovarian ultrasound in the follicular phase) or a healthy sperm count (20–200 million/mL, >60% grade I motility and

FURTHER READING

Bremner WJ. Testosterone deficiency and replacement in older men. *N Engl J Med* 2010; 363:189–191.

HRT is not recommended purely for prevention of postmenopausal osteoporosis in the absence of menopausal symptoms.

Symptomatic treatment is the main indication with the lowest effective dose given for short-term rather than long-term treatment.

Selective oestrogen receptor modulators, SERMs (e.g. raloxifene), offer a potentially attractive combination of positive oestrogen effects on bone and cardiovascular system with no effects on oestrogen receptors of uterus and breast and possible reduction in breast cancer incidence; long-term outcome studies, however, are still awaited.

Premature menopause and ovarian failure

The most common cause of premature menopause in women (before age 40) is ovarian failure. This may be autoimmune, and is rarely caused by identifiable genetic causes such as the fragile X pre-mutation but is most commonly of unknown aetiology, although often familial. Repeat LH/FSH levels are necessary before giving a diagnosis of premature menopause because of the psychological impact of this diagnosis and the possibility that a single elevation of LH/FSH might simply be the mid-cycle ovulatory surge. Bilateral oophorectomy and some chemotherapy regimens cause the same oestrogen deficiency state.

Treatment. HRT should almost always be given, as the risk of osteoporosis and other conditions related to oestrogen deficiency almost always outweighs the risks of HRT at this younger age. HRT may still also be actively recommended when normal menopause occurs relatively early (e.g. before the age of 50).

Table 19.19 Tests of gonadal function	
Test	Uses/comments
Male	
Basal testosterone	Normal levels exclude hypogonadism
Sperm count	Normal count excludes deficiency Motility and abnormal sperm forms should be noted
Female	
Basal oestradiol	Normal levels exclude hypogonadism
Luteal phase progesterone (days 18–24 of cycle)	If >30 nmol/L, suggests ovulation
Ultrasound of ovaries	To confirm ovulation
Both sexes	
Basal LH/FSH	Demonstrates state of feedback system for hormone production (LH) and germ cell production (FSH)
HCG test (testosterone or oestradiol measured)	Response shows potential of ovary or testis; failure demonstrates primary gonadal problem
Clomifene test (LH and FSH measured)	Tests hypothalamic negative feedback system; clomifene is oestrogen antagonist and causes LH/FSH to rise
LHRH test (rarely used)	Shows adequacy (or otherwise) of LH and FSH stores in pituitary

<20% abnormal forms), provide absolute confirmation of normal female or male reproductive endocrinology, but these tests are not always essential.

- Pregnancy provides complete demonstration of normal male and female function.
- Hyperprolactinaemia can be confirmed or excluded by direct measurement. Levels may increase with stress; if this is suspected, a cannula should be inserted and samples taken through it 30 min later.

More detailed tests are indicated in Table 19.19.

Disorders in the male

Hypogonadism

Clinical features

Male hypogonadism may be a presenting complaint or an incidental finding, such as during investigation for subfertility. The testes may be small and soft and there may be gynae-comastia. Except with subfertility, the symptoms are usually of androgen deficiency, primarily poor libido, erectile dysfunction and loss of secondary sexual hair (Table 19.20) rather than deficiency of semen production. Sperm makes up only a very small proportion of seminal fluid volume; most is prostatic fluid.

Causes of male hypogonadism are shown in Table 19.21.

Investigations

Testicular disease may be immediately apparent but basal levels of testosterone, LH and FSH should be measured. These will allow the distinction between primary gonadal (testicular) failure and hypothalamic-pituitary disease to be made. Depending on the causes, semen analysis, chromosomal analysis (e.g. to exclude Klinefelter's syndrome) and bone age estimation are required.

Table 19.20 Effects of androgens and consequences of androgen deficiency in the male	
Physiological effect	Consequences of deficiency
General	
Maintenance of libido	Loss of libido
Deepening of voice	High-pitched voice (if prepubertal)
Frontotemporal balding	No temporal recession
Facial, axillary and limb hair	Decreased hair
Maintenance of erectile and ejaculatory function	Loss of erections/ejaculation
Pubic hair	
Maintenance of male pattern	Thinning and loss of pubic hair
Testes and scrotum	
Maintenance of testicular size/consistency (needs gonadotrophins as well)	Small soft testes
Rugosity of scrotum	Poorly developed penis/scrotum
Stimulation of spermatogenesis	Subfertility
Musculoskeletal	
Epiphyseal fusion	Eunuchoidism (if prepubertal)
Maintenance of muscle bulk and power	Decreased muscle bulk
Maintenance of bone mass	Osteoporosis

Table 19.21 Causes of male hypogonadism

Reduced gonadotrophins (hypothalamic-pituitary disease)
Hypopituitarism Selective gonadotrophic deficiency, Kallmann's syndrome, normosmic idiopathic hypogonadotropic hypogonadism Severe systemic illness Severe underweight
Hyperprolactinaemia
Primary gonadal disease (congenital)
Anorchia/Leydig cell agenesis Cryptorchidism (testicular maldescent) Chromosome abnormality (e.g. Klinefelter's syndrome) Enzyme defects: 5 α -reductase deficiency
Primary gonadal disease (acquired)
Testicular torsion Orchidectomy Local testicular disease Chemotherapy/radiation toxicity Orchitis (e.g. mumps) Chronic kidney disease Cirrhosis/alcohol Sickle cell disease
Androgen receptor deficiency/abnormality

In clear-cut gonadotrophin deficiency, pituitary MRI scan, prolactin levels and other pituitary function tests are needed. However, equivocal lowering of serum testosterone (7–10 nmol/L) without elevation of gonadotrophins is a relatively common biochemical finding, and is a frequent cause of referral in men with poor libido or erectile dysfunction. Such tests are compatible with mild gonadotrophin deficiency, but may also be seen in acute illness of any cause and often

Table 19.22 Androgen replacement therapy

Route	Preparation	Dose	Remarks
Dermal	Testosterone gel	50–100 mg	Rubs on Shoulders
	Testosterone patch	300 µg/24 h	Self-adhesive
Intra muscular.	Testosterone enanthate	250 mg every 3 weeks	Frequent injections. Painful
	Testosterone undecanoate	1000 mg every 3 months	Smooth passile; 4 mL injection
	Testosterone propionate	50–100 mg every 2–3 weekly	Very frequent injections. Short half-life
Oral	Testosterone undecanoate	1200–160 mg daily, in divided doses	Variable dose, irregular absorption
Implant	Testosterone implant	600 mg every 4–5 months	Requires implant procedure Scarring, infection

simply represent the lower end of the normal range or the normal circadian rhythm of testosterone when bloods are checked in afternoon or evening surges. 'Anabolic' steroid (i.e. androgen) abuse causes similar biochemical findings, and is likely if the patient appears well virilized. People with obesity and diabetes mellitus commonly have low circulating SHBG levels associated with insulin resistance and therefore low total testosterone levels.

A therapeutic trial of testosterone replacement is often justified and forms part of the investigation in some patients; full pituitary evaluation may be required in such cases to exclude other pituitary disease.

Treatment

The cause of hypogonadism can rarely be reversed and testosterone replacement therapy should be commenced to control current symptoms and prevent osteoporosis in the long term. Replacement is usually given by transdermal gel or by intramuscular injection (Table 19.22). In gonadotrophin deficiency LH and FSH (purified or synthetic) or pulsatile GnRH may be used when fertility is required.

Special instances of hypogonadism

Cryptorchidism

Cryptorchidism (or undescended testes) is usually treated by surgical exploration and orchidopexy in early childhood. After that age, the germinal epithelium is increasingly at risk, and lack of descent by puberty is associated with subfertility. A short trial of HCG occasionally induces descent: an HCG test with a testosterone response 72 h later excludes anorchia. Intra-abdominal testes have an increased risk of developing malignancy; if presentation is after puberty, orchidectomy is advised. Patients may present in adulthood with primary testicular failure (due to the testicular damage before or during surgery) or gonadotrophin deficiency (presumably the cause of maldescent initially).

Klinefelter's syndrome

Klinefelter's syndrome is a common congenital abnormality, affecting 1 in 1000 males. It is a chromosomal disorder (47XXY and variants, e.g. 46XY/47XXY mosaicism), i.e. a male with an extra X chromosome. There is both a loss of Leydig cells and seminiferous tubular dysgenesis. Patients usually present in adolescence with poor sexual development, small or undescended testes, gynaecomastia or infertility. In 47XXY there is long leg length with tall stature – the androgen deficiency leads to lack of epiphyseal closure in puberty. Patients occasionally have behavioural problems and learning difficulties. There is also a predisposition to diabetes mellitus, breast cancer, emphysema and bronchiectasis; these are all unrelated to the testosterone deficiency.

Clinical examination shows a wide spectrum of features with small pea-sized but firm testes, usually gynaecomastia

and other signs of *androgen deficiency*. Some patients have a normal puberty and may present later with infertility. Confirmation is by chromosomal analysis. Treatment is androgen replacement therapy unless testosterone levels are normal. No treatment is possible for the abnormal seminiferous tubules and infertility.

Kallmann's syndrome

This is isolated GnRH deficiency. It is associated with decreased or absent sense of smell (anosmia), and sometimes with other bony (cleft palate), renal and cerebral abnormalities (e.g. colour blindness). It is often familial and is usually X-linked, resulting from a mutation in the *KAL1* gene which encodes anosmin-1 (producing loss of smell); one sex-linked form is due to an abnormality of a cell adhesion molecule. Management is that of secondary hypogonadism (see p. 976). Fertility is possible.

Normosmic idiopathic hypogonadotropic hypogonadism

This refers to isolated GnRH deficiency in the absence of anosmia. Known mutations account for less than 15% of normosmic idiopathic hypogonadotropic hypogonadism (nIHH). Mutations include the *KISS1* gene which codes for kisspeptin, the protein which acts on GPR54 receptor, and the *FGFR1* gene.

Oligospermia or azoospermia

These may be secondary to gonadotrophin deficiency and can be corrected by gonadotrophin therapy. More often they result from primary testicular diseases, in which case they are rarely treatable.

Azoospermia with normal testicular size and low FSH levels suggests a vas deferens block, which is sometimes reversible by surgical intervention.

Lack of libido and erectile dysfunction

Lack of libido is a loss of sexual desire; erectile dysfunction (ED) is inability to achieve or maintain erection; they may occur together or separately, and each can precipitate the other. Both are common symptoms in hypogonadism, but most people with either symptom have normal hormones and many have no definable organic cause. ED may be psychological, neurogenic, vascular, endocrine or related to drugs, and often includes contributions from several causes. Vascular disease is a common aetiology, especially in smokers, and is often associated with vascular problems elsewhere. Autonomic neuropathy, most commonly from diabetes mellitus, is a common contributory cause (see p. 1025) and many drugs produce ED. The endocrine causes are those of hypogonadism (see above) and can be excluded by normal testosterone, gonadotrophin and prolactin levels. The

Table 19.23 Causes of gynaecomastia

Physiological	Drugs
Neonatal	Oestrogenic:
Pubertal	Oestrogens
Old age	Digoxin
Hyperthyroidism	Cannabis
Hyperprolactinaemia	Diamorphine
Renal disease	Antiandrogens:
Liver disease	Spironolactone
Hypogonadism (see Table 19.21)	Cimetidine
Oestrogen-producing tumours (testis, adrenal)	Cyproterone
HCG-producing tumours (testis, lung)	Others:
Starvation/refeeding	Gonadotrophins
Carcinoma of breast	Cytotoxics

presence of nocturnal emissions and frequent satisfactory morning erections make endocrine disease unlikely.

Psychogenic erectile dysfunction is frequently a diagnosis of exclusion, though complex tests of penile vasculature and function are available in some centres.

Treatment. Offending drugs should be stopped. Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil) which increase penile blood flow (see p. 1027) are first choice for therapy. Other treatments include apomorphine, intracavernosal injections of alprostadil, papaverine or phen-tolamine, vacuum expanders and penile implants.

If no organic disease is found, or if there is clear evidence of psychological problems, the couple should receive psychosexual counselling.

Gynaecomastia

Gynaecomastia is development of breast tissue in the male. Causes are shown in Table 19.23. It is due to an imbalance between free oestrogen and free androgen effects on breast tissue.

Pubertal gynaecomastia occurs in perhaps 50% of normal boys, often asymmetrically. It usually resolves spontaneously within 6–18 months, but after this duration may require surgical removal, as fibrous tissue will have been laid down. The cause is thought to be relative oestrogen excess, and the oestrogen antagonist tamoxifen is occasionally helpful.

Gynaecomastia in the older male requires a full assessment to exclude potentially serious underlying disease, such as bronchial carcinoma and testicular tumours (e.g. Leydig cell tumour). However, aromatase activity (p. 972) increases with age and may be the cause of gynaecomastia in this group. Aromatase is an enzyme of the cytochrome P450 family and converts androgens to produce oestrogens. Drug effects are common (especially digoxin and spironolactone), and once these and significant liver disease are excluded most cases have no definable cause. Surgery is occasionally necessary.

Disorders in the female

Hypogonadism

Impaired ovarian function, whether primary or secondary, will lead both to oestrogen deficiency and abnormalities of the menstrual cycle. The latter is very sensitive to disruption, cycles becoming anovulatory and irregular before disappearing altogether. Symptoms will depend on the age at which the failure develops. Thus, before puberty, primary

Table 19.24 Effects of oestrogens and consequences of oestrogen deficiency

Physiological effect	Consequence of deficiency

Box 19.8 Clinical assessment of amenorrhoea

History

- ? Pregnant
- Date of onset
- Age of menarche, if any
- Sudden or gradual onset
- General health
- Weight, absolute and changes in recent past
- Stress (job, lifestyle, exams, relationships)
- Excessive exercise
- Drugs
- Hirsutism, acne, virilization
- Headaches/visual symptoms
- Sense of smell
- Past history of pregnancies
- Past history of gynaecological surgery

Examination

- General health
- Body shape and skeletal abnormalities
- Weight and height
- Hirsutism and acne
- Evidence of virilization
- Maturity of secondary sexual characteristics
- Galactorrhoea
- Normality of vagina, cervix and uterus

amenorrhoea will occur, possibly with delayed puberty; if after puberty, secondary amenorrhoea and hypogonadism will result.

Oestrogen deficiency

The physiological effects of oestrogens and symptoms/signs of deficiency are shown in Table 19.24.

Amenorrhoea

Absence of periods or markedly irregular infrequent periods (oligomenorrhoea) is the commonest presentation of female gonadal disease. The clinical assessment of such patients is shown in Box 19.8, and common causes are listed in Table 19.25.

Gordon CM. Functional hypothalamic amenorrhea. *N Engl J Med* 2010; 363:365–371.

Polycystic ovary syndrome

Polycystic ovary syndrome is the most common cause of oligomenorrhoea and amenorrhoea (see below).

Weight-related amenorrhoea

A minimum body weight is necessary for regular menstruation. While anorexia nervosa is the extreme form of weight loss (see p. 1222), amenorrhoea is common and may be seen at weights within the 'normal' range. The biochemistry is indistinguishable from gonadotrophin deficiency and some patients have additional mild endocrine disease (e.g. polycystic ovarian disease). It is possible that alterations in leptin levels are responsible for the hypothalamic dysfunction seen in this situation. Restoration of body weight to above the 50th centile for height is usually effective in restoring menstruation, but in the many cases where this cannot be achieved then oestrogen replacement is necessary. Similar problems occur with intensive physical training in athletes and dancers.

Hypothalamic amenorrhoea

Amenorrhoea with low oestrogen and gonadotrophins in the absence of organic pituitary disease, weight loss or excessive exercise is described as hypothalamic amenorrhoea. This may be related to 'stress', to previous weight loss or stopping the contraceptive pill, but some patients appear to have defective cycling mechanisms without apparent explanation.

Hypothyroidism

Oligomenorrhoea and amenorrhoea are frequent findings in severe hypothyroidism in young women.

Other

Other causes include pregnancy. Genital tract abnormalities, such as an imperforate hymen, cause primary amenorrhoea.

Severe illness, even in the absence of weight loss, can lead to amenorrhoea.

Turner's syndrome (p. 983) is a cause of primary amenorrhoea. The phenotype is female with female external

genitalia. There is gonadal dysgenesis with streak ovaries. Features include short stature, webbing of the neck (up to 40%), a wide carrying angle of the elbows, high arched palate and low-set ears. These patients also have an increased incidence of autoimmune disease (2%), bicuspid aortic valves, aortic coarctation and dissection and coronary artery disease, hypertension, type 2 diabetes, horseshoe kidneys, lymphoedema, reduced bone density, hearing problems and inflammatory bowel disease (0.3%).

Investigations

Basal levels of FSH, LH, oestrogen and prolactin allow initial distinction between primary gonadal and hypothalamic–pituitary causes (Table 19.25). Ovarian biopsy may occasionally be necessary to confirm the diagnosis of primary ovarian failure, although elevation of LH and FSH to menopausal levels is usually adequate. Subsequent investigations are shown in Table 19.25.

Treatment

Treatment is that of the cause wherever possible (e.g. hypothyroidism, low weight, stress, excessive exercise).

Primary ovarian disease is rarely treatable except in the rare condition of ‘resistant’ ovary, where high-dose gonadotrophin therapy can occasionally lead to folliculogenesis. Hyperprolactinaemia should be corrected (see below). Polycystic ovary syndrome is discussed in detail below. In all other cases oestrogen replacement is usually indicated to prevent the long-term consequences of deficiency.

Hirsutism and polycystic ovary syndrome

Normal hair versus hirsutism

The extent of normal hair growth varies between individuals, families and races, being more extensive in the Mediterranean and some Asian subcontinent populations. These normal variations in body hair, and the more extensive hair growth seen in patients complaining of hirsutism, represent a continuum from no visible hair to extensive cover with thick dark hair. It is therefore impossible to draw an absolute dividing line between ‘normal’ and ‘abnormal’ degrees of facial and body hair in the female. Soft vellus hair is normally present all over the body, and this type of hair on the face and elsewhere is ‘normal’ and is not sex hormone dependent. Hair in the beard, moustache, breast, chest, axilla, abdominal midline, pubic and thigh areas is sex hormone dependent. Any excess in the latter regions is thus a marker of increased ovarian or adrenal androgen production, most commonly polycystic ovary syndrome (PCOS) but occasionally other rarer causes.

Causes of hirsutism

Polycystic ovary syndrome. PCOS is the most common cause of hirsutism in clinical practice, affecting about 1 in 5 women worldwide. It is characterized by multiple small cysts within the ovary (Fig. 19.23) (which represent arrested follicular development) and by excess androgen production from the ovaries (and to a lesser extent from the adrenals). It was originally described in its severe form as the Stein–Leventhal syndrome.

Measured levels of androgens in blood vary widely from patient to patient and may remain within the normal range but SHBG levels are often low (due to high insulin levels), leading to high free androgen levels. In PCOS there is thought to be increased frequency of the GnRH pulse generator, leading to an increase in LH pulses and androgen secretion.

Figure 19.23 Polycystic ovary syndrome. (a) Ultrasound of ovary, revealing multiple cysts with central ovarian stroma showing increased echo texture. (b) MR image (coronal) of polycystic ovaries, also showing pelvic anatomy. C, cyst; B, bowel; LO, left ovary; RO, right ovary; U, uterine cavity; V, vagina. (Reproduced by kind permission of Barbara Hochstein and Geoffrey Cox, Auckland Radiology Group.)

The response of the hair follicle to circulating androgens also seems to vary between individuals with otherwise identical clinical and biochemical features, and the reason for this variation in end-organ response remains poorly understood.

PCOS is frequently associated with:

- **hyperinsulinaemia and insulin resistance**, the prevalence of type 2 diabetes being 10 times higher than in normal women
- **hypertension, hyperlipidaemia and increased cardiovascular risk** (the metabolic syndrome, p. 201), which is 2–3 times higher in PCOS, although it is currently unclear whether PCOS per se confers an absolute increase in cardiovascular mortality.

Obesity with PCOS is an additional risk factor for insulin resistance. The precise mechanisms which link the aetiology of polycystic ovaries, hyperandrogenism, anovulation and insulin resistance remain to be elucidated and whether the basic defect is in the ovary, adrenal, pituitary or a more generalized metabolic defect remains unknown.

In routine clinical practice, the majority of people with objective signs of androgen-dependent hirsutism will have PCOS, and investigation is mainly required to exclude rarer and more serious causes of virilization.

Idiopathic hirsutism. People with hirsutism, no elevation of serum androgen levels and no other clinical features are sometimes labelled as having 'idiopathic hirsutism'. However, studies suggest that most people with 'idiopathic hirsutism' have some radiological or biochemical evidence of PCOS on more detailed investigation, and several studies have demonstrated evidence of mild PCOS in up to 20% of the normal female population.

Familial or idiopathic hirsutism does occur, but usually involves a distribution of hair growth which is not typically androgenic.

Other causes. Rarer and more serious endocrine causes of hirsutism and virilization include congenital adrenal hyperplasia (CAH, see p. 987), Cushing's syndrome (p. 957) and virilizing tumours of the ovary and adrenal.

Ovarian hyperthecosis is a non-malignant ovarian disorder characterized by luteinized thecal cells in the ovarian stroma which secrete testosterone. The clinical features are similar to PCOS but tend to present in perimenopausal women, and serum testosterone levels are higher than typically seen in PCOS.

Iatrogenic hirsutism also occurs after treatment with androgens, or more weakly androgenic drugs such as progestogens or danazol.

Non-androgen-dependent hair growth (hypertrichosis) occurs with drugs such as phenytoin, diazoxide, minoxidil and ciclosporin.

Clinical features of PCOS

PCOS presents with amenorrhoea/oligomenorrhoea, hirsutism and acne (alone or in combination), shortly after menarche. Clinical, biochemical and radiological features of PCOS merge imperceptibly into those of the normal populations. The development of hirsutism commonly provokes severe distress in young women and may lead to avoidance of normal social activities.

- **Hirsutism** should be recorded objectively, ideally using a scoring system, to document the problem and to monitor treatment. The method and frequency of physical removal (e.g. shaving, plucking) should also be recorded. Most patients who complain of hirsutism will have an objective excess of hair on examination, but occasionally very little will be found (and appropriate counselling is then indicated).
- **Age and speed of onset.** Hirsutism related to PCOS usually begins around the time of the menarche and increases slowly and steadily in the teens and twenties. Rapid progression and prepubertal or late onset suggest a more serious cause.
- **Accompanying virilization.** Hirsutism due to PCOS may be severe and affect all androgen-dependent areas on the face and body. However, more severe virilization (clitoromegaly, recent-onset frontal balding, male phenotype) implies substantial androgen excess, and usually indicates a rarer cause rather than PCOS. Thinning of head hair in a male pattern – androgenic

alopecia – occurs in a proportion of women with uncomplicated PCOS, typically with a familial tendency for premature androgen-related hair loss in both sexes.

- **Menstruation.** Most people with hirsutism will have some disturbance of menstruation, typically oligo-/amenorrhoea, although more frequent erratic bleeding can also occur. However, PCOS can present as hirsutism with regular periods or as irregular periods, with no evidence of hirsutism or acne.
- **Weight.** Many people with hirsutism are also overweight or obese. This worsens the underlying androgen excess and insulin resistance and inhibits the response to treatment, and is an indication for appropriate advice on diet and exercise. In severe cases the insulin resistance may have a visible manifestation as acanthosis nigricans on the neck and in the axillae (see Fig. 24.24).

Investigations and differential diagnosis

A variety of investigations aid the diagnosis of people with hirsutism:

- **Serum total testosterone** is often elevated in PCOS and is invariably substantially raised in virilizing tumours (usually >5 nmol/L). People with hirsutism and normal testosterone levels frequently have low levels of sex hormone-binding globulin (SHBG), leading to high free androgen levels. *The free androgen index* ([testosterone/SHBG] *100) is often used and is high; free testosterone is difficult to measure directly.
- **Other androgens.** Androstenedione and dehydroepiandrosterone sulphate are frequently elevated in PCOS, and even more elevated in congenital adrenal hyperplasia (CAH) and virilizing tumours.
- **17 α -Hydroxyprogesterone** is elevated in classical CAH, but may be apparent in late-onset CAH only after stimulation tests.
- **Gonadotrophin levels.** LH hypersecretion is a frequent feature of PCOS, but the pulsatile nature of secretion of this hormone means that a 'classic' increased LH/FSH ratio is not always observed on a random sample.
- **Oestrogen levels.** Oestradiol is usually normal in PCOS, but oestrone levels (which are rarely measured) are elevated because of peripheral conversion. Levels are variable in other causes.
- **Ovarian ultrasound** is a useful investigation (Fig. 19.23). Typical features are those of a thickened capsule, multiple 3–5 mm cysts and a hyperechogenic stroma. Prolonged hyperandrogenization from any cause may lead to polycystic changes in the ovary. Ultrasound may also reveal virilizing ovarian tumours, although these are often small.
- **Serum prolactin.** Mild hyperprolactinaemia is common in PCOS but rarely exceeds 1500 mU/L.

If a virilizing tumour is suspected clinically or after investigation, then more complex tests include dexamethasone suppression tests, CT or MRI of adrenals, and selective venous sampling.

Diagnosis

Most patients presenting with a combination of hirsutism and menstrual disturbance will be shown to have polycystic ovary syndrome, but the rarer alternative diagnoses should be excluded, e.g. late-onset congenital adrenal hyperplasia (early-onset, raised serum 17 α -OH-progesterone), Cushing's

syndrome (look for other clinical features) and virilizing tumours of the ovary or adrenals (severe virilization, markedly elevated serum testosterone).

The consensus (Rotterdam) criteria 2003 for diagnosis of PCOS are at least two of:

- Clinical or biochemical evidence of hyperandrogenism
- Evidence of oligo- or anovulation
- Presence of polycystic ovaries on ultrasound.

Treatment

The underlying cause should be removed in the rare instances where this is possible (e.g. drugs, adrenal or ovarian tumours). Treatment of CAH and Cushing's is discussed on [page 987](#) and [page 957](#), respectively. Other therapy depends upon whether the aim is to reduce hirsutism, regularize periods or produce fertility.

Local therapy for hirsutism

Regular plucking, bleaching, depilatory cream, waxing or shaving is used. Such removal neither worsens nor improves the underlying severity of hirsutism. More 'permanent' solutions include electrolysis and a variety of 'laser' hair removal systems – all appear effective but have not been evaluated in long-term studies, are expensive, and still often require repeated long-term treatment. *Eflornithine cream* (an antiprotozoal) inhibits hair growth by inhibiting ornithine decarboxylase but is effective in only a minority of cases and should be discontinued if there is no improvement after 4 months.

Systemic therapy for hirsutism

This always requires a year or more of treatment for maximal benefit, and long-term treatment is frequently required as the problem tends to recur when treatment is stopped. The patient must therefore always be an active participant in the decision to use systemic therapy and must understand the rare risks as well as the benefits.

- **Oestrogens** (e.g. oral contraceptives) suppress ovarian androgen production and reduce free androgens by increasing SHBG levels. Combined hormone pills, which contain ethinylestradiol and a non-androgenic progestogen, e.g. desogestrel drospirenone, or cyproterone acetate plus ethinylestradiol (co-cyprindiol), will result in a slow improvement in hirsutism in a majority of cases and should normally be used first unless there is a contraindication, e.g. history of thrombosis. The risk of venous thrombosis appears to be 2–4-fold higher than on other low-dose oral contraceptive pills. After the menopause, HRT preparations which contain medroxyprogesterone (rather than more androgenic progestogens) may be helpful.
- **Cyproterone acetate** (50–100 mg daily) is an antiandrogen but is also a progestogen, teratogenic and a weak glucocorticoid. Given continuously it produces amenorrhoea, and so is normally given for days 1–14 of each cycle. In women of childbearing age, contraception is essential.
- **Spirolactone** (200 mg daily) also has antiandrogen activity and can cause useful improvements in hirsutism.
- **Finasteride** (5 mg daily), a 5 α -reductase inhibitor which prevents the formation of dihydrotestosterone in the skin, has also been shown to be effective but long-term experience is limited.

- **Flutamide**, another antiandrogen, is less commonly used owing to the high incidence of hepatic side-effects.

Treatment of menstrual disturbance

- Cyclical oestrogen/progestogen administration will regulate the menstrual cycle and remove the symptom of oligo- or amenorrhoea. This is most frequently an additional benefit of the treatment of hirsutism, but may also be used when menstrual disturbance is the only symptom.
- Drugs to improve the hyperinsulinaemia associated with PCOS and obesity are increasingly used (and requested by patients). Metformin (500 mg three times daily) improves menstrual cyclicity and ovulation in short-term studies, and some patients also report improvement in hirsutism and ease of weight loss, but gastrointestinal upset may limit use.
- Thiazolidinediones are also effective, but concerns about the long-term cardiovascular effects of these agents now preclude their use.

Treatment for fertility

- Metformin alone may improve ovulation and achieve conception.
- Clomifene 50–100 mg can be given daily on days 2–6 of the cycle and is more effective than metformin alone in achieving ovulation. This can occasionally cause the *ovarian hyperstimulation syndrome*, an iatrogenic complication of ovulation induction therapy, consisting of ovarian enlargement, oedema, hypovolaemia, acute kidney injury, and possibly shock; specialist supervision is essential. It is recommended that clomifene should not normally be used for longer than six cycles (owing to a possible increased risk of ovarian cancer in patients treated for longer than recommended).
- **Reverse circadian rhythm.** Prednisolone (2.5 mg in the morning, 5 mg at night) suppresses pituitary production of ACTH, upon which adrenal androgens partly depend. Regular ovulatory cycles often ensue. A steroid instruction leaflet and a card must be supplied.

More intensive techniques to stimulate ovulation may also be indicated in specialist hands, including low-dose gonadotrophin therapy, and ovarian hyperstimulation techniques associated with *in vitro* fertilization.

Wedge resection of the ovary was a traditional therapy but is now rarely required, although laparoscopic ovarian electrodiathermy may be helpful.

Oral contraception

The combined oestrogen–progestogen pill is widely used for contraception and has a low failure rate (<1 per 100 woman-years). 'Pills' contain 20–40 μ g of oestrogen, usually ethinylestradiol, together with a variable amount of one of several progestogens. The mechanism of action is two-fold:

- Suppression by oestrogen of gonadotrophins, thus preventing follicular development, ovulation and luteinization
- Progestogen effects on cervical mucus, making it hostile to sperm, and on tubal motility and the endometrium.

Side-effects of these preparations are shown in [Box 19.9](#). Most of the serious ones are rare and are less common with typical modern 20–30 μ g oestrogen pills, although evidence suggests that thromboembolism may be slightly more common with 'third-generation pills' containing desogestrel

and gestodene (approximately 30/100 000 woman-years compared with 15/100 000 on older pills and 5/100 000 on no treatment). While some problems require immediate cessation of the pill, other milder side-effects must be judged against the hazards of pregnancy occurring with inadequate contraception, especially if other effective methods are not practicable or acceptable.

Hazards of the combined pill are increased in smokers, in obesity and in those with other risk factors for cardiovascular disease (e.g. hypertension, hyperlipidaemia, diabetes) especially in women aged over 35 years (avoid if over 50 years). The 'mini-pill' (progestogen only, usually norethisterone) is less effective but is often suitable where oestrogens are contraindicated (Box 19.9). A progesterone antagonist, mifepristone, in combination with a prostaglandin analogue (vaginal gemeprost), induces abortion of pregnancy at up to 9 weeks' gestation. It prevents progesterone-induced inhibition of uterine contraction.

Subfertility

Subfertility, or 'infertility', is defined as the inability of a couple to conceive after 1 year of unprotected intercourse. Investigation requires the combined skills of gynaecologist, endocrinologist and, ideally, andrologist. Both partners must be involved and every aspect of the physiology critically examined.

Causes (Fig. 19.24)

A significant proportion of couples have both male and female contributing factors.

Box 19.9 Adverse effects and drug interactions of oral contraceptives (mixed oestrogen–progesterone combinations)

General

- Weight gain
- Loss of libido
- Pigmentation (chloasma)
- Breast tenderness
- Increased growth rate of some malignancies

Cardiovascular

- Increased blood pressure^a
- Deep vein thrombosis^a
- Myocardial infarction
- Stroke (migraine is risk factor)

Gastrointestinal

- Nausea and vomiting
- Abnormal liver biochemistry^a
- Gallstones increased
- Hepatic tumours

Nervous system

- Headache
- Migraine^a
- Depression^a

Malignancy

- Increase in cancer of the breast (but reduced risk of ovarian and endometrial cancer)

Gynaecological

- Amenorrhoea
- 'Spotting'
- Cervical erosion

Haematological

- Increased clotting tendency

Endocrine/metabolic

- Mild impairment of glucose tolerance
- Worsened lipid profile, though variable

Drug interactions^b

- Antibiotics
- Barbiturates
- Phenytoin
- Carbamazepine
- Rifampicin
- St John's wort

^aCommon reasons for stopping oral contraceptives.

^bReduced contraceptive effect owing to enzyme induction.

Female factors				Joint factors	Male factors		
Ovulation ?	Tubal problems ?	Uterine problems ?	Cervix Vaginal problems ?	Adequate intercourse ?	Normal sperm count ?		
PCOS	Patency PID, chlamydia, GC Function	Anatomy e.g. fibroids Implantation	Infection e.g. GC Cervical hostility	Frequency Timing Technique	Potency, e.g. hypogonadism	Vas blockage e.g. previous STI	Testicular disease e.g. tumour

Investigation:					
Pelvic ultrasound	Hysterosalpingogram	Swabs	History	Semen analysis	LH, FSH
	Hysteroscopy				Testosterone
Serum progesterone					Testicular biopsy
Laparoscopy / Egg collection					

Figure 19.24 Major factors involved in subfertility and their investigation. LH, luteinizing hormone; FSH, follicle-stimulating hormone; PCOS, polycystic ovarian syndrome; PID, pelvic inflammatory disease; GC, gonorrhoea; STI, sexually transmitted infection.

Inadequate intercourse, hostile cervical mucus and vaginal factors are uncommon (5%). 15% of cases appear to be idiopathic, and natural fertility decreases with increasing age. Conception over 40 years of age for both males and females is reduced to below 30%.

Male factors

About 30–40% of couples have a major identifiable male factor. There is some evidence that male sperm counts are declining in many populations. Untreated male hypogonadism of any cause (see Table 19.21) is likely to be associated with subfertility.

Female factors

Female tubal problems due to pathologies such as pelvic inflammatory disease and endometriosis account for perhaps 20%; a similar proportion have ovulatory disorders. Any cause of oligomenorrhoea or amenorrhoea (see Table 19.25) is likely to be associated with suboptimal ovulation or anovulation.

Clinical assessment

Both partners should be seen and the following factors checked:

- **The man.** Look for previous testicular damage (orchitis, trauma), undescended testes, urethral symptoms and evidence of sexually transmitted infection, local surgery, and use of alcohol and drugs. A semen analysis early in the investigations is essential.
- **The woman.** Look for previous pelvic infection, regularity of periods, previous surgery, alcohol intake and smoking and body weight (see p. 978).
- **Together.** Check the frequency and adequacy of intercourse, and the use of lubricants.

Investigations

See Figure 19.24.

Treatment

Counselling of both partners is essential. Any defect(s) found should be treated if possible. Ovulation can usually be

induced by exogenous hormones if simpler measures fail, while *in vitro* fertilization (IVF) and similar techniques are widely used, especially where there is tubal blockage, oligospermia or 'idiopathic subfertility'. Intracytoplasmic sperm injection (ICSI) appears particularly effective for severe oligospermia and poor sperm function.

Disorders of sexual differentiation

Disorders of sexual differentiation are rare but may affect chromosomal, gonadal, endocrine and phenotypic development (Table 19.26). Such cases always require extensive, multidisciplinary clinical management. An individual's sex can be defined in several ways:

- **Chromosomal sex.** The normal female is 46XX, the normal male 46XY. The Y chromosome confers male sex; if it is not present, development follows female lines.
- **Gonadal sex.** This is determined predominantly by chromosomal sex, but requires normal embryological development.
- **Phenotypic sex.** This describes the normal physical appearance and characteristics of male and female body shape. This in turn is a manifestation of gonadal sex and subsequent sex hormone production.
- **Social sex (gender).** This is heavily dependent on phenotypic sex and normally assigned on appearance of the external genitalia at birth.
- **Sexual orientation** – heterosexual, homosexual or bisexual.

THE ADRENAL AXIS

Adrenal gland: anatomy and function

(see Table 19.3)

The human adrenals weigh 8–10 g together and comprise an outer cortex and inner medulla. The cortex has three zones:

The adrenal axis

Condition	Chromosomes	Gonads	Phenotype	Remarks
Turner's syndrome	45X (50%) 46,X,i (Xq) (5–10%) 45,X, mosaicism (remainder)	Streak	Female	Often morphological features (e.g. short stature, web neck, coarctation of aorta)
Gonadal dysgenesis	46XY	Streak or minimal testes ^a	Immature female	
Congenital adrenal hyperplasia	46XX	Ovary	Female with variable virilization	Obvious androgen excess
Virilizing tumour	46XX	Ovary	Female with variable virilization	Obvious androgen excess
True hermaphroditism	46XX/XY or mosaic	Testis and ovary	Male or ambiguous	
Klinefelter's syndrome	47XXY	Small testes	Male, often with gynaecomastia	Many are hypogonadal
Testicular feminization	46XY	Testes ^a	Ambiguous or infantile female	Androgen receptor defective
Testicular synthetic defects	46XY	Testes ^a	Cryptorchid, ambiguous	
5 α -Reductase deficiency	46XY	Testes	Cryptorchid, ambiguous	Impaired conversion of testosterone to dihydrotestosterone
Anorchia	46XY	Absent	Immature female	

^aGonadectomy advised because of high risk of malignancy. i, isochromosome.

the zona glomerulosa, which secretes aldosterone under the control of the renin-angiotensin system, and the zona reticularis and zona fasciculata, which produce cortisol and androgens under feedback control of the hypothalamic-pituitary-adrenal (HPA) axis. The inner medulla synthesizes, stores and secretes catecholamines (see below and Fig. 19.25).

The adrenal cortex

The steroids produced by the adrenal cortex are grouped into three classes based on their predominant physiological effects: glucocorticoids, mineralocorticoids and androgens.

Glucocorticoids

These are so named after their effects on carbohydrate metabolism. Major actions are listed in Table 19.27. They act on intracellular corticosteroid receptors and combine with coactivating proteins to bind the 'glucocorticoid response element' (GRE) in specific regions of DNA to cause gene transcription. Glucocorticoid action is modified locally by the action of 11β -hydroxysteroid dehydrogenase (11β HSD). 11β HSD type 1 converts inactive cortisone in cortisol, hence amplifying the hormone signal, whilst 11β HSD type 2 does the opposite.

The relative potency of common steroids is shown in Table 19.28.

Mineralocorticoids

The predominant effect of mineralocorticoids is on the extracellular balance of sodium and potassium in the distal tubule of the kidney. Aldosterone, produced solely in the zona glomerulosa, is the predominant mineralocorticoid in humans (about 50%); corticosterone makes a small contribution to overall mineralocorticoid activity. Mineralocorticoids act on type 1 corticosteroid receptors, whilst glucocorticoids act on type 2 receptors, both having a very similar structure. The mineralocorticoid activity of cortisol is weak but cortisol is present in considerable excess. The mineralocorticoid receptor in the kidney is largely protected

Figure 19.25 The adrenal gland and its hormones.

Table 19.27 The major actions of glucocorticoids	
Increased or stimulated	Decreased or inhibited
Gluconeogenesis	Protein synthesis
Glycogen deposition	Host response to infection

Potassium loss	Circulating eosinophils
Free water clearance	
Uric acid production	
Circulating neutrophils	

from this excess by the intrarenal conversion ('shuttle') of cortisol to cortisone by 11β -hydroxysteroid dehydrogenase type 2.

Androgens

Although secreted in considerable quantities, most androgens have only relatively weak intrinsic androgenic activity until metabolized peripherally to testosterone or dihydrotestosterone. Dihydrotestosterone is metabolized from testosterone by 5α -reductase and is a potent androgen receptor agonist. The androgen receptor has been well characterized and mutations within this gene may cause androgen insensitivity syndromes.

Biochemistry

All steroids have the same basic skeleton (Fig. 19.26b) and the chemical differences between them are slight. The major biosynthetic pathways are shown in Fig. 19.22a.

Physiology

Glucocorticoid production by the adrenal is under hypothalamic-pituitary control (Fig. 19.27).

Corticotrophin-releasing hormone (CRH) is secreted in the hypothalamus in response to circadian rhythm, stress and other stimuli. CRH travels down the portal system to stimulate **adrenocorticotrophin (ACTH)** release from the anterior pituitary. Hypothalamic vasopressin (ADH) also stimulates ACTH secretion and acts synergistically. ACTH is derived from the prohormone pro-opiomelanocortin (POMC), which undergoes complex processing within the pituitary to produce ACTH and a number of other peptides including beta-lipotrophin and beta-endorphin. Many of these peptides, including ACTH, contain melanocyte-stimulating hormone (MSH)-like sequences which cause pigmentation when levels of ACTH are markedly raised.

Circulating ACTH stimulates cortisol production in the adrenal. The secreted cortisol (or any other synthetic corticosteroid administered to the patient) causes negative feedback on the hypothalamus and pituitary to inhibit further CRH/ACTH release. The set-point of this system clearly varies through the day according to the circadian rhythm, and is usually overridden by severe stress. Unlike cortisol, mineralocorticoids and sex steroids do not cause negative feedback on the CRH/ACTH axis.

Following adrenalectomy or other adrenal damage (e.g. Addison's disease), cortisol secretion will be absent or reduced; ACTH levels will therefore rise.

Mineralocorticoid secretion is mainly controlled by the renin-angiotensin system (see p. 566).

Table 19.28 The relative glucocorticoid and mineralocorticoid potency of equal amounts of common natural and synthetic steroids

Steroid	Glucocorticoid effect	Mineralocorticoid effect
Cortisol (hydrocortisone) ^a	1	1
Prednisolone	4	0.7
Dexamethasone	40	2
Aldosterone	0.1	400
Fludrocortisone	10	400

^aCortisol is arbitrarily defined as 1.

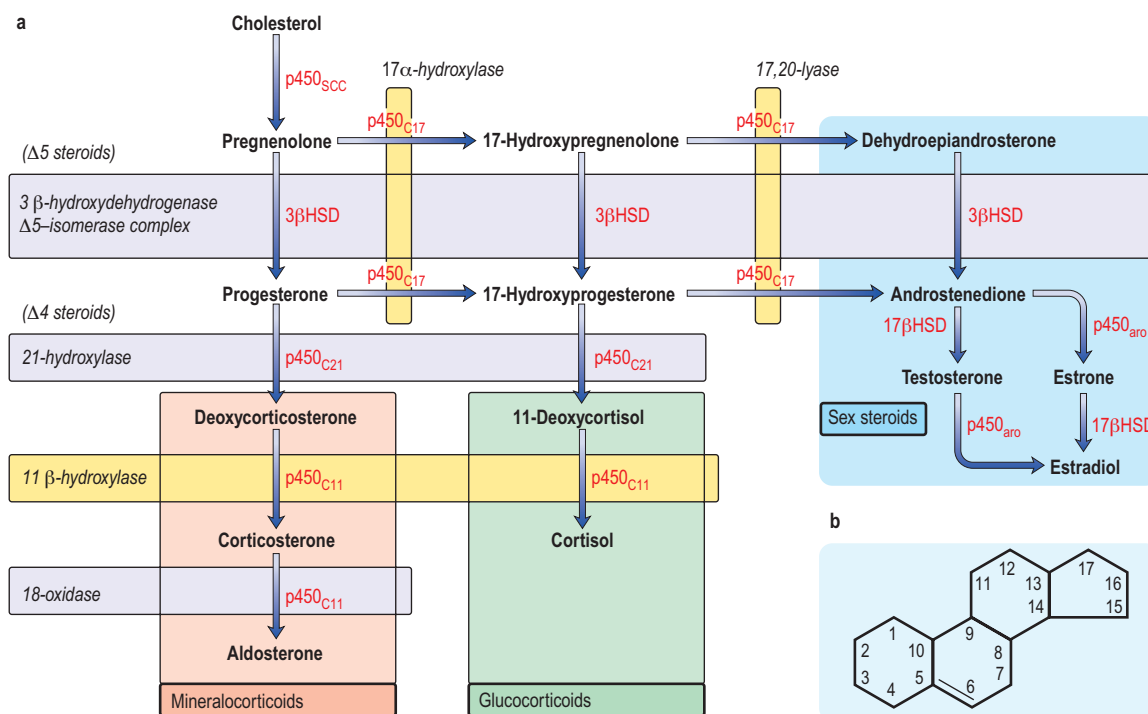

Figure 19.26 (a) The major steroid biosynthetic pathways. Steroid hormones are synthesized in adrenal and gonads from the initial substrate via a series of interconnected enzymatic steps. The reactions catalysed are shown by shaded boxes with italic labels. The molecular identity of the enzymes is shown in red – some catalyse more than one reaction. $p450$ enzymes are in mitochondria, 3β HSD (hydroxysteroid dehydrogenase) in cytoplasm. 17β HSD and $p450_{aro}$ (aromatase) are found mainly in gonads. **(b) The steroid molecule.**

Figure 19.27 Control of the hypothalamic-pituitary-adrenal axis. Pituitary ACTH is secreted in response to hypothalamic CRH (corticotrophin-releasing hormone) triggered by circadian rhythm, stress and other factors, and stimulates secretion of cortisol from the adrenal. Cortisol has multiple actions in peripheral tissues and exerts negative feedback on pituitary and hypothalamus.

Investigation of glucocorticoid abnormalities

Basal levels

ACTH and cortisol are released episodically and in response to stress. When taking a blood sample, remember:

- Sampling time should be recorded. Basal levels should be taken between 08:00 hours and 09:00 hours near the peak of the circadian variation.
- Stress should be minimized.
- Appropriate reference ranges (for time and assay method) should be used.

Suppression and stimulation tests are used in suspected excess and deficient cortisol production, respectively.

Dexamethasone suppression tests

Administration of a synthetic glucocorticoid (dexamethasone) to a normal subject produces prompt feedback suppression of CRH and ACTH levels and thus of endogenous cortisol secretion (dexamethasone is not measured by most cortisol assays). Three forms of the test, used in the diagnosis and differential diagnosis of Cushing's syndrome, are available (see Table 19.11).

ACTH stimulation tests

Synthetic ACTH (tetracosactide, which consists of the first 24 amino acids of human ACTH) is given to stimulate adrenal cortisol production. Details are given in Box 19.1 and Figure 19.5 (p. 944).

Addison's disease: primary hypoadrenalism

Pathophysiology and causes

In this condition, there is destruction of the entire adrenal cortex. Glucocorticoid, mineralocorticoid and sex steroid

production are therefore all reduced. (This differs from hypothalamic-pituitary disease, in which mineralocorticoid secretion remains largely intact, being predominantly stimulated by angiotensin II. Adrenal sex steroid production is also largely independent of pituitary action.) In Addison's disease reduced cortisol levels lead, through feedback, to increased CRH and ACTH production, the latter being directly responsible for the hyperpigmentation.

Incidence. Addison's disease is rare, with an incidence of 3–4/million per year and prevalence of 40–60/million. Primary hypoadrenalism shows a marked female preponderance and is most often caused by autoimmune disease (>90% in UK) but in countries with a high prevalence of HIV/AIDS, tuberculosis is an increasing cause. Autoimmune adrenalitis results from the destruction of the adrenal cortex by organ-specific autoantibodies, with 21-hydroxylase as the common antigen. There are associations with other autoimmune conditions in the polyglandular autoimmune syndromes types I and II (e.g. type 1 diabetes mellitus, pernicious anaemia, thyroiditis, hypoparathyroidism, premature ovarian failure) (p. 997).

All other causes are rare (Table 19.29).

Clinical features

These are shown in Figure 19.28. The symptomatology of Addison's disease is often vague and nonspecific. These symptoms may be the prelude to an Addisonian crisis with severe hypotension and dehydration precipitated by intercurrent illness, accident or operation.

Pigmentation (dull, slaty, grey-brown) is the predominant sign in over 90% of cases.

Postural systolic hypotension, due to hypovolaemia and sodium loss, is present in 80–90% of cases, even if supine

blood pressure is normal. Mineralocorticoid deficiency is the cause of the hypotension.

Investigations

Once Addison's disease is suspected, investigation is urgent. If the patient is seriously ill or hypotensive, hydrocortisone 100 mg should be given intravenously or intramuscularly together with intravenous 0.9% saline. Ideally this should be done immediately after a blood sample is taken for later measurement of plasma cortisol. Alternatively, an ACTH stimulation test can be performed immediately. Full investigation should be delayed until emergency treatment (see below) has improved the patient's condition. Otherwise, tests are as follows:

- **Single cortisol measurements** are of little value, although a random cortisol below 100 nmol/L during the day is highly suggestive, and a random cortisol >550 nmol/L makes the diagnosis unlikely.
- **The short ACTH stimulation test** should be performed (see Box 19.11 and Fig. 19.5). Note that an absent or impaired cortisol response confirms the presence of hypoadrenalism but does not differentiate Addison's disease from ACTH deficiency or iatrogenic suppression by steroid medication.
- The long ACTH test is no longer used because of the availability of accurate ACTH assays.
- **A 09:00 hours plasma ACTH level** – a high level (>80 ng/L) with low or low-normal cortisol confirms primary hypoadrenalism.
- **Electrolytes and urea** classically show hyponatraemia, hyperkalaemia and a high urea, but they can be normal.
- **Blood glucose** may be low, with hypoglycaemia.
- **Adrenal antibodies** are present in many cases of autoimmune adrenalitis.
- **Chest and abdominal X-rays** may show evidence of tuberculosis and/or calcified adrenals.
- **Plasma renin activity** is high due to low serum aldosterone.
- **Hypercalcaemia and anaemia** (after rehydration) are sometimes seen.

Treatment

Acute hypoadrenalism needs urgent treatment (Emergency Box 19.1).

Table 19.29 Causes of primary hypoadrenalism

Autoimmune disease
Tuberculosis (<10% in UK)
Surgical removal
Haemorrhage/infarction
Meningococcal septicaemia
Venography
Infiltration
Malignant destruction
Amyloid
Schilder's disease (adrenal leucodystrophy)

Symptoms
Weight loss
Anorexia
Malaise
Weakness
Fever
Depression
Impotence/amenorrhoea
Nausea/vomiting
Diarrhoea
Confusion
Syncopal from postural hypotension
Abdominal pain
Constipation
Myalgia
Joint or back pain

Signs
Pigmentation, especially of new scars and palmar creases
Buccal pigmentation
Postural hypotension
Loss of weight
General wasting
Dehydration
Loss of body hair (Vitiligo)

Emergency Box 19.1

Management of acute hypoadrenalism

Clinical context

Hypotension, hyponatraemia, hyperkalaemia, hypoglycaemia, dehydration, pigmentation often with precipitating infection, infarction, trauma or operation. The major deficiencies are of salt, steroid and glucose.

Assuming normal cardiovascular function, the following are required:

- 1 litre of 0.9% saline should be given over 30–60 min with 100 mg of intravenous bolus hydrocortisone.
- Subsequent requirements are several litres of saline within 24 hours (assessing with central venous pressure line if necessary) plus hydrocortisone, 100 mg i.m., 6-hourly, until the patient is clinically stable.
- Glucose should be infused if there is hypoglycaemia.
- Oral replacement medication is then started, unless unable to take oral medication, initially hydrocortisone 20 mg, 8-hourly, reducing to 20–30 mg in divided doses over a few days (Table 19.30).
- Fludrocortisone is unnecessary acutely as the high cortisol doses provide sufficient mineralocorticoid activity – it should be introduced later.

Table 19.30 Average replacement steroid dosages for adults with primary hypoadrenalism

Drug	Dose
Glucocorticoid	
Hydrocortisone	20–30 mg daily (e.g. 10 mg on waking, 5 mg at 12:00 hours, 5 mg at 18:00 hours)
<i>or</i>	
Prednisolone	7.5 mg daily (5 mg on waking, 2.5 mg at 18:00 hours)
<i>rarely</i>	
Dexamethasone	0.75 mg daily (0.5 mg on waking, 0.25 mg at 18:00 hours)
Mineralocorticoid	
Fludrocortisone	50–300 µg daily

Long-term treatment is with replacement glucocorticoid and mineralocorticoid; tuberculosis must be treated if present or suspected. Replacement dosage details are shown in Table 19.30. Dehydroepiandrosterone (DHEA) replacement has also been advocated, and some studies suggest that this may cause symptomatic improvements, although others show no clear benefit.

Adequacy of glucocorticoid dose is judged by:

- Clinical wellbeing and restoration of normal, but not excessive, weight
- Normal cortisol levels during the day while on replacement hydrocortisone (cortisol levels cannot be used for synthetic steroids).

Adequacy of fludrocortisone replacement is assessed by:

- Restoration of serum electrolytes to normal
- Blood pressure response to posture (it should not fall >10 mmHg systolic after 2 minutes' standing)
- Suppression of plasma renin activity to normal.

Patient advice

All patients requiring replacement steroids should:

- know how to increase steroid replacement dose for intercurrent illness

- carry a 'Steroid Card'
- wear a Medic-Alert bracelet (or similar), which gives details of their condition so that emergency replacement therapy can be given if found unconscious
- keep an (up-to-date) ampoule of hydrocortisone at home in case oral therapy is impossible, for administration by self, family or doctor.

Secondary hypoadrenalism

This may arise from:

- hypothalamic-pituitary disease (inadequate ACTH production) *or*
- long-term steroid therapy leading to hypothalamic-pituitary-adrenal suppression.

Most people with hypothalamic-pituitary disease have panhypopituitarism (see p. 950) and need T₄ replacement as well as cortisol; in this case hydrocortisone must be started before T₄.

Long-term corticosteroid medication for non-endocrine disease is the most common cause of secondary hypoadrenalism. The hypothalamic-pituitary axis and the adrenal may both be suppressed and the patient may have vague symptoms of feeling unwell. ACTH levels are low in secondary hypoadrenalism. Weaning off steroids is often a long and difficult process.

Congenital adrenal hyperplasia (CAH)

Pathophysiology

This condition results from an autosomal recessive deficiency of an enzyme in the cortisol synthetic pathways. There are six major types, but most common is 21-hydroxylase deficiency (CYP21A2), which occurs in about 1 in 15000 births and which has been shown to be due to defects on chromosome 6 near the HLA region affecting one of the cytochrome p450 enzymes (p450C21).

As a result, cortisol secretion is reduced and feedback leads to increased ACTH secretion to maintain adequate cortisol – leading to adrenal hyperplasia. Diversion of the steroid precursors into the androgenic steroid pathways occurs (see Fig. 19.26a). Thus, 17-hydroxyprogesterone, androstenedione and testosterone levels are increased, leading to virilization. Aldosterone synthesis may be impaired with resultant salt wasting.

The other forms affect 11β-hydroxylase, 17α-hydroxylase, 3β-hydroxysteroid dehydrogenase and a cholesterol side-chain cleavage enzyme (p450scc) (see Fig. 19.26a).

Clinical features

If severe, CAH presents at birth with sexual ambiguity or adrenal failure (collapse, hypotension, hypoglycaemia), sometimes with a salt-losing state (hypotension, hyponatraemia). In the female, clitoral hypertrophy, urogenital abnormalities and labioscrotal fusion are common, but the syndrome may be unrecognized in the male.

Precocious puberty with hirsutism is a later presentation, whereas rare, milder cases only present in adult life, usually accompanied by primary amenorrhoea. Hirsutism developing before puberty is suggestive of CAH.

Investigations

Expert advice is essential in the confirmation and differential diagnosis of 21-hydroxylase deficiency, and with ambiguous genitalia such advice must be sought urgently before any assignment of gender is made.

A profile of adrenocortical hormones is measured before and one hour after ACTH administration.

- 17-Hydroxyprogesterone levels are increased
- Urinary pregnanetriol excretion is increased
- Androstenedione levels are raised
- Basal ACTH levels are raised.

Treatment

Glucocorticoid activity must be replaced, as must mineralocorticoid activity if deficient. In CAH the larger dose of glucocorticoid is often given at night to suppress the morning ACTH peak with a smaller dose in the morning (cf. Addison's disease, p. 987; Table 19.30). Correct dosage is often difficult to establish in the child but should ensure normal 17-hydroxyprogesterone levels while allowing normal growth; excessive replacement leads to stunting of growth. In adults, clinical features and biochemistry (plasma renin, androstenedione and 17-OH-progesterone) are used to modify treatment. Genetic counselling (p. 43) and antenatal diagnosis is essential, particularly in 21-hydroxylase deficiency. The mother of an affected fetus can take dexamethasone daily to prevent virilization.

Uses and problems of therapeutic steroid therapy

Apart from their use as therapeutic replacement for endocrine deficiency states, synthetic glucocorticoids are widely used for many non-endocrine conditions (Box 19.10). Short-term use (e.g. for acute asthma) carries only small risks of significant side-effects except for the simultaneous suppression of immune responses. The danger lies in their continuance, often through medical oversight or patient default. In general, therapy for 3 weeks or less, or a dose of prednisolone less than 5 mg per day, will not result in significant long-term suppression of the normal adrenal axis.

Long-term therapy with synthetic or natural steroids will, in most respects, mimic endogenous Cushing's syndrome. Exceptions are the relative absence of hirsutism, acne, hypertension and severe sodium retention, as the common synthetic steroids have low androgenic and mineralocorticoid activity.

Excessive doses of steroids may also be absorbed from skin when strong dermatological preparations are used, but inhaled steroids rarely cause Cushing's syndrome, although they commonly cause adrenal suppression.

The major hazards are detailed in Box 19.11. In the long term, many are of such severity that the clinical need for high-dose steroids should be continually and critically assessed. Steroid-sparing agents (e.g. azathioprine) should always be considered and screening and prophylactic therapy for osteoporosis introduced (see p. 556). New targeted biological therapies for inflammatory conditions may reduce the incidence of steroid-induced adrenal suppression.

Supervision of steroid therapy

All patients receiving steroids should carry a 'Steroid Card'. They should be made aware of the following points:

- Long-term steroid therapy must never be stopped suddenly.
- Doses should be reduced very gradually, with most being given in the morning at the time of withdrawal – this minimizes adrenal suppression. Many authorities believe that 'alternate-day therapy' produces less suppression.
- Doses need to be increased in times of serious intercurrent illness (defined as presence of a fever), accident and stress. Double doses should be taken during these times.
- Other physicians, anaesthetists and dentists must be told about steroid therapy.

Patients should also be informed of potential side-effects, and all this information should be documented in the clinical record. If prophylactic use of bisphosphonate therapy is required to prevent the development of osteoporosis (NICE guidance), they should be informed of the rationale.

Steroids and surgery

Any patient receiving steroids or who has recently received them (within the last 12 months) and may still have adrenal

Table 19.31 Steroid cover for operative procedures

Procedure	Premedication	Intra- and postoperative	Resumption of normal maintenance
Simple procedures (e.g. gastroscopy, simple dental extractions)	Hydrocortisone 100 mg i.m.	–	Immediately if no complications and eating normally
Minor surgery (e.g. laparoscopic surgery, veins, hernias)	Hydrocortisone 100 mg i.m.	Hydrocortisone 20 mg orally 6-hourly or 50 mg i.m. every 6 h for 24 h if not eating	After 24 h if no complications
Major surgery (e.g. hip replacement, vascular surgery)	Hydrocortisone 100 mg i.m.	Hydrocortisone 50–100 mg i.m. every 6 h for 72 h	After 72 h if normal progress and no complications Perhaps double normal dose for next 2–3 days
GI tract surgery or major thoracic surgery (not eating or ventilated)	Hydrocortisone 100 mg i.m.	Hydrocortisone 100 mg i.m. every 6 h for 72 h or longer if still unwell	When patient eating normally again Until then, higher doses (to 50 mg 6-hourly) may be needed
A useful summary of surgical steroid guidelines can be found at: http://www.addisons.org.uk/comms/publications/surgicalguidelines-colour.pdf			

suppression requires special control of steroid medication around the time of surgery. Details are shown in Table 19.31.

Incidental adrenal tumours ('incidentalomas')

With the advent of abdominal CT, MRI and high-resolution ultrasound scanning, unsuspected adrenal masses have been discovered in 3–10% of scans (increasing with age). The two issues of concern with an incidental adrenal mass are:

- whether the lesion is functional or non-functional, and
- whether it is benign or malignant.

Most incidentalomas are asymptomatic and benign, but direct questioning may reveal symptoms of endocrine hypersecretion such as cushingoid features, catecholamine excess, virilization in women, or evidence of endocrine hypertension (p. 943). Even in the absence of symptoms, functional tests to exclude secretory activity should be performed as adrenal adenomas often secrete cortisol at a low level, 'sub-clinical Cushing's syndrome', which may confer increased cardiovascular risk. If no endocrine activity is found then most authorities recommend removal only of large adrenal tumours (>4–5 cm) because of the risk of malignancy. Smaller hormonally inactive lesions are usually observed as long as there are no worrying radiological features.

Phaeochromocytoma must be excluded before surgery due to the risk of perioperative hypertensive or hypotensive crises (see p. 991).

Primary hyperaldosteronism

Increased mineralocorticoid secretion from the adrenal cortex, termed primary hyperaldosteronism, is thought to account for 5–10% of all hypertension. Other endocrine causes of hypertension should also be considered if there is clinical suspicion (Table 19.32). It is impracticable and unnecessary to screen all hypertensive patients for secondary endocrine causes. The highest chances of detecting such causes are in patients:

- under 35 years, especially those without a family history of hypertension
- with accelerated (malignant) hypertension
- with hypokalaemia before diuretic therapy
- resistant to conventional antihypertensive therapy (e.g. more than three drugs) or
- with unusual symptoms (e.g. sweating attacks or weakness).

Table 19.32 Endocrine causes of hypertension

Excessive renin, and thus angiotensin II, production
Renal artery stenosis Other local renal disease Renin-secreting tumours
Excessive production of catecholamines
Phaeochromocytoma
Excessive GH production
Acromegaly
Excessive aldosterone production
Adrenal adenoma (Conn's syndrome) Idiopathic adrenal hyperplasia Dexamethasone-suppressible hyperaldosteronism
Excessive production of other mineralocorticoids
Cushing's syndrome (massive excess of cortisol, a weak mineralocorticoid) Congenital adrenal hyperplasia (in rare cases) Tumours producing other mineralocorticoids, e.g. corticosterone
Exogenous 'mineralocorticoids' or enzyme inhibitors
Liquorice ingestion (inhibits 11 β -hydroxylase) Misuse of mineralocorticoid preparations

Pathophysiology

Primary hyperaldosteronism is a disorder of the adrenal cortex characterized by excess aldosterone production leading to sodium retention, potassium loss and the combination of hypokalaemia and hypertension. This must be distinguished from secondary hyperaldosteronism, which arises when there is excess renin (and hence angiotensin II) stimulation of the zona glomerulosa. Common causes of secondary hyperaldosteronism are accelerated hypertension and renal artery stenosis, when the patient will also be hypertensive. Causes associated with normotension include congestive cardiac failure and cirrhosis, where excess aldosterone production contributes to sodium retention.

Causes (see Table 19.32)

Adrenal adenomas (Conn's syndrome) originally accounted for 60% of cases of in series of primary hyperaldosteronism but represented a rare cause of hypertension. The use of the aldosterone:renin ratio in the routine investigation of hypertension now suggests that hyperaldosteronism due to bilateral adrenal hyperplasia (idiopathic hyperaldosteronism) is

much more common than the classical Conn's adenoma. Some claim that idiopathic hyperaldosteronism is the cause of up to 10% of cases of 'essential' hypertension.

Clinical features

The usual presentation is simply hypertension; hypokalaemia (<3.5 mmol/L) is not frequently present. The few symptoms are nonspecific; rarely muscle weakness, nocturia and tetany are seen. The hypertension may be severe and associated with renal, cardiac and retinal damage.

Adenomas, often very small, are more common in young females, while bilateral hyperplasia rarely occurs before age 40 years and is more common in males.

Investigations

Beta-blockers and other drugs may interfere with renin activity, and spironolactone, ACE inhibitors and angiotensin II receptor antagonists will all affect results and all should be discontinued if possible. The characteristic features are as follows:

- **Plasma aldosterone:renin ratio (ARR)** is now most frequently used as a screening test for the condition, but raised ARR alone does not confirm the diagnosis (if the renin is low enough ARR will always be high). Note that normal ranges are highly assay-dependent.
- **Elevated plasma aldosterone levels** that are not suppressed with 0.9% saline infusion (2 L over 4 hours) or fludrocortisone administration. Between 30% and 50% of people with raised ARR on screening will suppress normally, excluding the diagnosis.
- **Suppressed plasma renin activity** or immunoreactivity.
- **Hypokalaemia** is often present but a normal serum potassium does not exclude the diagnosis.
- **Urinary potassium loss.** Levels >30 mmol daily during hypokalaemia are inappropriate.

Once a diagnosis of hyperaldosteronism is established, differentiation of adenoma from hyperplasia involves adrenal CT or MRI, but small adenomas may be missed and non-functioning incidentalomas also occur. Further information is obtained from diurnal/postural changes in plasma aldosterone levels (which tend to rise with adenomas between 09:00 hours supine and 13:00 hours erect samples; in contrast, they fall with hyperplasia), measurement of 18-OH cortisol levels (raised in adenoma) and venous catheterization for aldosterone levels. All of these tests have their pitfalls and exceptions.

Treatment

An adenoma can be removed surgically – usually laparoscopically; blood pressure falls in 70% of patients. Those with hyperplasia should be treated with the aldosterone antagonist spironolactone (100–400 mg daily); frequent side-effects include nausea, rashes and gynaecomastia, and the pure aldosterone receptor antagonist eplerenone can be a useful alternative if side-effects preclude the use of spironolactone (p. 640). Spironolactone metabolites have been linked with tumour development in animals but this has not been described in humans. Amiloride and calcium-channel blockers are moderately effective in controlling the hypertension but do not correct the hyperaldosteronism.

Glucocorticoid (or dexamethasone)-suppressible hyperaldosteronism

This rare condition is caused by a chimeric gene on chromosome 8. A fusion gene resulting from an unusual cross-over

at meiosis between the genes encoding aldosterone synthase and adrenal 11 β -hydroxylase produces aldosterone which is under ACTH control. Treatment with glucocorticoid resolves the problem.

Syndrome of apparent mineralocorticoid excess

This causes the clinical syndrome of primary hyperaldosteronism but with low renin and aldosterone levels. Reduced activity of the enzyme 11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD2) prevents the normal conversion in the kidney of cortisol (which is active at the mineralocorticoid receptor) to cortisone (which is not) and therefore 'exposes' the mineralocorticoid receptor in the kidney to the usual molar excess of cortisol over aldosterone in the blood. While the inherited syndrome is rare, the same clinical syndrome can occur with excessive ingestion of liquorice, which inhibits the 11 β -HSD2 enzyme.

The adrenal medulla

The adrenal medulla is the innermost part of the adrenal gland, consisting of cells that secrete the major catecholamines, noradrenaline (norepinephrine) and adrenaline (epinephrine), which produce the sympathetic nervous response. The catecholamines are interconverted in the adrenal medulla and an increase in levels of their metabolites in the urine is a marker of abnormal hypersecretion (Fig. 19.29).

Phaeochromocytoma and paraganglioma

These are very rare tumours of the sympathetic nervous system (less than 1 in 1000 cases of hypertension) that secrete catecholamines, noradrenaline (norepinephrine) adrenaline (epinephrine) and their metabolites (Fig. 19.29):

- 90% arise in the adrenal medulla (*phaeochromocytomas*)
- 10% occur elsewhere in the sympathetic chain (*paragangliomas*).

Massive left-sided phaeochromocytoma (MRI scan)

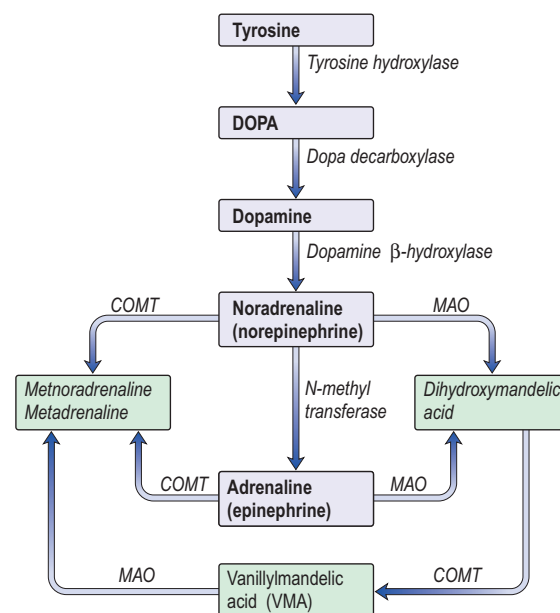

Figure 19.29 The synthesis and metabolism of catecholamines. COMT, catechol-O-methyl transferase; MAO, monoamine oxidase.

Some are associated with MEN 2 syndromes (see below) and the von Hippel–Lindau (VHL) syndrome (p. 1143). Most tumours release both noradrenaline (norepinephrine) and adrenaline (epinephrine) but large tumours and extra-adrenal tumours produce almost entirely noradrenaline.

Paragangliomas typically occur in the head and neck but are also found in the thorax, pelvis and bladder. They are more closely associated with other genetic associations than is pheochromocytoma. The association of paraganglioma, bilateral adrenal pheochromocytomas, positive family history or young age at presentation is seen in multiple endocrine neoplasms (p. 997). Mutations in the succinate dehydrogenase (SDHD) gene have been shown to be strongly associated with the development of paraganglioma.

Pathology

Oval groups of cells occur in clusters and stain for chromogranin A. Some 25% are multiple and 10% malignant, the latter being more frequent in the extra-adrenal tumours. Malignancy cannot be determined on simple histological examination alone.

Clinical features

The clinical features are those of catecholamine excess and are frequently, but not necessarily, intermittent (Table 19.33). All people with suspected pheochromocytomas must be investigated because pheochromocytomas may cause acute cardiovascular compromise during routine medical procedures, and can also present with sudden death if the diagnosis is missed.

Diagnosis

Specific tests are:

- **Measurement of urinary catecholamines and metabolites** (metanephrines are most sensitive and specific – Fig. 19.29) is a useful screening test; normal levels on three 24-hour collections of metanephrines virtually exclude the diagnosis. Many drugs and dietary vanilla interfere with these tests.
- **Resting plasma catecholamines** are raised.
- **Plasma chromogranin A** (a storage vesicle protein) is raised.
- **Clonidine suppression test** may be appropriate, but should only be performed in specialist centres.
- **CT scans**, initially of the abdomen, are helpful to localize the tumours, which are often large.
- **MRI** usually shows the lesion clearly.

Table 19.33 Symptoms and signs of pheochromocytoma

Symptoms	Signs
Anxiety or panic attacks	Hypertension
Palpitations	Tachycardia/arrhythmias
Tremor	Bradycardia
Sweating	Orthostatic hypotension
Headache	Pallor or flushing
Flushing	Glycosuria
Nausea and/or vomiting	Fever
Weight loss	(Signs of hypertensive damage)
Constipation or diarrhoea	
Raynaud's phenomenon	
Chest pain	
Polyuria/nocturia	

- **Scanning with [¹³¹I]meta-iodobenzylguanidine (MIBG)** produces specific uptake in sites of sympathetic activity with about 90% success. It is particularly useful with extra-adrenal tumours. ¹⁸F-deoxyglucose PET is also used by some centres in the localization of pheochromocytomas.
- **Genetic testing** for MEN2, VHL and SDHD mutations should be performed in all people with confirmed pheochromocytoma or paraganglioma.

Treatment

Tumours should be removed if this is possible; 5-year survival is about 95% for non-malignant tumours. Medical preoperative and perioperative treatment is vital and includes complete alpha- and beta-blockade with phenoxybenzamine (20–80 mg daily initially in divided doses), then propranolol (120–240 mg daily), plus transfusion of whole blood to re-expand the contracted plasma volume. The alpha-blockade must precede the beta-blockade, as worsened hypertension may otherwise result. Labetalol is not recommended. Surgery in the unprepared patient is fraught with dangers of both hypertension and hypotension; expert anaesthesia and an experienced surgeon are both vital, and sodium nitroprusside and phentolamine (a rapid acting alpha blocker) should be available in case sudden severe hypertension develops.

When operation is not possible, combined alpha- and beta-blockade can be used long term. Radionuclide treatment with MIBG has been used but with limited success in malignant pheochromocytoma.

Patients should be kept under clinical and biochemical review after tumour resection as over 10% recur or develop a further tumour. Catecholamine excretion measurements should be performed at least annually.

THE THIRST AXIS

Thirst and water regulation are largely controlled by vasopressin, also known as antidiuretic hormone (ADH), which is synthesized in the hypothalamus and then migrates in neurosecretory granules along axonal pathways to the posterior pituitary. Pituitary disease alone without hypothalamic involvement therefore does not lead to ADH deficiency as the hormone can still 'leak' from the damaged end of the intact axon.

At normal concentrations the kidney is the predominant site of action of vasopressin. Vasopressin stimulation of the V₂ receptors allows the collecting ducts to become permeable to water via the migration of aquaporin-2 water channels, thus permitting reabsorption of hypotonic luminal fluid (p. 640). Vasopressin therefore reduces diuresis and results in overall retention of water. At high concentrations vasopressin also causes vasoconstriction via the V₁ receptors in vascular tissue.

Changes in plasma osmolality are sensed by osmoreceptors in the anterior hypothalamus. Vasopressin secretion is suppressed at levels below 280 mOsm/kg, thus allowing maximal water diuresis. Above this level, plasma vasopressin increases in direct proportion to plasma osmolality. At the upper limit of normal (295 mOsm/kg) maximum antidiuresis is achieved and thirst is experienced at about 298 mOsm/kg (Fig. 19.30).

Other factors affecting vasopressin release are shown in Table 19.34.

Disorders of vasopressin secretion or activity include:

- deficiency as a result of hypothalamic disease ('cranial' diabetes insipidus)

Nicotine	
Antidepressants	

- inappropriate excess of the hormone
- 'nephrogenic' diabetes insipidus – a rare condition in which the renal tubules are insensitive to vasopressin; an example of a receptor abnormality.

While all these are uncommon, they need to be distinguished from the occasional patient with 'primary polydipsia' and those whose renal tubular function has been impaired by electrolyte abnormalities, such as hypokalaemia or hypercalcaemia.

Diabetes insipidus (DI)

Clinical features

Deficiency of vasopressin (ADH) or insensitivity to its action leads to polyuria, nocturia and compensatory polydipsia. Daily urine output may reach as much as 10–15 L, leading to dehydration that may be very severe if the thirst mechanisms or consciousness are impaired or the patient is denied fluid.

Causes of DI are listed in Table 19.35. The most common is hypothalamic-pituitary surgery, following which transient DI is common, frequently remitting after a few days or weeks.

DI may be masked by simultaneous cortisol deficiency – cortisol replacement allows a water diuresis and DI then becomes apparent.

Familial isolated vasopressin deficiency causes DI from early childhood and is dominantly inherited, caused by a mutation in the AVP-NP11 gene. *DIDMOAD (Wolfram) syndrome* is a rare autosomal recessive disorder comprising diabetes insipidus, diabetes mellitus, optic atrophy and deafness due to mutations in the *WFS1* gene on chromosome 4. MR scanning may show an absent or poorly developed posterior pituitary.

Table 19.35 Causes of diabetes insipidus

Hypokalaemia	
Hypercalcaemia	
Drugs (e.g. lithium, demeclocycline, glibenclamide)	
Sickle cell disease	
Mild temporary nephrogenic DI can occur after prolonged polyuria due to any cause, including cranial DI and primary polydipsia.	

Biochemistry

- High or high-normal plasma osmolality with low urine osmolality (in primary polydipsia plasma osmolality tends to be low).
- Resultant high or high-normal plasma sodium (hypernatraemia).
- High 24-h urine volumes (less than 2 L excludes the need for further investigation).
- Failure of urinary concentration with fluid deprivation.
- Restoration of urinary concentration with vasopressin or an analogue.

The latter two points are studied with a formal water deprivation test (Box 19.12). In normal subjects, plasma osmolality remains normal while urine osmolality rises above 600 mOsm/kg. In DI, plasma osmolality rises while the urine remains dilute, only concentrating after exogenous vasopressin is given (in 'cranial' DI) or not concentrating after vasopressin if nephrogenic DI is present. An alternative is measurement of plasma vasopressin during hypertonic saline infusion, but these measurements are not widely available.

Treatment

The synthetic vasopressin (ADH) analogue desmopressin is the treatment of choice. It has a longer duration of action than vasopressin and has no vasoconstrictive effects. It is most reliably given intranasally as a spray 10–40 μ g once or twice daily, but can also be given orally as 100–200 μ g three

Box 19.12 Water deprivation test
Indication

- Diagnosis or exclusion of diabetes insipidus.

Procedure

- Fasting and no fluids from 07:30 hours (or overnight if only mild DI is expected and polyuria is only modest).
- Monitor serum and urine osmolality, urine volume and weight hourly for up to 8 hours.
- Abandon fluid deprivation if weight loss >3% occurs.
- If serum osmolality >300 mOsm/kg and/or urine osmolality <600 mOsm/kg give desmopressin 2 µg i.m. at end of test. Allow free fluid but measure urine osmolality for 2–4 hours.

Interpretation

- *Normal response.* Serum osmolality remains within normal range (275–295 mOsm/kg). Urine osmolality rises to >600 mOsm/kg.
- *Diabetes insipidus (DI).* Serum osmolality rises above normal without adequate concentration of urine osmolality (i.e. serum osmolality >300 mOsm/kg; urine osmolality <600 mOsm/kg).
- *Nephrogenic DI* – if desmopressin does not concentrate urine.
- *Cranial DI* – if urine osmolality rises by >50% after desmopressin.

times daily, or intramuscularly 2–4 µg daily. Response is variable and must be monitored carefully with enquiry about fluid input/output and plasma osmolality measurements. The main problem is avoiding water overload and consequent hyponatraemia (p. 650). Where there is a reversible underlying cause (e.g. a hypothalamic tumour) this should be investigated and treated.

Alternative agents in mild DI, probably working by sensitizing the renal tubules to endogenous vasopressin, include thiazide diuretics, carbamazepine (200–400 mg daily) or chlorpropamide (200–350 mg daily) but these are rarely used.

Nephrogenic diabetes insipidus

In this condition, renal tubules are resistant to normal or high levels of plasma vasopressin (ADH). It may be inherited as a rare sex-linked recessive, with an abnormality in the vasopressin-2 receptor, or as an autosomal post-receptor defect in an ADH-sensitive water channel, aquaporin-2. More commonly it can be acquired as a result of renal disease, sickle cell disease, drug ingestion (e.g. lithium), hypercalcaemia or hypokalaemia. Wherever possible the cause should be reversed. Polyuria is helped by thiazide diuretics.

Other causes of polyuria and polydipsia

Diabetes mellitus, hypokalaemia and hypercalcaemia should be excluded. In the case of diabetes mellitus the cause is an osmotic diuresis secondary to glycosuria which leads to dehydration and an increased perception of thirst owing to hypertonicity of the extracellular fluid.

Primary polydipsia

This is a relatively common cause of thirst and polyuria. It is a psychiatric disturbance characterized by the excessive intake of water. Plasma sodium and osmolality fall as a result and the urine produced is appropriately dilute. Vasopressin levels become virtually undetectable. Prolonged primary polydipsia may lead to the phenomenon of 'renal medullary washout', with a fall in the concentrating ability of the kidney.

Table 19.36 Common causes of the syndrome of inappropriate ADH secretion (SIADH)

Tumours	Metabolic causes
Small-cell carcinoma of lung Prostate Thymus Pancreas Lymphomas	Alcohol withdrawal Porphyria
Pulmonary lesions	Drugs
Pneumonia Tuberculosis Lung abscess	Chlorpropamide Carbamazepine Cyclophosphamide Vincristine Phenothiazines
CNS causes	
Meningitis Tumours Head injury Subdural haematoma Cerebral abscess SLE Vasculitis	

Characteristically the diagnosis is made by a water deprivation test. A low plasma osmolality is usual at the start of the test, and since vasopressin secretion and action can be stimulated, the patient's urine becomes concentrated (albeit 'maximum' concentrating ability may be impaired); the initially low urine osmolality gradually increases with the duration of the water deprivation.

Syndrome of inappropriate antidiuretic hormone (SIADH)

Clinical features

Inappropriate secretion of ADH (also called vasopressin) leads to retention of water and hyponatraemia. The presentation is usually vague, with confusion, nausea, irritability and, later, fits and coma. There is no oedema. Mild symptoms usually occur with plasma sodium levels below 125 mmol/L and serious manifestations are likely below 115 mmol/L. The elderly may show symptoms with milder abnormalities.

The syndrome must be distinguished from dilutional hyponatraemia due to excess infusion of glucose/water solutions or diuretic administration (thiazides or amiloride, see p. 651).

Diagnosis

The usual features are:

- Dilutional hyponatraemia due to excessive water retention
- Euvolaemia (in contrast to hypovolaemia of sodium and water depletion states)
- Low plasma osmolality with 'inappropriate' urine osmolality >100 mOsm/kg (and typically higher than plasma osmolality)
- Continued urinary sodium excretion >30 mmol/L (lower levels suggest sodium depletion and should respond to 0.9% saline infusion)
- Absence of hypokalaemia (or hypotension)
- Normal renal and adrenal and thyroid function.

The causes are listed in Table 19.36.

Hyponatraemia is very common during illness in frail elderly patients and it may sometimes be clinically difficult to distinguish SIADH from salt and water depletion, particularly when mixed clinical features are present. Under these circumstances, a trial infusion of 1–2 L 0.9% saline is given.

SIADH will not respond (but will excrete the sodium and water load effectively) – sodium depletion will respond. ACTH deficiency can give a very similar biochemical picture to SIADH, therefore it is necessary to ensure the hypothalamic-pituitary-adrenal axis is intact, particularly in neurosurgical patients, in whom ACTH deficiency may be relatively common.

Treatment

The underlying cause should be corrected where possible. Symptomatic relief can be obtained by the following measures:

- Fluid intake should be restricted to 500–1000 mL daily. If tolerated, and complied with, this will correct the biochemical abnormalities in almost every case.
- Plasma osmolality, serum sodium and body weight should be measured frequently.
- If water restriction is poorly tolerated or ineffective, demeclocycline (600–1200 mg daily) is given; this inhibits the action of vasopressin on the kidney, causing a reversible form of nephrogenic diabetes insipidus. It often, however, causes photosensitive rashes.
- When the syndrome is very severe (i.e. acute and symptomatic), hypertonic saline may be indicated but this is potentially dangerous and should only be used with extreme caution (p. 650).
- Vasopressin V_2 antagonists, e.g. tolvaptan 15 mg daily, are being used with good results.

DISORDERS OF CALCIUM METABOLISM

Serum calcium levels are mainly controlled by parathyroid hormone (PTH) and vitamin D. Hypercalcaemia is much more common than hypocalcaemia and is frequently detected incidentally with multichannel biochemical analysers. Mild asymptomatic hypercalcaemia occurs in about 1 in 1000 of the population, with an incidence of 25–30 per 100 000 population. It occurs mainly in elderly females, and is usually due to primary hyperparathyroidism (primary HPT).

Parathyroid hormone

There are normally four parathyroid glands which are situated posterior to the thyroid, but occasionally additional glands exist or they may be found elsewhere in the neck or mediastinum. PTH, an 84-amino-acid hormone derived from a 115-residue preprohormone, is secreted from the chief cells of the parathyroid glands. PTH levels rise as serum ionized calcium falls. The latter is detected by specific G protein coupled calcium-sensing receptors on the plasma membrane of the parathyroid cells. PTH has several major actions, all serving to increase plasma calcium by:

- increasing osteoclastic resorption of bone (occurring rapidly)
- increasing intestinal absorption of calcium (a slow response)
- increasing synthesis of $1,25-(OH)_2D_3$
- increasing renal tubular reabsorption of calcium
- increasing excretion of phosphate.

PTH effects are mediated at specific membrane receptors on the target cells, resulting in an increase of adenyl cyclase messenger activity.

Vitamin D metabolism is discussed on page 550.

PTH measurements use two-site immunometric assays that measure only the intact PTH molecule; interpretation requires a simultaneous calcium measurement in order to differentiate most causes of hyper- and hypocalcaemia.

Hypercalcaemia

Pathophysiology and causes

The major causes of hypercalcaemia are listed in Table 19.37; primary hyperparathyroidism and malignancies are by far the most common (>90% of cases). Hyperparathyroidism itself may be primary, secondary or tertiary. Primary hyperparathyroidism is caused by single (>80%) parathyroid adenomas or by diffuse hyperplasia of all the glands (15–20%); multiple parathyroid adenomas are rare. Involvement of multiple parathyroid glands may be part of a familial syndrome (e.g. multiple endocrine neoplasia (MEN) syndrome type 1 or 2a). Parathyroid carcinoma is rare (<1%), though it usually produces severe and intractable hypercalcaemia. Hyperparathyroidism-jaw tumour syndrome is a rare familial cause of hyperparathyroidism which may be associated with parathyroid carcinoma and maxillary or mandibular tumours.

Primary hyperparathyroidism is of unknown cause, though it appears that adenomas are monoclonal. Hyperplasia may also be monoclonal. Chromosomal rearrangements in the 5' regulatory region of the parathyroid hormone gene have been identified, and inactivation of some tumour suppressor genes at a variety of sites may also be involved.

Secondary hyperparathyroidism (see p. 618) is physiological compensatory hypertrophy of all parathyroids because of hypocalcaemia, such as occurs in chronic kidney disease or vitamin D deficiency. PTH levels are raised but calcium levels are low or normal, and PTH falls to normal after correction of the cause of hypocalcaemia where this is possible.

Table 19.37 Causes of hypercalcaemia

Excessive parathormone (PTH) secretion
Primary hyperparathyroidism (commonest by far), adenoma (common), hyperplasia or carcinoma (rare)
Tertiary hyperparathyroidism
Ectopic PTH secretion (very rare indeed)
Malignant disease – low PTH levels (second commonest cause)
Myeloma
Secondary deposits in bone
Production of osteoclastic factors by tumours
PTH-related protein secretion
Excess action of vitamin D
Iatrogenic or self-administered excess
Granulomatous diseases, e.g. sarcoidosis, TB
Lymphoma
Excessive calcium intake
'Milk-alkali' syndrome
Other endocrine disease (mild hypercalcaemia only)
Thyrotoxicosis
Addison's disease
Drugs
Thiazide diuretics
Vitamin D analogues
Lithium administration (chronic)
Vitamin A
Miscellaneous
Long-term immobility
Familial hypocalciuric hypercalcaemia

FURTHER READING

Fraser WD. Hyperparathyroidism. *Lancet* 2009; 374: 145–158.

Marcocci C, Cetani F. Primary hyperparathyroidism. *N Engl J Med* 2011; 365:2389–2397.

Tertiary hyperparathyroidism is the development of apparently autonomous parathyroid hyperplasia after long-standing secondary hyperparathyroidism, most often in renal failure. Plasma calcium and phosphate are both raised, the latter often grossly so. Parathyroidectomy is necessary at this stage.

Symptoms and signs

Mild hypercalcaemia (e.g. adjusted calcium <3 mmol/L) is frequently asymptomatic, but more severe hypercalcaemia can produce a number of symptoms:

- **General.** There may be tiredness, malaise, dehydration and depression.
- **Renal.** Renal colic from stones, polyuria or nocturia, haematuria and hypertension occurs. The polyuria results from the effect of hypercalcaemia on renal tubules, reducing their concentrating ability – a form of mild nephrogenic diabetes insipidus. Primary hyperparathyroidism is present in about 5% of patients who present with renal calculi.
- **Bones.** There may be bone pain. Hyperparathyroidism mainly affects cortical bone, and bone cysts and locally destructive ‘brown tumours’ occur but only in advanced disease. Only 5–10% of all cases have definite bony lesions even when sought. Bone disease may be more apparent when there is co-existing vitamin D deficiency.
- **Abdomen.** There may be abdominal pain.
- **Chondrocalcinosis** and ectopic calcification. These are occasional features.
- **Corneal calcification.** This is a marker of longstanding hypercalcaemia but causes no symptoms.

There may also be symptoms from the underlying cause. Malignant disease is usually advanced by the time hypercalcaemia occurs, typically with bony metastases. The common primary tumours are bronchus, breast, myeloma, oesophagus, thyroid, prostate, lymphoma and renal cell carcinoma. True ‘ectopic PTH secretion’ by the tumour is very rare, and most cases are associated with raised levels of PTH-related protein. This is a 144-amino-acid polypeptide, the initial sequence of which shows an approximate homology with the biologically active part of PTH, which is necessary in fetal development but does not have a clearly defined role in the adult. Local bone-resorbing cytokines and prostaglandins may be involved locally where there are metastatic skeletal lesions, leading to local mobilization of calcium by osteolysis with subsequent hypercalcaemia.

Severe hypercalcaemia (>3 mmol/L) is usually associated with malignant disease, hyperparathyroidism, chronic kidney disease or vitamin D therapy.

Investigations and differential diagnosis

Biochemistry

Several fasting serum calcium and phosphate samples should be performed.

- **Serum PTH.** The hallmark of primary hyperparathyroidism is hypercalcaemia and hypophosphataemia with detectable or elevated intact PTH levels during hypercalcaemia. When this combination is present in an asymptomatic patient then further investigation is usually unnecessary. However, an undetectable PTH level in the context of hypercalcaemia always requires further investigation to exclude malignancy or other pathology (Table 19.37).

- **Hyperchloraemic acidosis – often mild.**
- **Renal function** is usually normal but should be measured as a baseline.
- **24-hour urinary calcium** or single calcium creatinine ratio should be measured in a young patient with modest elevation in calcium and PTH to exclude familial hypocalciuric hypercalcaemia (see p. 996).
- **Elevated serum alkaline phosphatase** is found in severe parathyroid bone disease, but otherwise it suggests an alternative cause for hypercalcaemia. Where PTH is undetectable or equivocal, a number of other tests may lead to the diagnosis:
 - Protein electrophoresis/immunofixation: to exclude myeloma
 - Serum TSH: to exclude hyperthyroidism
 - 09:00 hours cortisol and/or ACTH test: to exclude Addison’s disease
 - Serum ACE: helpful in the diagnosis of sarcoidosis
 - Hydrocortisone suppression test: hydrocortisone 40 mg three times daily for 10 days leads to suppression of plasma calcium in sarcoidosis, vitamin D-mediated hypercalcaemia and some malignancies.

Imaging

Abdominal X-rays may show renal calculi or nephrocalcinosis. High-definition hand X-rays can show subperiosteal erosions in the middle or terminal phalanges. DXA bone density scan is useful to detect bone effects in asymptomatic people with hyperparathyroidism (HPT) in whom conservative management is planned.

The success of parathyroid imaging is highly operator dependent and choice therefore depends on local skills and experience. Imaging is frequently far less accurate than parathyroid exploration by an expert surgeon where the success rate is at least 90%. Methods include:

- Ultrasound, which, although insensitive for small tumours, is simple and safe
- High-resolution CT scan or MRI (more sensitive)
- Radioisotope scanning using ^{99m}Tc -sestamibi, which is approximately 90% sensitive in detecting adenomas.

Treatment of hypercalcaemia

Details of emergency treatment for severe hypercalcaemia are given in [Emergency Box 19.2](#). This should be followed by oral therapy unless the underlying disease can be treated.

Treatment of primary hyperparathyroidism

Medical management

There are no effective medical therapies at present for primary hyperparathyroidism, but a high fluid intake should be maintained, a high calcium or vitamin D intake avoided, and exercise encouraged. New therapeutic agents that target the calcium-sensing receptors (e.g. cinacalcet) are of proven value in parathyroid carcinoma and in dialysis patients (p. 631), and are used in primary hyperparathyroidism where surgical intervention is contraindicated.

Surgery

There is agreement that surgery is indicated in primary hyperparathyroidism for:

- people with renal stones or impaired renal function
- bone involvement or marked reduction in cortical bone density

Emergency Box 19.2

Treatment of acute severe hypercalcaemia

Acute hypercalcaemia often presents with dehydration, nausea and vomiting, nocturia and polyuria, drowsiness and altered consciousness. The serum Ca^{2+} is over 3 mmol/L and sometimes as high as 5 mmol/L. While investigation of the cause is under way, immediate treatment is mandatory if the patient is seriously ill or if the Ca^{2+} is above 3.5 mmol/L.

- **Rehydrate** at least 4–6 L of 0.9% saline on day 1, and 3–4 L for several days thereafter. Central venous pressure (CVP) may need to be monitored to control the hydration rate.
- **Intravenous bisphosphonates** are the treatment of choice for hypercalcaemia of malignancy or of undiagnosed cause. Pamidronate is preferred (60–90 mg as an intravenous infusion in 0.9% saline or glucose over 2–4 hours or, if less urgent, over 2–4 days). Levels fall after 24–72 hours, lasting for approximately two weeks. Zoledronate is an alternative.
- **Prednisolone** (30–60 mg daily) is effective in some instances (e.g. in myeloma, sarcoidosis and vitamin D excess) but in most cases is ineffective.
- **Calcitonin** (200 units i.v. 6-hourly) has a short-lived action and is little used.
- **Oral phosphate** (sodium cellulose phosphate 5 g three times daily) produces diarrhoea.

- unequivocal marked hypercalcaemia (in UK typically >3.0 mmol/L; USA guidelines state >1 mg/dL above reference range)
- the uncommon younger patient, below age 50 years
- a previous episode of severe acute hypercalcaemia.

The situation where plasma calcium is mildly raised (2.65–3.00 mmol/L) is more controversial. Most authorities feel that young patients should be operated on, as should those who have reduced cortical bone density or significant hypercalcaemia, as this is associated with stone formation.

In older patients without these problems, or in those unfit for or unwilling to have surgery, conservative management is indicated. Regular measurement of serum calcium and of renal function is necessary. Bone density of cortical bone should be monitored if conservative management is used. Hyperparathyroidism can cause nonspecific symptoms of weakness, fatigue and depression, and it can be difficult to determine whether these symptoms are related to hypercalcaemia or coincidental.

Surgical technique and complications

Parathyroid surgery should be performed only by experienced surgeons, as the minute glands may be very difficult to define, and it is difficult to distinguish between an adenoma and normal parathyroid. In expert centres over 90% of operations are successful, involving removal of the adenoma, or removal of all four hyperplastic parathyroids. Minimal access surgery is used, and some centres measure PTH levels intraoperatively to ensure the adenoma has been removed.

Other than postoperative hypocalcaemia (see below), the other rare complications are those of thyroid surgery – bleeding and recurrent laryngeal nerve palsies ($<1\%$). Vocal cord function should be checked preoperatively.

If initial exploration is unsuccessful, a full work-up including venous catheterization and scanning is essential, remembering that parathyroid tissue can be ectopic.

Postoperative care

The major danger after operation is hypocalcaemia, which is more common in patients who have significant bone disease and/or vitamin D deficiency – the ‘hungry bone’ syndrome. Some authorities pre-treat such patients, with alfacalcidol 2 μg daily from 2 days preoperatively for 10–14 days, and routine vitamin D replacement (preferably without calcium) is always indicated if deficiency is diagnosed. Chvostek’s and Trousseau’s signs (see p. 997) are monitored as well as biochemistry. Plasma calcium measurements are performed at least daily until stable – with or without replacement – a mild transient hypoparathyroidism often continues for 1–2 weeks. Depending on its severity, oral or intravenous calcium should be given temporarily, as only a few patients ($<1\%$) will develop longstanding surgical hypoparathyroidism.

Familial hypocalciuric hypercalcaemia

This uncommon autosomal dominant, and usually asymptomatic, condition demonstrates increased renal reabsorption of calcium despite hypercalcaemia. PTH levels are normal or slightly raised and urinary calcium is low. It is caused by loss of function mutations in the gene on the long arm of chromosome 3 encoding for the calcium-ion-sensing G-protein coupled receptor in the kidney and parathyroid gland. Family members are often affected, detected by genetic analysis. Parathyroid surgery is not indicated as the course appears benign. This diagnosis can be differentiated from hyperparathyroidism in an isolated case by the calcium creatinine ratio in blood and urine.

Hypocalcaemia and hypoparathyroidism

Pathophysiology

Hypocalcaemia may be due to deficiencies of calcium homeostatic mechanisms, secondary to high phosphate levels or other causes of hypocalcaemia (Table 19.38). All forms of hypoparathyroidism, except transient surgical effects, are uncommon.

Table 19.38 Causes of hypocalcaemia

Increased phosphate levels
Chronic kidney disease (common) Phosphate therapy
Hypoparathyroidism
Surgical – after neck exploration (thyroidectomy, parathyroidectomy – common) Congenital deficiency (DiGeorge’s syndrome) Idiopathic hypoparathyroidism (rare) Severe hypomagnesaemia
Vitamin D deficiency
Osteomalacia/rickets Vitamin D resistance
Resistance to PTH
Pseudohypoparathyroidism
Drugs
Calcitonin Bisphosphonates
Other
Acute pancreatitis (quite common) Citrate blood in massive transfusion (not uncommon) Low plasma albumin, e.g. malnutrition, chronic liver disease Malabsorption, e.g. coeliac disease

FURTHER READING

Shoback D.
Hypoparathyroidism.
N Engl J Med 2008;
359:391–403.

Causes

- **Chronic kidney disease** is the most common cause of hypocalcaemia.
- **Severe vitamin D deficiency** may cause mild, and occasionally severe, hypocalcaemia.
- **Hypocalcaemia after thyroid or parathyroid surgery** is common but usually transient – fewer than 1% of thyroidectomies leave permanent damage (see above).
- **Idiopathic hypoparathyroidism** is one of the rarer autoimmune disorders, often accompanied by vitiligo, cutaneous candidiasis and other autoimmune disease.

DiGeorge's syndrome (p. 66) is a familial condition in which the hypoparathyroidism is associated with intellectual impairment, cataracts and calcified basal ganglia, and occasionally with specific autoimmune disease.

Pseudohypoparathyroidism is a syndrome of end-organ resistance to PTH owing to a mutation in the $G_{s\alpha}$ -protein (GNAS1) which is coupled to the PTH receptor. It is associated with short stature, short metacarpals, subcutaneous calcification and sometimes intellectual impairment. Variable degrees of resistance involving other G protein-linked hormone receptors may also be seen (TSH, LH, FSH).

Pseudo-pseudohypoparathyroidism describes the phenotypic defects but without any abnormalities of calcium metabolism. These individuals may share the same gene defect as individuals with pseudohypoparathyroidism and be members of the same families.

Clinical features

Hypoparathyroidism presents as neuromuscular irritability and neuropsychiatric manifestations. Paraesthesiae, circum-oral numbness, cramps, anxiety and tetany (**Box 19.13**) are followed by convulsions, laryngeal stridor, dystonia and psychosis. Two signs of hypocalcaemia are Chvostek's sign (gentle tapping over the facial nerve causes twitching of the ipsilateral facial muscles) and Trousseau's sign, where inflation of the sphygmomanometer cuff above systolic pressure for 3 min induces tetanic spasm of the fingers and wrist. Severe hypocalcaemia may cause papilloedema and frequently a prolonged QT interval on the ECG.

Investigations

The clinical history and picture is usually diagnostic and is confirmed by a low serum calcium (after correction for any albumin abnormality). Additional tests include:

- **Serum and urine creatinine** for renal disease
- **PTH levels** in the serum: absent or inappropriately low in hypoparathyroidism, high in other causes of hypocalcaemia
- **Parathyroid antibodies** (present in idiopathic hypoparathyroidism)

- **25-hydroxy vitamin D serum level** (low in vitamin D deficiency)
- **Magnesium level:** severe hypomagnesaemia results in functional hypoparathyroidism which is reversed by magnesium replacement
- **X-rays of metacarpals**, showing short fourth metacarpals which occur in pseudohypoparathyroidism.

Treatment

In vitamin D deficiency, cholecalciferol is the most appropriate treatment (see p. 559). In other cases, alpha-hydroxylated derivatives of vitamin D are preferred for their shorter half-life, and especially in renal disease as the others require renal hydroxylation. Usual daily maintenance doses are 0.25–2 µg for alfacalcidol (1α-OH-D₃). During treatment, plasma calcium must be monitored frequently to detect hypercalcaemia. Oral calcium supplements may be used in early stages of treatment and severe hypocalcaemia presenting as an emergency may occasionally require replacement with i.v. calcium gluconate.

OTHER ENDOCRINE DISORDERS

Diseases of many glands

Multiple gland failure (polyglandular autoimmune syndromes)

These are caused by autoimmune disease as detailed in **Table 19.2** on **page 939**. Most common are the associations of primary hypothyroidism and type 1 diabetes, and either of these with Addison's disease or pernicious anaemia.

Autoimmune polyendocrinopathy type 1 (APS-1) is an autosomal recessive disorder and is caused by *AIRE* gene mutations. The *AIRE* gene is present in the epithelium of the thymus and is involved in the presentation of self-antigens to thymocytes. Mutations will allow persistence of thymic lymphocytes, which react against self-antigens and cause development of autoimmune disorders. Mucocutaneous candidiasis often develops before the onset of endocrine deficiencies, such as Addison's disease, type 1 diabetes, hypoparathyroidism, nail dystrophy, vitiligo and dental enamel hypoplasia.

APS-2 is not associated with candidiasis and is also known as Schmidt's syndrome, typically when hypothyroidism, Addison's disease and type 1 diabetes are present in combination; coeliac disease is also an association.

Multiple endocrine neoplasias

This is the name given to the simultaneous or metachronous occurrence of tumours involving a number of endocrine glands (**Table 19.39**). The condition is inherited in an autosomal dominant manner and arises from the expression of recessive oncogenic mutations, most of which have been isolated. Affected persons may pass on the mutation to their offspring in the germ cell, but for the disease to become evident a somatic mutation must also occur, such as deletion or loss of a normal homologous chromosome.

MEN 1

The defect in MEN 1 is in a novel gene (*menin*) on the long arm of chromosome 11 which encodes for a 610-amino-acid protein. *Menin* represses a transcription factor (*JunD*) and lack of *JunD* suppression leads to decreased apoptosis and oncogenesis. People with the *MEN1* gene carry one mutant

Box 19.13 Causes of tetany

In the presence of alkalosis

- Hyperventilation
- Excess antacid therapy
- Persistent vomiting
- Hypochloraemic alkalosis, e.g. primary hyperaldosteronism

In the presence of hypocalcaemia

(see **Table 19.38**)

Table 19.39 Multiple endocrine neoplasia (MEN) syndromes

Organ	Frequency	Tumours/manifestations
Type 1		
Parathyroid	95%	Adenomas/hyperplasia
Pituitary	70%	Adenomas – prolactinoma, ACTH or growth hormone secreting (acromegaly)
Pancreas	50%	Islet cell tumours (secreting insulin, glucagon, somatostatin, VIP, pancreatic polypeptide, growth hormone-releasing factor)
		Zollinger–Ellison syndrome (gastrinoma)
		Non-functional tumour
Adrenal	40%	Non-functional adenoma
Thyroid	20%	Adenomas – multiple or single
Type 2a		
Adrenal	Most	Phaeochromocytoma (70% bilateral)
		Cushing's syndrome
Thyroid	Most	Medullary carcinoma (calcitonin producing)
Parathyroid	60%	Hyperplasia
Type 2b		
Type 2a with marfanoid phenotype and intestinal and visceral ganglioneuromas but not hyperparathyroidism. Neuromas also present around lips and tongue.		

Multiple liver metastases from a pancreatic endocrine tumour in multiple endocrine neoplasia type 1.

gene and a wild type gene (i.e. are heterozygous). When the wild type gene undergoes a random somatic mutation during life, this leads to loss of heterozygosity and explains the late onset of tumours at any stage (the 'two hit' hypothesis). MEN 1 is classically associated with pancreatic, parathyroid and pituitary tumours, although other glands may be affected (Table 19.39).

MEN 2a and 2b

MEN 2a and 2b are caused by mutations of the *RET* proto-oncogene on chromosome 10 (see medullary thyroid cancer, p. 971). This gene encodes for a transmembrane glycoprotein receptor. For MEN 2a the mutation is in the extracellular domain; for 2b it is in the intracellular domain. MEN 2 is classically associated with parathyroid tumours, phaeochromocytoma and medullary thyroid carcinoma (Table 19.39). Unlike MEN 2a, MEN 2b is associated with a marfanoid phenotype and intestinal and visceral ganglioneuromas, as well as neuromas around the lips and tongue.

Management

Treatment of established tumours in MEN is largely the same as treatment for similar tumours occurring sporadically. In MEN 1 four-gland parathyroidectomy is usually recommended when surgery is needed since all glands are typically involved. However, the essence of management in MEN is annual screening to detect tumours at an early, treatable stage.

Screening

A careful family history is essential. If the precise gene mutation has been identified in a particular family, then family members at risk can be offered genetic screening for the presence of the mutation, ideally in childhood. In affected individuals, biochemical screening and periodic imaging is then required.

Screening for MEN 1

Hyperparathyroidism is usually the first manifestation, and serum calcium is the simplest screening test in families with no identified mutation. In an established case (or gene-positive family member) other screening bloods include prolactin, GH/IGF-1 and 'gut hormones' (p. 247). Periodic imaging of pancreas, adrenals and pituitary is usually performed. People with MEN 1 can develop metastases to the liver from

non-functional pancreatic tumours which are clinically silent; this emphasizes the need for regular screening imaging.

Screening for MEN 2

Serum calcium levels will easily detect hyperparathyroidism.

- **Medullary carcinoma of thyroid (MCT)** – with the known presence of the gene defect, total thyroidectomy is recommended in early childhood or as soon as the gene defect is identified. Calcitonin is a useful tumour marker.
- **Phaeochromocytoma** – metanephrine or catecholamine estimations.

McCune–Albright syndrome

This condition is associated with autonomous hypersecretion of a number of endocrine glands at a young age. Gonadotrophin-independent puberty with Leydig cell hyperplasia in males and ovarian oestrogen production in girls occurs. Pituitary hypersecretion may lead to hyperprolactinaemia, acromegaly or gigantism. Cushing's syndrome due to nodular hyperplasia of the adrenal cortex is observed, as well as autonomous functioning thyroid nodules. Non-endocrine manifestations include café-au-lait patches and increased bone deformity and fractures due to polyostotic fibrous dysplasia. The pathological basis is a point mutation of the *GNAS1* gene that inhibits GTPase activity, leading to persistent activation of cAMP-mediated endocrine secretion.

Ectopic hormone secretion

This term refers to hormone synthesis, and normally secretion, from a neoplastic non-endocrine cell, most usually seen in tumours that have some degree of embryological resemblance to specialist endocrine cells. The clinical effects are those of the hormone produced, with or without manifestations of systemic malignancy. The most common situations seen are the following:

- **Hypercalcaemia of malignant disease**, often from squamous cell tumours of lung and breast, often with bone metastases. Where metastases are not present, most cases are mediated by secretion of PTH-related

protein (PTHrP), which has considerable sequence homology to PTH; a variety of other factors may sometimes be involved, but very rarely PTH itself (see p. 995). Treatment is also discussed on page 995.

- **SIADH** (see p. 993). Again, this is most common from a primary lung tumour.
- **Ectopic ACTH syndrome** (see p. 953). Small-cell carcinoma of the lung, carcinoid tumours and medullary thyroid carcinomas are the most common causes, though many other tumours rarely cause it.
- **Production of insulin-like activity** may result in hypoglycaemia (see p. 1029).

Endocrine treatment of other malignancies

DIABETES MELLITUS

HYPERGLYCAEMIA, INSULIN AND INSULIN ACTION

Introduction

Diabetes mellitus (DM) is a syndrome of chronic hyperglycaemia due to relative insulin deficiency, resistance or both. It affects more than 220 million people worldwide, and it is estimated that it will affect 440 million by the year 2030. Diabetes is usually irreversible and, although patients can lead a reasonably normal lifestyle, its late complications result in reduced life expectancy and major health costs. These include macrovascular disease, leading to an increased prevalence of coronary artery disease, peripheral vascular disease and stroke, and microvascular damage causing diabetic retinopathy and nephropathy. Neuropathy is another major complication.

Insulin structure and secretion

Insulin is the key hormone involved in the storage and controlled release within the body of the chemical energy available from food. It is coded for on chromosome 11 and synthesized in the beta cells of the pancreatic islets (Fig. 20.1). The synthesis, intracellular processing and secretion of insulin by the beta cell is typical of the way that the body produces and manipulates many peptide hormones. Figure 20.2 illustrates the cellular events triggering the release of insulin-containing granules. After secretion, insulin enters the portal circulation and is carried to the liver, its prime target organ. About 50% of secreted insulin is extracted and degraded in the liver; the residue is broken down by the

kidneys. C-peptide is only partially extracted by the liver (and hence provides a useful index of the rate of insulin secretion) but is mainly degraded by the kidneys.

An outline of glucose metabolism

Blood glucose levels are closely regulated in health and rarely stray outside the range of 3.5–8.0 mmol/L (63–144 mg/dL), despite the varying demands of food, fasting and exercise. The principal organ of glucose homeostasis is the liver, which absorbs and stores glucose (as glycogen) in the post-absorptive state and releases it into the circulation between meals to match the rate of glucose utilization by peripheral tissues. The liver also combines 3-carbon molecules derived from breakdown of fat (glycerol), muscle glycogen (lactate) and protein (e.g. alanine) into the 6-carbon glucose molecule by the process of gluconeogenesis.

Glucose production

About 200 g of glucose is produced and utilized each day. More than 90% is derived from liver glycogen and hepatic gluconeogenesis, and the remainder from renal gluconeogenesis.

Glucose utilization

The brain is the major consumer of glucose, and its function depends upon an uninterrupted supply of this substrate. Its requirement is 1 mg/kg bodyweight per minute, or 100 g daily in a 70 kg man. Glucose uptake by the brain is obligatory and is not dependent on insulin, and the glucose used is oxidized to carbon dioxide and water. Other tissues, such as muscle and fat, are facultative glucose consumers. The effect of insulin peaks associated with meals is to lower

Figure 20.1 Part of a beta cell. The ribosomes manufacture pre-proinsulin from insulin mRNA. The hydrophobic 'pre' portion of pre-proinsulin allows it to transfer to the Golgi apparatus, and is subsequently enzymatically cleaved off. Proinsulin is parcelled into secretory granules in the Golgi apparatus. These mature and pass towards the cell membrane where they are stored before release. The proinsulin molecule folds back on itself and is stabilized by disulphide bonds. The biochemically inert peptide fragment known as connecting (C) peptide splits off from proinsulin in the secretory process, leaving insulin as a complex of two linked peptide chains. Equimolar quantities of insulin and C-peptide are released into the circulation via the 'regulated pathway'. A small amount of insulin is secreted by the beta cell directly via the 'constitutive pathway', which bypasses the secretory granules.

the threshold for glucose entry into cells; at other times, energy requirements are largely met by fatty-acid oxidation. Glucose taken up by muscle is stored as glycogen or metabolized to lactate or carbon dioxide and water. Fat uses glucose as a source of energy and as a substrate for triglyceride synthesis; lipolysis releases fatty acids from triglyceride together with glycerol, a substrate for hepatic gluconeogenesis.

Hormonal regulation

Insulin is a major regulator of intermediary metabolism, although its actions are modified in many respects by other hormones. Its actions in the fasting and postprandial states differ (Fig. 20.3). In the fasting state, its main action is to regulate glucose release by the liver, and in the postprandial state, it additionally promotes glucose uptake by fat and muscle. The effect of counter-regulatory hormones (glucagon, epinephrine (adrenaline), cortisol and growth hormone) is to cause greater production of glucose from the liver and less utilization of glucose in fat and muscle for a given level of insulin.

Glucose transport

Cell membranes are not inherently permeable to glucose. A family of specialized glucose-transporter (GLUT) proteins carry glucose through the membrane into cells.

- **GLUT-1** – enables basal non-insulin-stimulated glucose uptake into many cells (see Fig. 6.29).
- **GLUT-2** – transports glucose into the beta cell, a prerequisite for glucose sensing, and is also present in the renal tubules and hepatocytes.
- **GLUT-3** – enables non-insulin-mediated glucose uptake into brain neurones and placenta.
- **GLUT-4** – enables much of the peripheral action of insulin. It is the channel through which glucose is taken up into muscle and adipose tissue cells following stimulation of the insulin receptor (Fig. 20.4).

Figure 20.2 Local forces regulating insulin secretion from beta cells. Glucose enters the beta cell via the GLUT-2 transporter protein, which is closely associated with the glycolytic enzyme glucokinase. Metabolism of glucose within the beta cell generates ATP. ATP closes potassium channels in the cell membrane (a). If a sulfonyleurea binds to its receptor, this also closes potassium channels. Closure of potassium channels predisposes to cell membrane depolarization, allowing calcium ions to enter the cell via calcium channels in the cell membrane (b). The rise in intracellular calcium triggers activation of calcium-dependent phospholipid protein kinase which, via intermediary phosphorylation steps, leads to fusion of the insulin-containing granules with the cell membrane and exocytosis of the insulin-rich granule contents. Similar mechanisms produce hormone-granule secretion in many other endocrine cells.

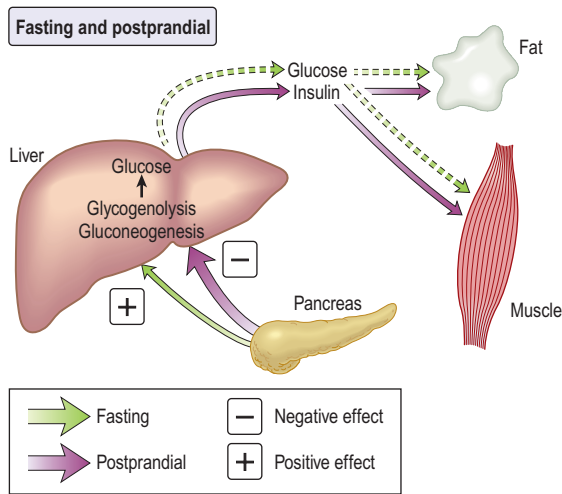

Figure 20.3 Fasting and postprandial effects of insulin. In the **fasting state**, insulin concentrations are low and it acts mainly as a hepatic hormone, modulating glucose production (via glycogenolysis and gluconeogenesis) from the liver. Hepatic glucose production rises as insulin levels fall. In the **postprandial state** insulin concentrations are high and it then suppresses glucose production from the liver and promotes the entry of glucose into peripheral tissues (increased glucose utilization).

Figure 20.4 Insulin signalling in peripheral cells (e.g. muscle and adipose tissue). The insulin receptor (consists of α - and β -subunits linked by disulphide bridges (top right of figure)). The β -subunits straddle the cell membrane. The transporter protein GLUT-4 (bottom left of figure) is stored in intracellular vesicles. The binding of insulin to its receptor initiates many intracellular actions including translocation of these vesicles to the cell membrane, carrying GLUT-4 with them; this allows glucose transport into the cell.

The insulin receptor

This is a glycoprotein (400 kDa), coded for on the short arm of chromosome 19, which straddles the cell membrane of many cells (Fig. 20.4). It consists of a dimer with two α -subunits, which include the binding sites for insulin, and two β -subunits, which traverse the cell membrane. When insulin binds to the α -subunits it induces a conformational change in the β -subunits, resulting in activation of tyrosine

kinase and initiation of a cascade response involving a host of other intracellular substrates. One consequence of this is migration of the GLUT-4 glucose transporter to the cell surface and increased transport of glucose into the cell. The insulin-receptor complex is then internalized by the cell, insulin is degraded, and the receptor is recycled to the cell surface.

CLASSIFICATION OF DIABETES

Diabetes may be primary (idiopathic) or secondary (Table 20.1). Primary diabetes is classified into:

- **Type 1 diabetes**, which has an immune pathogenesis and is characterized by severe insulin deficiency
- **Type 2 diabetes**, which results from a combination of insulin resistance and less severe insulin deficiency.

The key clinical features of the two main forms of diabetes are listed in Table 20.2. Type 1 and type 2 diabetes represent two distinct diseases from the epidemiological point of view, but clinical distinction can sometimes be difficult. The two diseases should from a clinical point of view be seen as a spectrum, distinct at the two ends but overlapping to some extent in the middle. Hybrid forms are increasingly recognized, and patients with immune-mediated diabetes (type 1) may, for example, also be overweight and insulin resistant. This is sometimes referred to as 'double diabetes'. It is more relevant to give the patient the right treatment on clinical grounds than to worry about how to label their diabetes. The classification of primary diabetes continues to evolve. Monogenic forms have been identified (see p. 1007), in some cases with significant therapeutic implications. Although secondary diabetes accounts for barely 1–2% of all new cases at presentation, it should not be missed because the cause can sometimes be treated. All forms of diabetes derive from inadequate insulin secretion relative to the needs of the body, and progressive insulin secretory failure is characteristic of both common forms of diabetes. Thus, some patients with immune-mediated diabetes type 1 may not at first require insulin, whereas many with type 2 diabetes will eventually do so.

Type 1 diabetes mellitus

Epidemiology

Type 1 diabetes is a disease of insulin deficiency. In western countries almost all patients have the immune-mediated form of the disease, otherwise known as type 1A. Type 1 diabetes is a disease of childhood, reaching a peak incidence around the time of puberty, but can present at any age. A 'slow-burning' variant with slower progression to insulin deficiency occurs in later life and is sometimes called *latent autoimmune diabetes in adults (LADA)*. LADA may be difficult to distinguish from type 2 diabetes. Clinical clues are: leaner build, rapid progression to insulin therapy following an initial response to other therapies, and the presence of circulating islet autoantibodies. The highest rates of type 1 diabetes in the world are seen in Finland and other Northern European countries, and on the island of Sardinia, which for unknown reasons, has the second highest rate in the world (Fig. 20.5). The incidence of type 1 diabetes appears to be increasing in most populations. In Europe, the annual increase is of the order of 2–3%, and is most marked in children under the age of 5 years. WHO estimated in 1995 that there were 19.4 million people with type 1 diabetes and that the number will rise to 57.2 million by 2025.

DIABETES MELLITUS

Hyperglycaemia, insulin and insulin action

Classification of diabetes

Table 20.1 Aetiological classification of diabetes mellitus, based on classification by the American Diabetes Association (ADA)

Type 1 diabetes Beta-cell destruction, usually leading to absolute insulin deficiency Immune mediated Idiopathic Type 2 diabetes May range from predominantly insulin resistance with relative insulin deficiency to a predominantly secretory defect with insulin resistance Other specific types Genetic defects of beta-cell function Genetic defects in insulin action (mainly receptor mutations) <i>Diseases of the exocrine pancreas</i> Pancreatitis Trauma/pancreatectomy Neoplasia Cystic fibrosis Haemochromatosis Fibrocalculous pancreatopathy Other <i>Endocrinopathies</i> Acromegaly Cushing's syndrome Glucagonoma Pheochromocytoma Hyperthyroidism Somatostatinoma Aldosteronoma Others <i>Drug- or chemical-induced</i> Vacor (pyrinuron) Pentamidine Nicotinic acid (Niacin) Beta-blockers Thyroid hormone Diazoxide	β -adrenergic agonists Thiazides Phenytoin α -Interferon Protease inhibitors <i>Immunosuppressive agents</i> Glucocorticoids Ciclosporin Tacrolimus Sirolimus <i>Anti-psychotic agents</i> Clozapine Olanzapine Others <i>Infections</i> Congenital rubella Cytomegalovirus Others Uncommon forms of immune-mediated diabetes 'Stiff-person' syndrome Anti-insulin receptor antibodies Other genetic syndromes sometimes associated with diabetes: Down's syndrome Friedreich's ataxia Huntington's chorea Klinefelter's syndrome Laurence-Moon-Biedl syndrome Myotonic dystrophy Porphyria Prader-Willi syndrome Turner's syndrome Wolfram's syndrome Other Gestational diabetes mellitus
---	---

Note: Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient. (Adapted from ADA. Diagnosis and classification of diabetes mellitus. *Diabetes Care* 2008; 31(Suppl 1):S55-S60.)

Table 20.2 The spectrum of diabetes: a comparison of type 1 and type 2 diabetes mellitus

	Type 1	Type 2
Age	Younger (usually <30)	Older (usually >30)
Weight	Lean	Overweight
Symptom duration	Weeks	Months/years
Higher risk ethnicity	Northern European	Asian, African, Polynesian and American-Indian
Seasonal onset	Yes	No
Heredity	HLA-DR3 or DR4 in >90%	No HLA links
Pathogenesis	Autoimmune disease	No immune disturbance
Ketonuria	Yes	No
Clinical	Insulin deficiency \pm ketoacidosis Always need insulin	Partial insulin deficiency initially \pm hyperosmolar state Need insulin when beta cells fail over time
Biochemical	C-peptide disappears	C-peptide persists

Causes

Type 1 diabetes belongs to a family of HLA-associated immune-mediated organ-specific diseases. Genetic susceptibility is polygenic, with the greatest contribution from the HLA region. Autoantibodies directed against pancreatic islet constituents appear in the circulation within the first few years of life, and often predate clinical onset by many years. Autoantibodies are also found in older patients with LADA and carry an increased risk of progression to insulin therapy.

Genetic susceptibility and inheritance

Increased susceptibility to type 1 diabetes is inherited, but the disease is not genetically predetermined. The identical twin of a patient with type 1 diabetes has a 30–50% chance of developing the disease, which implies that non-genetic factors must also be involved. The risk of developing diabetes by age 20, curiously, is greater with a diabetic father (3–7%) than with a diabetic mother (2–3%). If one child in a family has type 1 diabetes, each sibling has a ~6% risk of developing diabetes by age 20. This risk rises to about 20% in HLA-identical siblings who have the same HLA type as the proband. Since type 1 diabetes can present at any age, the lifetime risk for a sibling or child is at least double the risk by age 20.

HLA system

The HLA genes on chromosome 6 are highly polymorphic and modulate the immune defence system of the body.

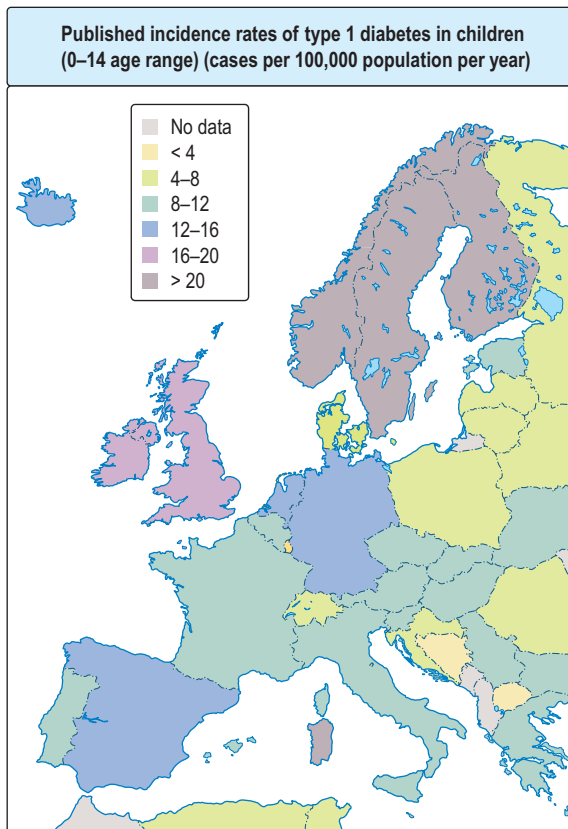

Figure 20.5 Age-standardized incidence rates of type 1 diabetes (onset 0–14 years) in Europe, per 100 000/year. (Data courtesy of International Diabetes Federation.)

More than 90% of patients with type 1 diabetes carry HLA-DR3-DQ2, HLA-DR4-DQ8 or both, as compared with some 35% of the background population. All DQB1 alleles with an aspartic acid at residue 57 confer neutral to protective effects with the strongest effect from DQB1*0602 (DQ6), while DQB1 alleles with an alanine at the same position (i.e. DQ2 and DQ8) confer strong susceptibility. Genotypic combinations have a major influence upon risk of disease. For example, HLA DR3-DQ2/HLA DR4-DQ8 heterozygotes have a considerably increased risk of disease, and some HLA class I alleles also modify the risk conferred by class II susceptibility genes.

Other genes or gene regions

Genome-wide association studies have greatly broadened our understanding of the genetic background to type 1 diabetes and more than 50 non-HLA genes or gene regions that influence risk have been identified to date. The greatest genetic contribution still comes from the HLA region, but this is modulated by a large number of genes with small effects. These include the gene encoding insulin (*INS*) on chromosome 11 and a number of genes involved in immune responses, including the cytotoxic T-lymphocyte-associated protein-4 (*CTLA4*) gene, the lymphoid-specific protein tyrosine phosphatase (*PTPN22*) gene and the IL-2R α -subunit of the IL-2 receptor complex locus (*IL2RA*), all of which are implicated in a variety of HLA-associated autoimmune conditions.

Autoimmunity and type 1 diabetes

Type 1 diabetes is associated with other organ-specific autoimmune diseases including autoimmune thyroid disease,

Figure 20.6 Islet autoantibodies. Islet cell antibodies are detected by a fluorescent antibody technique which detects binding of autoantibodies to islet cells. Much of this staining reaction is due to antibodies specific for glutamic acid decarboxylase (GAD) and protein tyrosine phosphatase – IA-2 (also known as ICA512). Not all the staining seen with ICA is due to these two autoantibodies, so it is assumed that other islet autoantibodies are also involved. Insulin autoantibodies also appear in the circulation but do not contribute to the ICA reaction.

coeliac disease, Addison's disease and pernicious anaemia. Autopsies of patients who died following diagnosis of type 1 diabetes show infiltration of the pancreatic islets by mononuclear cells. This appearance, known as insulinitis, resembles that in other autoimmune diseases such as thyroiditis. Several islet antigens have been characterized, and these include insulin itself, the enzyme glutamic acid decarboxylase (GAD), protein tyrosine phosphatase (IA-2) (Fig. 20.6) and the cation transporter ZnT8. Recent studies have shown that GAD immunotherapy has no benefit. The observation that treatment with immunosuppressive agents such as ciclosporin prolongs beta-cell survival in newly diagnosed patients has confirmed that the disease is immune-mediated.

Environmental factors

The incidence of childhood type 1 diabetes is rising across Europe at the rate of 2–3% each year, suggesting that environmental factor(s) are involved in its pathogenesis. Islet autoantibodies (see above) appear in the first few years of life, indicating prenatal or early postnatal interactions with the environment. Exposures to dietary constituents, enteroviruses such as Coxsackie B4 and relative deficiency of vitamin D are possible candidates, but their role in the causation of the disease has yet to be confirmed. A cleaner environment with less early stimulation of the immune system in childhood may increase susceptibility for type 1 diabetes, as for atopic/allergic conditions (the hygiene hypothesis) (see p. 824), and more rapid weight gain in childhood and adolescence leading to increased insulin resistance might accelerate clinical onset (the accelerator hypothesis).

Pre-type 1 diabetes and prevention of type 1 diabetes

Children who test positive for two or more autoantibodies have a >80% risk of progression to diabetes, and the risk approaches 100% in those who additionally lose their first phase insulin response to intravenous glucose and/or develop glucose intolerance. The ability to predict type 1 diabetes with this degree of precision has opened the way to trials of disease prevention, but intervention before clinical onset of diabetes has so far proved unsuccessful.

Pancreatic islet showing infiltration by chronic inflammatory cells (insulitis).

Type 2 diabetes mellitus**Epidemiology**

Type 2 diabetes is a common condition in all populations enjoying an affluent lifestyle, and has increased in parallel with the adoption of a western lifestyle and increasing obesity. The four major determinants are increasing age, obesity, ethnicity and family history. In poor countries, diabetes is a disease of the rich, but in rich countries, it is a disease of the poor; obesity being the common factor. Glucose intolerance or frank diabetes may be present in a subclinical or undiagnosed form for years before diagnosis, and 25–50% of patients already have some evidence of vascular complications at the time of diagnosis. Onset may be accelerated by the stress of pregnancy, drug treatment or intercurrent illness. The overall prevalence within the UK is 4–6%, and the lifetime risk is around 15–20%. Type 2 diabetes is 2–4 times as prevalent in people of South Asian, African and Caribbean ancestry who live in the UK, and the life-time risk in these groups exceeds 30%. High rates also affect people of Middle Eastern and Hispanic American origin living western lifestyles. Obesity increases the risk of type 2 diabetes 80–100 fold, and this is reflected by the increasing prevalence of diabetes in different populations. On average, the inhabitants of affluent countries gain almost 1 g daily between the ages of 25 and 55 years. This gain, due to a tiny excess in energy intake over expenditure – 90 kcal or one chocolate-coated digestive biscuit per day – is often due to reduced exercise rather than increased food intake. Further, our sedentary lifestyle means that the proportion of obese young adults is rising rapidly, and epidemic obesity will create a huge public health problem for the future. The increasing numbers of obese adolescents presenting with type 2 diabetes, particularly within high-risk ethnic groups, is a matter for concern.

Type 2 diabetes is associated with central obesity, hypertension, hypertriglyceridaemia, a decreased HDL-cholesterol, disturbed haemostatic variables and modest increases in a number of pro-inflammatory markers. Insulin resistance is strongly associated with many of these variables, as is increased cardiovascular risk. This group of conditions is referred to as the *metabolic syndrome* (see p. 223). The International Diabetes Federation has proposed criteria based on increased waist circumference (or BMI >30) plus two of the following: diabetes (or fasting glucose >6.0 mmol/L), hypertension, raised triglycerides or low HDL cholesterol. On this definition, about one-third of the adult population has features of the syndrome, not necessarily associated with diabetes. Critics would argue that the metabolic syndrome is not a distinct entity, but one end of a continuum in the relationship between exercise, lifestyle and bodyweight on the one hand, and genetic make-up on the other, and that diagnosis adds little to standard clinical practice in terms of diagnosis, prognosis or therapy.

Causes**Inheritance**

Identical twins of patients with type 2 diabetes have >50% chance of developing diabetes; the risk to non-identical twins or siblings is of the order of 25%, confirming a strong inherited component to the disease. Type 2 diabetes is a polygenic disorder, and, as with type 1 diabetes, genome-wide studies of associations between common DNA variants and disease have allowed identification of numerous susceptibility loci. Several of these loci subserve beta-cell development or function, and there is no overlap with the immune function genes identified for type 1 diabetes. There is no major gene

susceptibility, involving the HLA region. However, transcription factor-7-like (TCF7-L2) is the most common variant observed in type 2 diabetes in Europeans, and KCNQ1 (a potassium voltage-gated channel) in Asians. TCF7-L2 carries an increased risk of around 35%, while other common variants account for no more than 10–20%. TCF7-L2 has now been shown to modulate pancreatic islet cell function. Paradoxically, the genes for type 2 diabetes account for a relatively small fraction of its observed heritability. They do not allow subtypes of the condition to be identified with any confidence, or provide useful disease prediction.

Environmental factors: early and late

An association has been noted between low weight at birth and at 12 months of age and glucose intolerance later in life, particularly in those who gain excess weight as adults. The concept is that poor nutrition early in life impairs beta-cell development and function, predisposing to diabetes in later life. Low birthweight has also been shown to predispose to heart disease and hypertension.

Inflammation

Subclinical inflammatory changes are characteristic of both type 2 diabetes and obesity, and in diabetes, high-sensitivity C-reactive protein (CRP) levels are modestly elevated in association with raised fibrinogen and increased plasminogen activator inhibitor-1 (PAI-1), and contribute to cardiovascular risk. Circulating levels of the pro-inflammatory cytokines TNF- α and IL-6 are elevated in both diabetes and obesity.

Abnormalities of insulin secretion and action

The relative role of secretory failure versus insulin resistance in the pathogenesis of type 2 diabetes has been much debated, but even massively obese individuals with a fully functioning beta-cell mass do not necessarily develop diabetes, which implies that some degree of beta-cell dysfunction is necessary. Insulin binds normally to its receptor on the surface of cells in type 2 diabetes, and the mechanisms of 'insulin resistance' are still poorly understood. Insulin resistance is, however, associated with central obesity and accumulation of intracellular triglyceride in muscle and liver in type 2 diabetes, and a high proportion of patients have non-alcoholic fatty liver disease (NAFLD), see page 303. It has long been stated that patients with type 2 diabetes retain up to 50% of their beta-cell mass at the time of diagnosis, as compared with healthy controls, but the shortfall is greater than this when they are matched with healthy individuals who are equally obese. In addition, patients with type 2 diabetes almost all show islet amyloid deposition at autopsy, derived from a peptide known as amylin or islet amyloid polypeptide (IAPP), which is co-secreted with insulin. It is not known if this is a cause or consequence of beta-cell secretory failure.

Abnormalities of insulin secretion manifest early in the course of type 2 diabetes. An early sign is loss of the first phase of the normal biphasic response to intravenous insulin. Established diabetes is associated with hypersecretion of insulin by a depleted beta-cell mass. Circulating insulin levels are therefore higher than in healthy controls, although still inadequate to restore glucose homeostasis. Relative insulin lack is associated with increased glucose production from the liver (owing to inadequate suppression of gluconeogenesis) and reduced glucose uptake by peripheral tissues. Hyperglycaemia and lipid excess are toxic to beta cells, at least *in vitro*, a phenomenon known as glucotoxicity, and this is thought to result in further beta-cell loss and further deterioration of glucose homeostasis. Circulating insulin levels are typically higher than in non-diabetics

following diagnosis and tend to rise further, only to decline again after months or years due to secretory failure, an observation sometimes referred to as the 'Starling curve' of the pancreas. Type 2 diabetes is thus a condition in which insulin deficiency relative to increased demand leads to hypersecretion of insulin by a depleted beta-cell mass and progression towards absolute insulin deficiency requiring insulin therapy. Its time course varies widely between individuals.

Overview and prevention

Genetic predisposition determines whether an individual is susceptible to type 2 diabetes; if and when diabetes develops largely depends upon lifestyle. A dramatic reduction in the incidence of new cases of adult-onset diabetes was documented in the Second World War when food was scarce, and clinical trials in individuals with impaired glucose tolerance have shown that diet, exercise or agents such as metformin have a marked effect in deferring the onset of type 2 diabetes. Established diabetes can be reversed, even if temporarily, by successful diet and weight loss or by bariatric surgery. Diabetes is therefore largely preventable, although the most effective measures would be directed at the whole population and implemented early in life. Prevention is well worth while, for diabetes diagnosed in a man between the ages of 40 and 59 reduces life expectancy by 5–10 years. By contrast, type 2 diabetes diagnosed after the age of 70 has limited effect on life expectancy in men.

Monogenic diabetes mellitus

The genetic causes of some rare forms of diabetes are shown in Table 20.3. Considerable progress has been made in understanding these rare variants of diabetes. Genetic defects of beta-cell function (previously called 'maturity-onset diabetes of the young', MODY) are dominantly inherited, and several variants have been described, each associated with different clinical phenotypes (Table 20.4). These should be considered in people presenting with early-onset diabetes in association with an affected parent and early-onset diabetes in ~50% of relatives. They can often be treated with a sulfonylurea.

Infants who develop diabetes before 6 months of age are likely to have a monogenic defect and not true type 1 diabetes. Transient neonatal diabetes mellitus (TNDM) occurs soon after birth, resolves at a median of 12 weeks,

and 50% of cases ultimately relapse later in life. Most have an abnormality of imprinting of the *ZAC* and *HYMAI* genes on chromosome 6q. The commonest cause of permanent neonatal diabetes mellitus (PNDM) is mutations in the *KCNJ11* gene encoding the Kir6.2 subunit of the beta-cell potassium-ATP channel.

Neurological features are seen in 20% of patients. Diabetes is due to defective insulin release rather than beta-cell

Table 20.3 Rare genetic causes of type 2 diabetes

Disorder	Features
Insulin receptor mutations	Obesity, marked insulin resistance, hyperandrogenism in women, acanthosis nigricans (areas of hyperpigmented skin)
Maternally inherited diabetes and deafness (MIDD)	Mutation in mitochondrial DNA. Diabetes onset before age 40. Variable deafness, neuromuscular and cardiac problems, pigmented retinopathy
Wolfram's syndrome (DIDMOAD – diabetes insipidus, diabetes mellitus, optic atrophy and deafness)	Recessively inherited. Mutation in the transmembrane gene, <i>WFS1</i> . Insulin-requiring diabetes and optic atrophy in the first decade. Diabetes insipidus and sensorineural deafness in the second decade progressing to multiple neurological problems. Few live beyond middle age
Severe obesity and diabetes	Alström's, Bardet-Biedl and Prader-Willi syndromes. Retinitis pigmentosa, mental insufficiency and neurological disorders
Disorders of intracellular insulin signalling. All with severe insulin resistance	Leprechaunism, Rabson-Mendenhall syndrome, pseudoacromegaly, partial lipodystrophy: lamin A/C gene mutation
Genetic defects of beta-cell function	See Table 20.4

Table 20.4 Genetic defects of beta-cell function

	HNF-4a	Glucokinase	HNF-1a	IPF-1	HNF-1b
Chromosomal location	20q	7p	12q	13q	17q
Proportion of all cases	5%	15%	70%	<1%	2%
Onset	Teens/30s	Present from birth	Teens/20s	Teens/30s	Teens/20s
Progression	Progressive hyperglycaemia	Little deterioration with age	Progressive hyperglycaemia	Progression unclear	Progression unclear
Microvascular complications	Frequent	Rare	Frequent	Few data	Frequent
Other features	None	Reduced birthweight	Sensitivity to sulfonylureas	Pancreatic agenesis in homozygotes	Renal cysts, proteinuria, chronic kidney disease
The glucokinase gene is intimately involved in the glucose-sensing mechanism within the pancreatic beta cell. The hepatic nuclear factor (HNF) genes and the insulin promoter factor-1 (IPF-1) gene control nuclear transcription in the beta cell where they regulate its development and function. Abnormal nuclear transcription genes may cause pancreatic agenesis or more subtle progressive pancreatic damage. A handful of families with autosomal dominant diabetes have been described with mutations in neurogenic differentiation factor-1 (NeuroD1). (see: http://projects.exeter.ac.uk/diabetesgenes/mody/)

destruction, and patients can be treated successfully with sulfonylureas, even after many years of insulin therapy.

CLINICAL PRESENTATION OF DIABETES

Presentation may be acute, subacute or asymptomatic.

Acute presentation

Young people often present with a 2–6-week history and report the classic triad of symptoms:

- Polyuria – due to the osmotic diuresis that results when blood glucose levels exceed the renal threshold
- Thirst – due to the resulting loss of fluid and electrolytes
- Weight loss – due to fluid depletion and the accelerated breakdown of fat and muscle secondary to insulin deficiency.

Ketonuria is often present in young people and may progress to ketoacidosis if these early symptoms are not recognized and treated.

Subacute presentation

The clinical onset may be over several months or years, particularly in older patients. Thirst, polyuria and weight loss are typically present but patients may complain of such symptoms as lack of energy, visual blurring (owing to glucose-induced changes in refraction) or pruritus vulvae or balanitis that is due to *Candida* infection.

Complications as the presenting feature

These include:

- Staphylococcal skin infections
- Retinopathy noted during a visit to the optician
- A polyneuropathy causing tingling and numbness in the feet
- Erectile dysfunction
- Arterial disease, resulting in myocardial infarction or peripheral gangrene.

Asymptomatic diabetes

Glycosuria or a raised blood glucose may be detected on routine examination (e.g. for insurance purposes) in

individuals who have no symptoms of ill-health. Glycosuria is not diagnostic of diabetes but indicates the need for further investigations. About 1% of the population have renal glycosuria. This is an inherited low renal threshold for glucose, transmitted either as a Mendelian dominant or recessive trait.

Physical examination at diagnosis

Evidence of weight loss and dehydration may be present, and the breath may smell of ketones. Older patients may present with established complications, and the presence of the characteristic retinopathy is diagnostic of diabetes. In occasional patients, there will be physical signs of an illness causing secondary diabetes (see Table 20.1). Patients with severe insulin resistance may have acanthosis nigricans, which is characterized by blackish pigmentation at the nape of the neck and in the axillae (p. 1217).

DIAGNOSIS AND INVESTIGATION OF DIABETES

Diabetes is easy to diagnose when overt symptoms are present, and a glucose tolerance test is hardly ever necessary for clinical purposes. The oral glucose tolerance test has, however, allowed more detailed epidemiological characterization based on the existence of separate glucose thresholds for macrovascular and microvascular disease. These correspond with the levels for the diagnosis of impaired glucose tolerance (IGT) and diabetes as specified by the WHO criteria set out in Box 20.1. Epidemiological studies show that for every person with known diabetes, there is another undiagnosed in the population. A much larger proportion fall into the intermediate category of impaired glucose tolerance.

Impaired glucose tolerance (IGT)

This is not a clinical entity but a risk factor for future diabetes and cardiovascular disease. The diagnosis can only be made with a glucose tolerance test, and is complicated by poor reproducibility of the key 2-hour value in this test. The group is heterogeneous; some patients are obese, some have liver disease and others are on medication that impairs glucose tolerance. Individuals with IGT have the same risk of cardiovascular disease as those with frank diabetes, but do not develop the specific microvascular complications.

Box 20.1 WHO diagnostic criteria

WHO criteria for the diagnosis of diabetes are:

- Fasting plasma glucose >7.0 mmol/L (126 mg/dL)
- Random plasma glucose >11.1 mmol/L (200 mg/dL)
- One abnormal laboratory value is diagnostic in symptomatic individuals; two values are needed in asymptomatic people. The glucose tolerance test is only required for borderline cases and for diagnosis of gestational diabetes.
- HbA_{1c} >6.5 (48 mmol/mol)

The glucose tolerance test – WHO criteria

	Normal	Impaired glucose tolerance	Diabetes mellitus
Fasting	<7.0 mmol/L	<7.0 mmol/L	>7.0 mmol/L
2 h after glucose	<7.8 mmol/L	7.8–11.0 mmol/L	>11.1 mmol/L

- Adult: 75 g glucose in 300 mL water
- Child: 1.75 g glucose/kg bodyweight
- Only a fasting and a 120-min sample are needed
- Results are for venous plasma – whole blood values are lower.

Note: There is no such thing as mild diabetes. All patients who meet the criteria for diabetes are liable to disabling long-term complications.

Impaired fasting glucose (IFG)

This diagnostic category (fasting plasma glucose between 6.1 and 6.9 mmol/L) has the practical advantage that it avoids the need for a glucose tolerance test. It is not a clinical entity, but indicates future risk of frank diabetes and cardiovascular disease. IFG only overlaps with IGT to a limited extent, and the associated risks of cardiovascular disease and future diabetes are not directly comparable. A lower cut-off of 5.6 mmol/L (rather than 6.1 mmol/L) has been recommended by the American Diabetes Association (ADA) and would, if implemented, greatly increase the number of those in this category.

Haemoglobin A_{1c} (HbA_{1c})

HbA_{1c} is an integrated measure of an individual's prevailing blood glucose concentration over several weeks (see below). Standardization of this measure has enabled it to be proposed as an alternative diagnostic test for diabetes by the American Diabetes Association. As currently proposed, an HbA_{1c} >6.5% (48 mmol/mol) would be considered diagnostic of diabetes, whereas a level of 5.7–6.4% (39–46 mmol/mol) would denote increased risk of diabetes. A WHO Consultation recently also concluded that HbA_{1c} 'can be used as a diagnostic test for diabetes'. Unfortunately, there is relatively little concordance between IGT, IFG and HbA_{1c} as markers of 'prediabetes'. Furthermore, there will be many people in a mixed population who are 'diabetic' using the HbA_{1c} criteria but 'normal' on glucose tolerance testing. Many are uncomfortable with this concept.

Other investigations

No further tests are needed to diagnose diabetes. Other routine investigations include urine testing for protein, a full blood count, urea and electrolytes, liver biochemistry and random lipids. The latter test is useful to exclude an associated hyperlipidaemia and, if elevated, should be repeated fasting after diabetes has been brought under control. Diabetes may be secondary to other conditions (see Table 20.1), may be precipitated by underlying illness and be associated with autoimmune disease or hyperlipidaemia. Hypertension is present in 50% of patients with type 2 diabetes and a higher proportion of African and Caribbean patients.

TREATMENT OF DIABETES

The role of patient education and community care

The care of diabetes is based on self-management by the patient, who is helped and advised by those with specialized knowledge. The quest for improved glycaemic control has made it clear that whatever the technical expertise applied, the outcome depends on willing cooperation by the patient. This in turn depends on an understanding of the risks of diabetes and the potential benefits of glycaemic control and other measures such as maintaining a lean weight, stopping smoking and taking care of the feet. If accurate information is not supplied, misinformation from friends and other patients will take its place. For this reason the best time to educate the patient is soon after diagnosis. Organized education programmes involve all healthcare workers, including nurse specialists, dietitians and podiatrists, and should include ongoing support and updates wherever possible.

Diet

The diet for people with diabetes is no different from that considered healthy for everyone. Table 20.5 lists recommendations on the ideal composition of this diet. To achieve this, food for people with diabetes should be:

- low in sugar (though not sugar free)
- high in starchy carbohydrate (especially foods with a low glycaemic index), i.e. slower absorption
- high in fibre
- low in fat (especially saturated fat).

Table 20.5 Recommended composition of the diet for people with diabetes, with comments on how this may be achieved

Component of diet	Comment
Protein	1 g/kg ideal bodyweight (approx.)
Total fat	<35% of energy intake. Limit: fat/oil in cooking, fried foods, processed meats (burgers, salami, sausages), high-fat snacks (crisps, cake, nuts, chocolate, biscuits, pastry). Encourage: lower-fat dairy products (skimmed milk, reduced-fat cheese, low-fat yoghurt), lean meat
Saturated and <i>trans</i> -unsaturated fat	<10% of total energy intake
<i>n</i> -6 polyunsaturated fat	<10% of total energy intake
<i>n</i> -3 polyunsaturated fat	No absolute quantity recommended. Eat fish, especially oily fish, once or twice weekly. Fish oil supplements not recommended
<i>Cis</i> -monounsaturated fat	10–20% of total energy intake (olive oil, avocado)
Total carbohydrate	40–60% of total energy intake Encourage: artificial (intense) sweeteners instead of sugar (sugar-free fizzy drinks, squashes and cordials). Limit: fruit juices, confectionery, cake, biscuits
Sucrose	Up to 10% of total energy intake, provided this is eaten in the context of a healthy diet (examples: fibre-rich breakfast cereals, baked beans)
Fibre	No absolute quantity recommended. Soluble fibre has beneficial effects on glycaemic and lipid metabolism. Insoluble fibre has no direct effects on glycaemic metabolism, but benefits satiety and gastrointestinal health
Vitamins and antioxidants	Best taken as fruit and vegetables (five portions per day) in a mixed diet. There is no evidence for the use of supplements
Alcohol	Not forbidden. Its energy content should be taken into account, as should its tendency to cause delayed hypoglycaemia in those treated with insulin
Salt	<6 g/day (lower in hypertension)

SIGNIFICANT WEBSITE

http://www.who.int/diabetes/publications/report-hba1c_2011.pdf

The overweight or obese should be encouraged to lose weight by a combination of changes in food intake and physical activity.

Carbohydrates

The glucose peak seen in the blood after eating pasta is much flatter than that seen after eating the same amount of carbohydrate as white potato. Pasta has a lower 'glycaemic index'. Foods with a low glycaemic index prevent rapid swings in circulating glucose, and are thus preferred to those with a higher glycaemic index.

Prescribing a diet

Most people find it extremely difficult to modify their eating habits, and repeated advice and encouragement are needed if this is to be achieved. A diet history is taken, and the diet prescribed should involve the least possible interference with the person's lifestyle. Advice from dieticians is more likely to affect medium-term outcome than advice from doctors. People taking insulin or oral agents have traditionally been advised to eat roughly the same amount of food (particularly carbohydrate) at roughly the same time each day, so that treatment can be balanced against food intake and exercise. Knowledgeable and motivated patients with type 1 diabetes, who get feedback from regular blood glucose monitoring, can vary the amount of carbohydrate consumed, or meal times, by learning to adjust their exercise pattern and treatment. This is the basis of the DAFNE (Dose Adjustment For Normal Eating) regimen.

Exercise

Diet treatment is incomplete without exercise. Any increase in activity levels is to be encouraged, but participation in more formal exercise programmes is best. Where facilities for this exist, exercise should be prescribed for everyone with diabetes. Several trials have shown that regular exercise reduces the risk of progression to type 2 diabetes by 30–60%, and the lowest long-term morbidity and mortality is seen in those with established disease who have the highest levels of cardiorespiratory fitness. Both aerobic and resistance training improve insulin sensitivity and metabolic control in type 1 and type 2 diabetes, although reported effects on metabolic control are inconsistent. Patients on insulin or sulfonylureas should be warned that there is an increased risk of hypoglycaemia for up to 6–12 h following heavy exertion.

Tablet treatment for type 2 diabetes

Diet and lifestyle changes are the key to successful treatment of type 2 diabetes, and no amount of medication will succeed where these have failed. The concept is that controlling diabetes is not just a matter of swallowing tablets, and these should in general never be prescribed until lifestyle changes have been implemented. Tablets will however be needed if satisfactory metabolic control (see 'Measuring control' below) is not established within 4–6 weeks. A consensus treatment pathway is shown in Figure 20.9 (p. 1013). The three main options are metformin, a sulfonylurea or a thiazolidinedione.

Biguanide (metformin)

Metformin is the only biguanide currently in use, and remains the best validated primary treatment for type 2 diabetes. It activates the enzyme AMP-kinase, which is involved in regulation of cellular energy metabolism, but its precise mechanism of action remains unclear. Its effect is to reduce

the rate of gluconeogenesis, and hence hepatic glucose output, and to increase insulin sensitivity. It does not affect insulin secretion, does not induce hypoglycaemia and does not predispose to weight gain. It is thus particularly helpful in the overweight, although normal weight individuals also benefit, and may be given in combination with sulfonylureas, thiazolidinediones, dipeptidyl peptidase-4 (DPP4) inhibitors or insulin. Metformin was as effective as sulfonylurea or insulin in glucose control and reduction of microvascular risk in the UK Prospective Diabetic Study (UKPDS), but proved unexpectedly beneficial in reducing cardiovascular risk, an effect that could not be fully explained by its glucose-lowering actions. Adverse effects include anorexia, epigastric discomfort and diarrhoea, and these prohibit its use in 5–10% of patients. Diarrhoea should never be investigated in a diabetic patient without testing the effect of stopping metformin or changing to a slow release preparation. Lactic acidosis has occurred in patients with severe hepatic or renal disease, and metformin is contraindicated when these are present. A Cochrane review showed little risk of lactic acidosis with standard clinical use, but most clinicians withdraw the drug when serum creatinine exceeds 150 µmol/L.

Sulfonylureas (Table 20.6)

These act upon the beta cell to promote insulin secretion in response to glucose and other secretagogues. They are ineffective in patients without a functional beta-cell mass, and they are usually avoided in pregnancy. Their action is to bind to the sulfonylurea receptor on the cell membrane, which closes ATP-sensitive potassium channels and blocks potassium efflux. The resulting depolarization promotes influx of calcium, a signal for insulin release (Fig. 20.2). Sulfonylureas are cheap and more effective than the other agents in achieving short-term (1–3 years) glucose control, but their effect wears off as the beta-cell mass declines. There are theoretical concerns that they might hasten beta-cell apoptosis and they promote weight gain, and are best avoided in the overweight. They can also cause

Table 20.6 Properties of the most commonly used sulfonylureas

Drug	Features
Tolbutamide	Lower maximal efficacy than other sulfonylureas Short half-life – preferable in elderly Largely metabolized by liver – can use in renal impairment
Glibenclamide	Long biological half-life Severe hypoglycaemia Do not use in the elderly
Glipizide and Glimepiride	Active metabolites Renal excretion – avoid in renal impairment
Gliclazide	Intermediate biological half-life Largely metabolized by liver – can use in renal impairment More costly
Chlorpropamide	Very long biological half-life Renal excretion – avoid in renal impairment 1–2% develop inappropriate ADH-like syndrome Facial flush with alcohol Very inexpensive – major issue for developing countries Can produce fatal hypoglycaemia Not recommended in the elderly

hypoglycaemia and although the episodes are generally mild, fatal hypoglycaemia may occur. Severe cases should always be admitted to hospital, monitored carefully, and treated with a continuous glucose infusion since some sulfonylureas have long half-lives. Sulfonylureas should be used with care in patients with liver disease. Patients with renal impairment should only be given those primarily excreted by the liver. Tolbutamide is the safest drug in the very elderly because of its short duration of action.

Meglitinides

Meglitinides, e.g. *repaglinide* and *nateglinide*, are insulin secretagogues. Meglitinides are the non-sulfonylurea moiety of glibenclamide. As with the sulfonylureas, they act via closure of the K^+ -ATP channel in the beta cells (see Fig. 20.2). They are short-acting agents that promote insulin secretion in response to meals. Their effects are similar to that of the short-acting sulfonylurea tolbutamide, but they are much more costly.

Thiazolidinediones

The thiazolidinediones (more conveniently known as the 'glitazones') reduce insulin resistance by interaction with peroxisome proliferator-activated receptor- γ (PPAR- γ), a nuclear receptor which regulates large numbers of genes including those involved in lipid metabolism and insulin action. The paradox that glucose metabolism should respond to a drug that binds to nuclear receptors mainly found in fat cells is still not fully understood. One suggestion is that they act indirectly via the glucose-fatty acid cycle, lowering free fatty acid levels and thus promoting glucose consumption by muscle. They reduce hepatic glucose production, an effect that is synergistic with that of metformin, and also enhance peripheral glucose uptake. Like metformin, the glitazones potentiate the effect of endogenous or injected insulin. The glitazones have yet to demonstrate unique advantages in the treatment of diabetes, and their place in routine diabetes care remains uncertain. Troglitazone and rosiglitazone have been withdrawn for safety concerns (liver failure and increased cardiovascular risk, respectively), and pioglitazone is the only remaining agent in this class. *Unwanted effects* of pioglitazone include weight gain of 5–6 kg, together with fluid retention and heart failure. Mild anaemia and osteoporosis resulting in peripheral bone fractures have also been reported, and there is a possible increase in the risk of bladder cancer.

Dipeptidyl peptidase-4 (DPP4) inhibitors

These enhance the incretin effect (Box 20.2). The enzyme dipeptidyl peptidase 4 (DPP4) rapidly inactivates GLP-1 as

this is released into the circulation. Inhibition of this enzyme thus potentiates the effect of endogenous GLP-1 secretion. Four agents are currently available (linagliptin, saxagliptin, sitagliptin and vildagliptin) with more likely to be available in the future. They have a moderate effect in lowering blood glucose and are weight neutral. They are most effective in the early stages of type 2 diabetes when insulin secretion is relatively preserved, and are currently recommended for second-line use in combination with metformin or a sulfonylurea. Adverse events are uncommon: the main side-effect is nausea, and there have been occasional reports of acute pancreatitis. Their place in the management of type 2 diabetes has yet to be fully established. Although the short-term safety record is good, DPP4 is widely distributed in the body, and the long-term consequences of inhibition of this enzyme in other tissues are unknown.

Injection therapies for type 2 diabetes

GLP-1 agonists

Exenatide and *liraglutide* are injectable long-acting analogues of GLP-1, which enhance the incretin effect (Box 20.2). They promote insulin release, inhibit glucagon release, reduce appetite and delay gastric emptying, thus blunting the postprandial rise in plasma glucose and promoting weight loss. Their main clinical disadvantage is the need for subcutaneous injection (twice daily for exenatide and once daily for liraglutide), and their major advantage is improving glucose control whilst inducing useful weight reduction. They work well in 70% but have limited benefit in 30% of those treated. *Side-effects* include nausea, acute pancreatitis and acute kidney injury. At present they are used as an alternative to insulin, particularly in the overweight. A once weekly version of exenatide has been developed.

GLP-1 promotes beta-cell replication in immature rodents, but there is no evidence to suggest that it can do so in adult humans. GLP-1 receptors are also present in the exocrine pancreas, and the long-term clinical implications of this observation remain unclear.

Other therapies

- **Intestinal enzyme inhibitors** include *acarbose*, a sham sugar that competitively inhibits α -glucosidase enzymes situated in the brush border of the intestine, reducing absorption of dietary carbohydrate. Undigested starch may then enter the large intestine where it will be broken down by fermentation. Abdominal discomfort, flatulence and diarrhoea can result, and dosage needs careful adjustment to avoid these side-effects.
- **Orlistat** is a lipase inhibitor which reduces the absorption of fat from the diet. It benefits diabetes indirectly by promoting weight loss in patients under careful dietary supervision on a low fat diet. This is necessary to avoid unpleasant steatorrhoea.
- **Gastric banding and gastric bypass surgery** (see p. 220) have been used in those with marked obesity unresponsive to 6 months' intensive attempts at dieting and graded exercise. NICE recommends consideration of surgery in those with a BMI >40, or in those with BMI >35 and co-morbidities such as diabetes or hypertension which will be alleviated by weight loss. In the USA, the FDA-recommended BMI thresholds are lower. The risks of surgery are not insignificant, and long-term specialist care and follow-up are needed, including psychological support and nutritional supplements for those with bowel resection, but these

Box 20.2 The incretin effect

The insulin response to oral glucose is greater than the response to intravenous glucose.

Cause: two intestinal peptide hormones, glucose-dependent insulinotropic peptide (GIP) and glucagon-like peptide-1 (GLP-1) have a potentiating effect on pancreatic secretion of insulin.

- GIP causes 30%, and GLP-1 70%, of the incretin effect.
- Both hormones have very short half-lives in the circulation, being degraded predominantly by the enzyme dipeptidyl peptidase-4 (DPP4).
- GIP is secreted from the K cells in the duodenum and GLP-1 from the L cells of the ileum in response to food.

Magnitude: the incretin effect is diminished in type 2 diabetes.

concerns should be balanced against the risk of patients staying as they are. About one-third of patients become non-diabetic after gastric bypass, but the condition may recur.

Insulin treatment

Insulin is found in every vertebrate, and the key parts of the molecule show few species differences. Small differences in the amino acid sequence may alter the antigenicity of the molecule. The glucose and insulin profiles in normal subjects are shown in Figure 20.7.

Short-acting insulins

Insulins derived from beef or pig pancreas have been replaced in most countries by biosynthetic human insulin. This is produced by adding a DNA sequence coding for insulin or proinsulin into cultured yeast or bacterial cells. Short-acting insulins are used for pre-meal injection in multiple dose regimens, for continuous intravenous infusion in labour or during medical emergencies, and in patients using

insulin pumps. Human insulin is absorbed slowly, reaching a peak 60–90 min after subcutaneous injection, and its action tends to persist after meals, predisposing to hypoglycaemia. Absorption is delayed because soluble insulin is in the form of stable hexamers (six insulin molecules around a zinc core) and needs to dissociate to monomers or dimers before it can enter the circulation. *Short-acting insulin analogues* have been engineered to dissociate more rapidly following injection without altering the biological effect. *Insulin analogues* (Fig. 20.8) such as the *rapid-acting insulins* (*insulin lispro*, *insulin aspart* and *insulin glulisine*) enter the circulation more rapidly than human soluble insulin, and also disappear more rapidly. Although widely used, the short-acting analogues have little effect upon overall glucose control in most patients, mainly because improved postprandial glucose is balanced by higher levels before the next meal. A Cochrane review has concluded that there is little evidence as to their benefit in type 2 diabetes.

Intermediate and longer-acting insulins

The action of human insulin can be prolonged by the addition of zinc or protamine derived from fish sperm. The most widely used form is NPH (isophane insulin), which has the advantage that it can be premixed with soluble insulin to form stable mixtures (biphasic insulins), of which the combination of 30% soluble with 70% NPH is most widely used. Long-acting analogues have their structure modified to delay absorption or to prolong their duration of action. *Insulin glargine* is soluble in the vial as a slightly acidic (pH 4) solution, but precipitates at subcutaneous pH, thus prolonging its duration of action. *Insulin detemir* has a fatty acid 'tail' which allows it to bind to serum albumin, and its slow dissociation from the bound state prolongs its duration of action. Although popular and widely used, these insulins have little demonstrated advantage over NPH in many clinical situations, although useful in those on intensified therapy or with troublesome hypoglycaemia.

Inhaled insulin

The first inhaled insulin was withdrawn from the market in 2007 on the grounds of limited clinical demand, although lung cancer was also observed.

Figure 20.7 Glucose and insulin profiles in normal subjects.

Figure 20.8 Amino acid structure of human insulin. *Lispro* is a genetically engineered rapidly acting insulin analogue created by reversing the order of the amino acids proline and lysine in positions 28 and 29 of the B chain. *Insulin aspart* is a similar analogue created by replacing proline at position 28 of the B chain with an aspartic acid residue. *Insulin glargine* is a genetically engineered long-acting insulin created by replacing asparagine in position 21 of the A chain with a glycine residue and adding two arginines to the end of the B chain. *Insulin detemir* discards threonine in position 30 of the B chain and adds a fatty acyl chain to lysine in position B29.

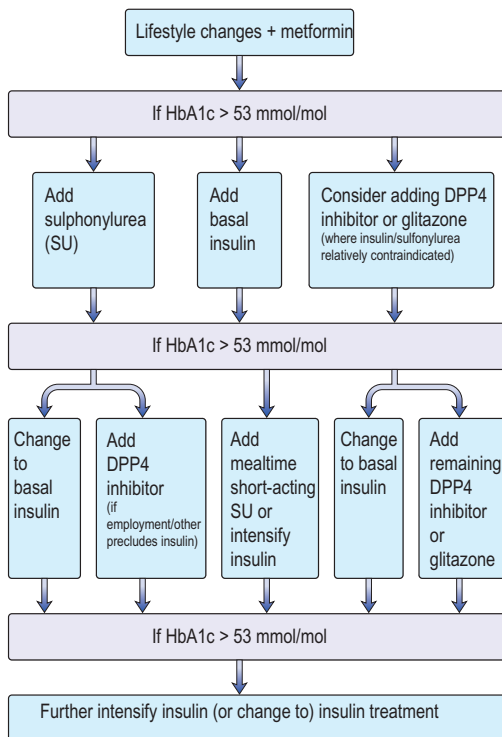

Figure 20.9 A treatment pathway for type 2 diabetes mellitus. Note that discussion of lifestyle changes and compliance should be undertaken at every stage. All patients require BP control, statin therapy and low-dose aspirin. GLP-1 agonists are also used in many countries, but not NICE-recommended in the UK. DPP4, dipeptidyl peptidase-4.

Practical management of diabetes

All patients with diabetes require advice about diet and lifestyle. Lifestyle changes, i.e. controlling weight, stopping smoking and taking regular exercise, can prevent or delay the onset of type 2 diabetes in people with glucose intolerance. Good glycaemic control is unlikely to be achieved with insulin or oral therapy when diet is neglected, especially when the patient is also overweight. Regular exercise helps to control weight and reduces cardiovascular risk. Blood pressure control is vital using an angiotensin converting enzyme (ACE) inhibitor or angiotensin II receptor (AIIIR) antagonist (see p. 782); Most patients will also benefit from a statin and low-dose aspirin (see p. 1022).

Type 2 diabetes

The great majority of patients presenting over the age of 40 will have type 2 diabetes, but do not miss the occasional type 1 patient presenting late. An approach to their management is illustrated in Figure 20.9. Goals of treatment are described on page 1016. Type 2 diabetes is characterized by progressive beta-cell failure, and glucose control deteriorates over time, requiring a progressive and pre-emptive escalation of diabetes therapy. Regular review is essential for this to be achieved. Most patients on tablets will eventually require insulin, and it is helpful to explain this from the outset. The most widespread error in management at this stage is procrastination; the patient whose control is inadequate on oral therapy should start insulin without undue delay. Targets for glucose control are discussed later (p. 1016).

There is little consensus regarding the optimal insulin regimen in type 2 diabetes, but an intermediate insulin given at night with metformin during the day is initially as effective

a Twice-daily mixed soluble and intermediate insulins

b Three-times-daily soluble with intermediate- or long-acting insulin given before bedtime

c Three-times-daily rapid-acting analogue with long-acting analogue insulin given before bedtime

Figure 20.10 Insulin regimens. Profiles of soluble insulins are shown as: dashed lines; intermediate- or long-acting insulin as solid lines (purple); and rapid-acting insulin as dotted lines (blue). The arrows indicate when the injections are given. B, breakfast; L, lunch; S, supper; Sn, snack (bedtime).

as multidose insulin regimens in controlling glucose levels, and is less likely to promote weight gain, which is a common complication of insulin therapy. Metformin is a useful adjunct to insulin in those able to tolerate it. Addition of a morning dose of insulin may become necessary to control postprandial hyperglycaemia. Twice-daily injections of pre-mixed soluble and isophane insulins (i.e. biphasic isophane insulin) are widely used and reasonably effective (Fig. 20.10a). More aggressive treatment, with multiple injections or continuous infusion pumps, is increasingly used in younger patients with type 2 diabetes.

Type 1 diabetes

Insulin is always indicated in a patient who has been in ketoacidosis, and is usually indicated in lean patients who present under the age of 40 years.

Principles of insulin treatment

Injections

The needles used to inject insulin are very fine and sharp. Even though most injections are virtually painless, patients are understandably apprehensive and treatment begins with a lesson in injection technique. Insulin is usually administered by a pen injection device but can be drawn up from a vial into special plastic insulin syringes marked in units (100 U in 1 mL). Injections are given into the fat below the skin on the abdomen, thighs or upper arm, and the needle is usually inserted to its full length. Slim adults and children usually use a 31 gauge 6 mm needle and fatter adults a 30 gauge 8 mm needle. Both reusable and disposable pen devices are available, together with a range of devices to aid injection. The

injection site used should be changed regularly to prevent areas of lipohypertrophy (fatty lumps). The rate of insulin absorption depends on local subcutaneous blood flow, and is accelerated by exercise, local massage or a warm environment. Absorption is more rapid from the abdomen than from the arm, and is slowest from the thigh. All these factors can influence the shape of the insulin profile.

Insulin administration

In healthy individuals a sharp increase in insulin occurs after meals; this is superimposed on a constant background of secretion (Fig. 20.7). Insulin therapy attempts to reproduce this pattern, but ideal control is difficult to achieve for four reasons:

- In normal subjects, insulin is secreted directly into the portal circulation and reaches the liver in high concentration; about 50% of the insulin produced by the pancreas is cleared by the liver. By contrast, insulin injected subcutaneously passes into the systemic circulation before passage to the liver. Insulin-treated patients therefore have lower portal levels of insulin and higher systemic levels relative to the physiological situation.
- Subcutaneous soluble insulin takes 60–90 min to achieve peak plasma levels, so the onset and offset of action are too slow.
- The absorption of subcutaneous insulin into the circulation is variable.
- Basal insulin levels are constant in normal people, but injected insulin invariably peaks and declines in people with diabetes, with resulting swings in metabolic control.

A multiple injection regimen with short-acting insulin and a longer-acting insulin at night is appropriate for most younger patients (Fig. 20.10b). The advantages of multiple injection regimens are that the insulin and the food go in at roughly the same time so that meal times and sizes can vary, without greatly disturbing metabolic control. The flexibility of multiple injection regimens is of great value to patients with busy jobs, shift workers and those who travel regularly. Some recovery of endogenous insulin secretion may occur over the first few months (the 'honeymoon period') in type 1 patients and the insulin dose may need to be reduced or even stopped for a period. Requirements rise thereafter. Strict glucose control from diagnosis in type 1 diabetes prolongs beta-cell function, resulting in better glucose levels and less hypoglycaemia. Target blood glucose values should normally be 4–7 mmol/L before meals and 4–10 mmol/L after meals, assuming that this can be achieved without troublesome hypoglycaemia.

All patients need careful training for a life with insulin. This is best achieved outside hospital, provided that adequate facilities exist for outpatient diabetes education. A scheme for adjusting insulin regimens is given in Table 20.7. DAFNE is described on page 1010.

When to use insulin analogues

Hypoglycaemia between meals and particularly at night is the limiting factor for many patients on multiple injection regimens. The more expensive rapid-acting insulin analogues (Fig. 20.10c) are a useful substitute for soluble insulin in some patients. They reduce the frequency of nocturnal hypoglycaemia due to reduced carry-over effect from the day-time. They are often used on grounds of convenience, since patients can inject shortly before meals but standard insulins injected at the same time give equivalent overall control. High or erratic morning blood sugar readings can prove a problem for about a quarter of all patients on conventional multiple injection regimens, because the bedtime intermediate-acting insulin falls and the absorption is variable. The long-acting insulin analogues insulin glargine and insulin detemir may help to overcome these problems and reduce the risk of nocturnal hypoglycaemia.

Infusion devices

CSII (continuous subcutaneous insulin infusion) is delivered by a small pump strapped around the waist that infuses a constant trickle of insulin via a needle in the subcutaneous tissues. Meal-time doses are delivered by the user telling the pump to deliver a bolus of insulin at the start of a meal.

This approach is particularly useful in the overnight period, since the basal overnight infusion rate can be programmed to fit each patient's needs. Disadvantages include the nuisance of being attached to a gadget, skin infections, the risk of ketoacidosis if the flow of insulin is broken (since these patients have no protective reservoir of injected depot insulin) and cost. Infusion pumps should only be used by specialized centres able to offer a round-the-clock service to their patients. This form of treatment has revolutionized the lives of some people with type 1 diabetes.

Complications of insulin therapy

At the injection site

Shallow injections result in intradermal insulin delivery and painful, reddened lesions or even scarring. Injection site abscesses occur but are extremely rare.

Local allergic responses sometimes occur early in therapy but usually resolve spontaneously. Generalized allergic responses are exceptionally rare. Fatty lumps, known as lipohypertrophy, may occur as the result of overuse of a single injection site with any type of insulin.

Insulin resistance

The most common cause of mild insulin resistance is obesity. Occasional unstable patients require massive insulin doses, sometimes with a fluctuating requirement. Rare syndromes of insulin resistance may be present, but most cases are unexplained. Insulin resistance associated with antibodies directed against the insulin receptor has been reported in patients with acanthosis nigricans (Table 20.3).

Pickup JC. Insulin-pump therapy for type 1 diabetes mellitus. *N Engl J Med* 2012; 366:1616–1624.

Table 20.7 Guide to adjusting insulin dosage according to blood glucose test results

	Blood glucose persistently too high	Blood glucose persistently too low
Before breakfast	Increase evening long-acting insulin	Reduce evening long-acting insulin
Before lunch	Increase morning short-acting insulin	Reduce morning short-acting insulin or increase mid-morning snack
Before evening meal	Increase morning long-acting insulin or lunch short-acting insulin	Reduce morning long-acting insulin or lunch short-acting insulin or increase mid-afternoon snack
Before bed	Increase evening short-acting insulin	Reduce evening short-acting insulin

Weight gain

Many patients show weight gain on insulin treatment, especially if the insulin dose is increased inappropriately, but this can to some extent be overcome by emphasis on the need for diet and exercise, plus addition of metformin. Patients who are in poor control when insulin is started tend to gain (or regain) most weight.

Hypoglycaemia during insulin treatment

This is the most common complication of insulin therapy, and limits what can be achieved with insulin treatment. It is a major cause of anxiety for patients and relatives. It results from an imbalance between injected insulin and a patient's normal diet, activity and basal insulin requirement. The times of greatest risk are before meals, during the night, and during exercise. Irregular eating habits, unusual exertion and alcohol excess may precipitate episodes; other cases appear to be due simply to variation in insulin absorption.

Symptoms develop when the blood glucose level falls below 3 mmol/L and typically develop over a few minutes, with most patients experiencing 'adrenergic' features of sweating, tremor and a pounding heartbeat. Virtually all patients with type 1 diabetes experience intermittent hypoglycaemia and one in three will go into a coma at some stage in their lives. A small minority suffer attacks that are so frequent and severe as to be virtually disabling.

Physical signs include pallor and a cold sweat. Many patients with longstanding diabetes report loss of these warning symptoms (*hypoglycaemic unawareness*) and are at a greater risk of central nervous dysfunction (neuroglycopenia) resulting in altered behaviour or conscious level. Such patients appear pale, drowsy or detached, signs that their relatives quickly learn to recognize. Behaviour is clumsy or inappropriate, and some become irritable or even aggressive. Others slip rapidly into hypoglycaemic coma. Occasionally, patients develop convulsions during hypoglycaemic coma, especially at night. This must not be confused with idiopathic epilepsy. Another presentation is with a hemiparesis that resolves when glucose is administered.

People with diabetes have an impaired ability to counter-regulate glucose levels after hypoglycaemia. The glucagon response is invariably deficient, even though the α cells are preserved and respond normally to other stimuli. The epinephrine (adrenaline) response may also fail in patients with a long duration of diabetes, and this is associated with hypoglycaemia unawareness. Recurrent hypoglycaemia may itself induce a state of hypoglycaemia unawareness, and the ability to recognize the condition may sometimes be restored by relaxing control for a few weeks.

Nocturnal hypoglycaemia. Basal insulin requirements fall during the night but increase again from about 4 a.m. onwards, at a time when levels of injected insulin are falling. As a result many patients wake with high blood glucose levels, but find that injecting more insulin at night increases the risk of hypoglycaemia in the early hours of the morning. The problem may be helped by the following:

- Checking that a bedtime snack is taken regularly
- Patients taking twice-daily mixed insulin can separate their evening dose and take the intermediate insulin at bedtime rather than before supper
- Reducing the dose of soluble insulin before supper, since the effects of this persist well into the night
- Changing to a rapid-acting insulin analogue, with a long-lasting insulin analogue at night.

- Changing to an insulin infusion pump which can be programmed to deliver lower doses of insulin at the time of night when a patient has been experiencing hypoglycaemia.

Mild hypoglycaemia

Any form of rapidly absorbed carbohydrate will relieve the early symptoms, and glucose or sweets should always be carried. Drowsy individuals will be able to take carbohydrate in liquid form (e.g. Lucozade). All patients and their close relatives need training about the risks of hypoglycaemia. More carbohydrate than necessary should not be taken during the recovery period, since this causes a rebound to hyperglycaemia. Alcohol excess increases the risk of hypoglycaemia, and this requires careful explanation, together with the need to guard against hypoglycaemia while driving.

Severe hypoglycaemia

The diagnosis of severe hypoglycaemia resulting in confusion or coma is simple and can usually be made on clinical grounds, backed by a bedside blood test. If real doubt exists, blood should be taken for glucose estimation before treatment is given. Patients should carry a card or wear a bracelet or necklace to say that they have diabetes, and these should be looked for in unconscious patients.

Unconscious patients should be given either intramuscular glucagon (1 mg) or intravenous glucose (25–50 mL of 50% glucose solution) followed by a flush of 0.9% saline to preserve the vein (since 50% glucose scleroses veins). Glucagon acts by mobilizing hepatic glycogen, and works almost as rapidly as glucose. It is simple to administer and can be given at home by relatives. It does not work when liver glycogen levels are low, as after a prolonged fast. Oral glucose is given to replenish glycogen reserves once the patient revives.

Whole pancreas and pancreatic islet transplantation

Whole pancreas transplantation has been performed for some 30 years, usually in diabetic patients who require immunosuppression for a kidney transplant. Surgical advances have greatly improved the outcome of this procedure. In experienced hands graft function lasts longer with considerable improvement in quality of life. Patient survival is better in those who receive simultaneous pancreas and kidney grafts, mainly because of the delay involved in waiting for a pancreas to become available following renal transplantation. There is some evidence of protection against or reversal of some complications of diabetes, but this comes at the cost of long-term immunosuppression.

Islet transplantation is performed by harvesting pancreatic islets from cadavers (two or three pancreata are usually needed); these are then injected into the portal vein and seed themselves into the liver. This form of treatment had limited success for many years, but improved treatment protocols have now achieved more promising results. The main indication is disabling hypoglycaemia, and the main disadvantage is the need for powerful immunosuppressive therapy, with its associated costs and complications.

Measuring the metabolic control of diabetes

Urine tests

Urine dipstick tests, although less informative than blood tests, offer some feedback on metabolic control. Patients

FURTHER READING

Yudkin JS, Richter B, Gale EA. Intensified glucose control in type 2 diabetes – whose agenda? *Lancet* 2011; 377: 1220–1222.

with consistently negative tests and no symptoms of hypoglycaemia are generally well controlled. Nevertheless, the correlation between urine tests and simultaneous blood glucose is poor for three reasons:

- Changes in urine glucose lag behind changes in blood glucose.
- The mean renal threshold is around 10 mmol/L but the range is wide (7–13 mmol/L). The threshold also rises with age.
- Urine tests can give no guidance concerning blood glucose levels below the renal threshold.

Home blood glucose testing

Blood tests offer invaluable feedback to everyone affected by diabetes, but their routine use varies according to need. Patients soon learn to provide their own profiles using finger-prick blood samples and reagent strips which can be read with the aid of a meter. Blood is taken from the side of a finger tip (not from the tip, which is densely innervated) using a special lancet usually fitted to a spring-loaded device, a range of which are available. The fasting blood glucose concentration is reproducible in diet or tablet-treated type 2 diabetes, and is therefore a useful guide to therapy, supplemented by occasional tests after meals. Those on insulin treatment require more frequent testing in order to adjust their therapy and avoid hypoglycaemia. Regular profiles (e.g. four daily samples on at least two days each week) are needed in those on intensified therapy, and should be recorded electronically or in a record book. Patients on insulin are encouraged to adjust their insulin dose as appropriate (Table 20.7) and should be able to obtain advice over the telephone when needed. Blood glucose monitoring does not in itself result in better control, but is essential to those wishing to achieve it.

Glycosylated haemoglobin (HbA_{1c} or HbA_{1c}) and fructosamine

Glycosylation of haemoglobin occurs as a two-step reaction, resulting in the formation of a covalent bond between the glucose molecule and the terminal valine of the β chain of the haemoglobin molecule. The rate at which this reaction occurs is related to the prevailing glucose concentration. Glycosylated haemoglobin is expressed as a percentage of the normal haemoglobin (standardized range 4–6.1%; 20–44 mmol/mol). This test provides an index of the average blood glucose concentration over the life of the haemoglobin molecule (approximately 6 weeks). The figure will be misleading if the life-span of the red cell is reduced or if an abnormal haemoglobin or thalassaemia is present. There is considerable interindividual variation in HbA_{1c} levels, even in health. Although the glycosylated haemoglobin test provides a rapid assessment of glycaemic control in a given patient, blood glucose testing is needed before the clinician can know what to do about it.

Glycosylated plasma proteins ('fructosamine') may also be measured as an index of control. Glycosylated albumin is the major component, and fructosamine measurement relates to glycaemic control over the preceding 2–3 weeks. It is useful in patients with anaemia or haemoglobinopathy and in pregnancy (when haemoglobin turnover is changeable) and other situations where changes of treatment need a swift means of assessing progress.

Targets for glucose control

Data from the UK Prospective Diabetic Study (UKPDS) and the Diabetes Control and Complications Trial (DCCT) suggest

Table 20.8 Target goals of risk factors for diabetic patients

Parameter	Ideal	Reasonable but not ideal
HbA _{1c}	<7% (53 mmol/mol)	<8% (64 mmol/mol)
Blood pressure (mmHg)	<130/80	<140/80
Total cholesterol (mmol/L)	<4.0	<5.0
LDL	<2.0	<3.0
HDL*	>1.1	>0.8
Triglycerides	<1.7	<2.0
Standards from American Diabetes Association (2003). *In women >1.3 mmol/L.		

that patients with both type 1 diabetes and type 2 diabetes should ideally aim to run their glycosylated haemoglobin readings below 7.0% (53 mmol/mol) in order to reduce the risk of long-term microvascular complications (Table 20.8). Hypoglycaemia, patterns of eating and lifestyle, weight problems and problems accepting and coping with diabetes limit what can be achieved (see p. 1017). Some will, but most will not, be able to reach these target values, particularly as their duration of diabetes increases. Realistic goals should be set for each patient, taking into account what is likely to be achievable, and this applies in particular to elderly patients and those with a limited prognosis.

Does good glucose control matter?

Blood glucose is just one measure of the diverse metabolic consequences of diabetes which not only affect carbohydrate metabolism but also the metabolism of lipids and proteins.

The DCCT in the USA compared standard and intensive insulin therapy in a large prospective controlled trial of young patients with type 1 diabetes. Despite intensive therapy, mean blood glucose levels were still 40% above the non-diabetic range, but even at this level of control, the risk of progression to retinopathy was reduced by 60%, nephropathy by 30% and neuropathy by 20% over the 7 years of the study. Near-normoglycaemia should, therefore, be the goal for all young patients with type 1 diabetes. The unwanted effects of this policy include weight gain and a two- to three-fold increase in the risk of severe hypoglycaemia. Control should be less strict in those with a history of recurrent severe hypoglycaemia.

The UKPDS compared standard and intensive treatment in a large prospective controlled trial of type 2 diabetes patients. There was a 25% overall reduction in microvascular disease end-points, a 33% reduction in albuminuria and a 30% reduction in the need for laser treatment for retinopathy in the more intensively treated patients. These benefits persisted for many years after conclusion of the trial (the 'legacy effect'). This study also showed blood pressure control to be equally necessary in the prevention of retinopathy, but there is no legacy effect and good blood pressure control needs to be maintained. There appeared to be little difference in outcome between the agents used to achieve good metabolic control (metformin, sulfonylurea or insulin). Intensive blood pressure control very considerably reduced the cardiovascular risk.

Recent trials in type 2 diabetes. Three large outcome studies in type 2 diabetes have confirmed the benefits of

Box 20.3 Regular checks for patients with diabetes

Checked each visit

- Review of self-monitoring results and current treatment
- Talk about targets and change where necessary
- Talk about any general or specific problems
- Continued education

Checked at least once a year

- Biochemical assessment of metabolic control (e.g. glycosylated Hb test)
- Measure bodyweight
- Measure blood pressure
- Measure plasma lipids (except in extreme old age)
- Measure visual acuity
- Examine state of retina (ophthalmoscope or retinal photo)
- Test urine for proteinuria/microalbuminuria
- Test blood for renal function (creatinine, eGFR)
- Check condition of feet, pulses and neurology
- Review cardiovascular risk factors
- Review self-monitoring and injection techniques
- Review eating habits

good glucose control upon microvascular complications, although these benefits diminish with increasing age. Glucose control appears to be of less value in prevention of arterial disease, and the current trend is to aim for more relaxed glucose control in older patients (e.g. $HbA_{1c} < 8\%$ (< 64 mmol/mol)), while attention to blood pressure and lipids should take priority. In the recent ACCORD study the use of intensive therapy to target a glycated hemoglobin level below 6% in people with type 2 diabetes increased 5-year mortality. Such an intensive strategy thus cannot be recommended, particularly for high-risk patients with advanced type 2 diabetes.

Regular checks for patients with diabetes

Box 20.3 is modified from the guidelines set out in *The European Patients' Charter* published by the St Vincent Declaration Steering Committee of the WHO. The charter sets out goals for both the healthcare team and the patient.

PSYCHOSOCIAL IMPLICATIONS OF DIABETES

Patients starting tablet or insulin treatment should live as normal a life as possible, but this is not always easy. Tact, empathy, encouragement and practical support are needed from all members of the clinical team. Diabetes, like any chronic disease, has psychological sequelae. Most patients will experience periods of not coping, of helplessness, of denial and of acceptance often fluctuating over time. Other problems include:

- **You cannot take a 'holiday' from diabetes** – yet the human psyche is poorly developed to cope with unremitting adversity.
- **Concessions or sympathy are often denied** to the person with diabetes, since its presence is invisible.
- **The treatment is complex and demanding**, and the person with diabetes must make trade-offs between short-term and long-term wellbeing.
- **Embarrassing loss of control over personal behaviour** or consciousness can occur in insulin-treated patients when minor miscalculation leads to hypoglycaemia.
- **Risk-taking behaviour** is indulged in by all humans when emotion is in conflict with logical thought, but its effects can be much greater for the person with

diabetes (particularly the risks of unplanned pregnancy, alcohol and tobacco).

- **Poor self-image** is a very common problem.
- **Eating disorders** are more common in people with diabetes – 30–40% of young women will report disordered eating at some stage of their diabetes.
- **Omission of tablets or insulin** is common since non-adherence to treatment regimens is universal in all illness. Between one in four and one in five tablets prescribed for diabetes is not consumed within the designated treatment period. Insulin omission is very common in young women in whom the pressure to lose weight may overcome concerns about long-term complications.

Adolescence

A period of poor metabolic control, or dropping out of medical care for a time and re-emerging with complications, is very common in adolescence. Diabetic Summer Camps (e.g. run by Diabetes UK) help prevent a feeling of isolation and not knowing anyone else with the same problem. Separate adolescent clinics allow:

- **Treatment without marginalization** in a larger group of older people
- **Meeting peers with similar problems** in the waiting room
- **Gradual separation from parents** and assumption of personal responsibility for the illness
- **Age-appropriate literature** should be available.

Practical aspects

Patients need to inform the driving and vehicle licensing authority and their insurance companies after diagnosis. They would also be wise to inform their family, friends and employers in case unexpected hypoglycaemia occurs. Insulin treatment can be undertaken by people in most walks of life. A few jobs are unsuitable; these include driving Heavy Goods or Public Service vehicles; working at heights; piloting aircraft or working close to dangerous machinery in motion. Certain professions such as the police and the armed forces are barred to all diabetic patients. There are few other limitations, although a considerable amount of ill-informed prejudice exists. Doctors can sometimes help support patients in the face of misinformed work practices.

DIABETIC METABOLIC EMERGENCIES

The main terms used are defined in Table 20.9.

Diabetic ketoacidosis

Diabetic ketoacidosis (DKA) is the hallmark of type 1 diabetes. It is usually seen in the following circumstances:

- Previously undiagnosed diabetes (10%)
- Interruption of insulin therapy (15%)
- The stress of intercurrent illness (30%).

The majority of cases reaching hospital could have been prevented by earlier diagnosis, better communication between patient and doctor and better patient education. The most common error of management is for patients to reduce or omit insulin because they feel unable to eat, owing to nausea or vomiting. This is a factor in at least 25% of all

Psychosocial implications of diabetes

Diabetic metabolic emergencies

Table 20.9 Terms used in uncontrolled diabetes

Ketonuria	Detectable ketone levels in the urine; it should be appreciated that ketonuria occurs in fasted non-diabetics and may be found in relatively well-controlled patients with insulin-dependent diabetes mellitus
Ketosis	Elevated plasma ketone levels in the absence of acidosis
Diabetic ketoacidosis	A metabolic emergency in which hyperglycaemia is associated with a metabolic acidosis due to greatly raised (>5 mmol/L) ketone levels
Hyperosmolar hyperglycaemic state	A metabolic emergency in which uncontrolled hyperglycaemia induces a hyperosmolar state in the absence of significant ketosis
Lactic acidosis	A metabolic emergency in which elevated lactic acid levels induce a metabolic acidosis. In diabetic patients it is rare and associated with biguanide therapy

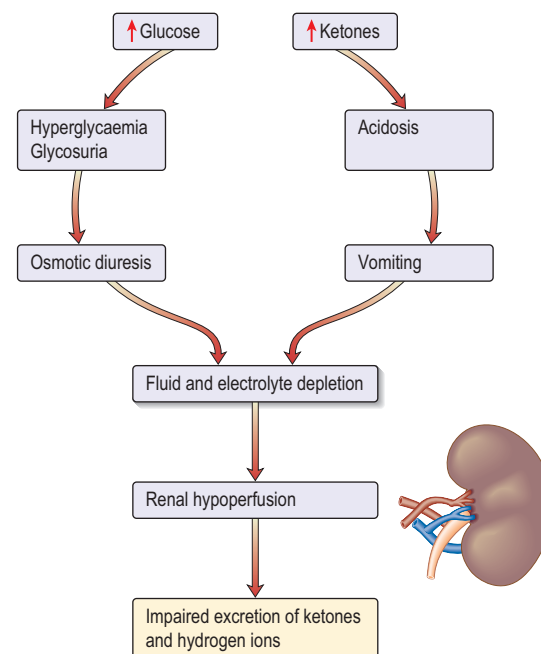

hospital admissions. Insulin may need adjusting up or down but should never be stopped.

Pathogenesis

Ketoacidosis is a state of uncontrolled catabolism associated with insulin deficiency. Insulin deficiency is a necessary precondition since only a modest elevation in insulin levels is sufficient to inhibit hepatic ketogenesis, and stable patients do not readily develop ketoacidosis when insulin is withdrawn. Other factors include counter-regulatory hormone excess and fluid depletion. The combination of insulin deficiency with excess of its hormonal antagonists leads to the parallel processes shown in Figure 20.11. In the absence of insulin, hepatic glucose production accelerates, and peripheral uptake by tissues such as muscle is reduced. Rising glucose levels lead to an osmotic diuresis, loss of fluid and electrolytes, and dehydration. Plasma osmolality rises and renal perfusion falls. In parallel, rapid lipolysis occurs, leading to elevated circulating free fatty-acid levels. The free fatty acids are broken down to fatty acyl-CoA within the liver cells, and this in turn is converted to ketone bodies within the mitochondria (Fig. 20.12). Accumulation of ketone bodies produces a metabolic acidosis. Vomiting leads to further loss of fluid and electrolytes. The excess ketones are excreted in the urine but also appear in the breath, producing a distinctive smell similar to that of acetone. Respiratory compensation for the acidosis leads to hyperventilation, graphically described as 'air hunger'. Progressive dehydration impairs renal excretion of hydrogen ions and ketones, aggravating the acidosis. As the pH falls below 7.0 ($[H^+] > 100 \text{ nmol/L}$), pH-dependent enzyme systems in many cells function less effectively. Untreated, severe ketoacidosis is invariably fatal.

Clinical features

The features of ketoacidosis are those of uncontrolled diabetes with acidosis, and include prostration, hyperventilation (Kussmaul respiration), nausea, vomiting and, occasionally, abdominal pain. The latter is sometimes so severe that it can be confused with a surgical acute abdomen.

**Figure 20.11** Dehydration occurs during ketoacidosis as a consequence of two parallel processes.

Hyperglycaemia results in osmotic diuresis, and hyperketonaemia results in acidosis and vomiting. Renal hypoperfusion then occurs and a vicious circle is established as the kidney becomes less able to compensate for the acidosis.

**Figure 20.12** Ketogenesis. During insulin deficiency, lipolysis accelerates and free fatty acids taken up by liver cells form the substrate for ketone formation (acetoacetate, acetone and β-hydroxybutyrate) within the mitochondrion. These ketones pass into the blood, producing acidosis.

Some patients are mentally alert at presentation, but confusion and stupor are present in more severe cases. Up to 5% present in coma. Evidence of marked dehydration is present and the eyeball is lax to pressure in severe cases. Hyperventilation is present but becomes less marked in very severe acidosis owing to respiratory depression. The smell of ketones on the breath allows an instant diagnosis to be made by those able to detect the odour. The skin is dry and the body temperature is often subnormal, even in the presence of infection; in such cases, pyrexia may develop later.

Diagnosis

This is confirmed by demonstrating hyperglycaemia with ketonaemia or heavy ketonuria, and acidosis. No time should be lost, and treatment is started as soon as the first blood sample has been taken. Hyperglycaemia is demonstrated by dipstick, while a venous blood sample is sent to the laboratory for confirmation. Ketonaemia is confirmed by centrifuging a blood sample and testing the plasma with a dipstick that measures ketones. Hand-held sensors measuring β -hydroxybutyrate in 30 s are available. An arterial blood sample is taken for blood gas analysis.

The severity of DKA can be assessed as follows. One or more suggest severe DKA.

Clinical

- Pulse >100 b.p.m. or <60 b.p.m.
- Systolic BP <90 mmHg
- Glasgow Coma Score of <12 (see Table 22.10, p. 1092) or abnormal 'Alert, Voice, Pain, Unresponsive' scale (AVPU)
- O₂ saturation <92% on air (if normal respiratory function)

Bloods

- Blood ketones >6 mmol/L
- Bicarbonate <12 mmol/L
- Venous/arterial pH <7.1
- Hypokalaemia on admission <3.5 mmol/L

Management (pathophysiology)

The principles of management are as follows (Emergency Box 20.1); these should be carried out in a high dependency area.

- Replace the **fluid losses** with 0.9% saline. Average loss of water is 5–7 litres with a sodium loss of 500 mmol.
- Replace the **electrolyte losses**. Patients have a total body potassium deficit of 350 mmol, although initial plasma levels may not be low. Insulin therapy leads to uptake of potassium by the cells with a consequent fall in plasma K⁺ levels. Potassium is therefore given as soon as insulin is started.
- **Restore the acid–base balance**. A patient with healthy kidneys will rapidly compensate for the metabolic

Emergency Box 20.1

Guidelines for the diagnosis and management of diabetic ketoacidosis

Diagnosis

- Hyperglycaemia: measure blood glucose.
- Ketonaemia: test plasma with Ketostix. Finger-prick sample for β -hydroxybutyrate.
- Ketonuria: measure urine ketone levels where plasma ketone measurements are not available.
- Acidosis: measure
 - pH in arterial blood
 - bicarbonate in venous blood.

What to do immediately

1. Assess
2. Send bloods to laboratory
3. Set up i.v. infusion
 - Blood glucose
 - measure baseline and hourly initially
 - aim for fall of 3–6 mmol/L (55–110 mg/dL) per hour
 - Urea and electrolytes – do at baseline and hourly until 6 hours, then at 12 hours and 24 hours
 - Potassium – add when K⁺ <3.5 mmol/L. Give 20 mmol/h in infusion. 10 mmol/h when K⁺ = 3.5–5 mmol
 - Full blood count
 - Blood gases – at 0, 2 hours, 6 hours
 - Creatinine – at 0, 6, 12, 24 hours
 - Bicarbonate – at 0, 1, 2, 3, 6, 12, 24 hours.

Phase 1

- Admit to Level 2 HDU.
- **INSULIN**: soluble insulin i.v. 0.1 U/kg/h by infusion, or 20 units i.m. stat. followed by 6 units i.m. hourly.
- **FLUID AND ELECTROLYTE REPLACEMENT**: i.v. 0.9% sodium chloride with 20 mmol KCl/L.
 - 1 L in 30 min, then
 - 1 L in 1 h
 - 1 L in 2 h
 - 1 L in 4 h
 - 1 L in 8 h.
- Adjust KCl concentration depending on results of regular blood K⁺ measurement.

IF:

- Blood pressure below 80 mmHg, give 500 mL 0.9% sodium chloride over 15 min; if no response, give plasma expander
- pH below 7.0 give 500 mL of sodium bicarbonate 1.26% plus 10 mmol KCl. Repeat if necessary to bring pH up to 7.0.

Phase 2

INSULIN AND GLUCOSE: When blood glucose falls to 10–12 mmol/L, change infusion fluid to 1 L 5% glucose plus 20 mmol KCl 6-hourly. Continue insulin with dose adjusted according to hourly blood glucose test results (e.g. i.v. 3 U/h glucose 15 mmol/L; 2 U/h when glucose 10 mmol/L).

Phase 3

Once stable and able to eat and drink normally, transfer patient to four times daily subcutaneous insulin regimen (based on previous 24 hours' insulin consumption and trend in consumption).

Other semi-urgent procedures

- Blood and urine culture
- Cardiac enzymes
- CXR
- ECG (monitor if electrolyte problems or severe DKA)
- Catheterization if no urine passed after 3 hours of hydration
- If conscious – nasogastric tube
- Antibiotics if infection.

Special measures

- Broad-spectrum antibiotic if infection likely
- Bladder catheter if no urine passed in 2 hours
- Nasogastric tube if drowsy
- Consider CVP pressure monitoring if shocked or if previous cardiac or renal impairment
- Give s.c. prophylactic LMW heparin.

Subsequent management

- Monitor glucose hourly for 8 hours.
- Monitor electrolytes 2-hourly for 8 hours.
- Adjust K replacement according to results.

Note: The regimen of fluid replacement set out above is a guide for patients with severe ketoacidosis. Excessive fluid can precipitate pulmonary and cerebral oedema; inadequate replacement may cause renal failure. Fluid replacement must therefore be tailored to the individual and monitored carefully throughout treatment.

acidosis once the circulating volume is restored. Bicarbonate is seldom necessary and is only used if the pH is below 7.0 ($[H^+] > 100 \text{ nmol/L}$), and is best given as an isotonic (1.26%) solution.

- **Replace the deficient insulin.** Relatively modest doses of insulin lower blood glucose by suppressing hepatic glucose output rather than by stimulating peripheral uptake, and are therefore much less likely to produce hypoglycaemia. Insulin and glucose together both inhibit gluconeogenesis, and thus ketone production, and are needed to metabolize ketones into less harmful substances. Short-acting insulin is given as an intravenous infusion where facilities for adequate supervision exist or as hourly intramuscular injections. The subcutaneous route is avoided because subcutaneous blood flow is reduced in shocked patients.
- **Monitor blood glucose closely** (see [Emergency Box 20.1](#)).
- **Seek the underlying cause.** Physical examination may reveal a source of infection (e.g. a perianal abscess). Two common markers of infection are misleading: fever is unusual even when infection is present, and polymorpholeucocytosis is present even in the absence of infection. Relevant investigations include a chest X-ray, urine and blood cultures and an ECG (to exclude myocardial infarction). The serum amylase may be elevated in the absence of pancreatitis. If infection is suspected, broad-spectrum antibiotics are started once the appropriate cultures have been taken.

Problems of management

- **Hypotension.** This may lead to renal shutdown. Plasma expanders (or whole blood) are therefore given if the systolic blood pressure is below 80 mmHg. A central venous pressure line is useful in this situation. A bladder catheter is inserted if no urine is produced within 2 h, but routine catheterization is not necessary.
- **Coma.** The usual principles apply (see [p. 1093](#)). It is essential to pass a nasogastric tube to prevent aspiration, since gastric stasis is common and carries the risk of aspiration pneumonia if a drowsy patient vomits.
- **Cerebral oedema.** This is a rare, but serious complication and has mostly been reported in children or young adults. Excessive rehydration and use of hypertonic fluids such as 8.4% bicarbonate may sometimes be responsible. The mortality is high.
- **Hypothermia.** Severe hypothermia with a core temperature below 33°C may occur and can be overlooked unless a rectal temperature is taken with a low-reading thermometer.
- **Late complications.** These include pneumonia and deep-vein thrombosis (DVT prophylaxis, see [p. 429](#) is essential) and occur especially in the comatose or elderly patient.
- **Complications of therapy.** These include hypoglycaemia and hypokalaemia, due to loss of K^+ in the urine from osmotic diuresis. Overenthusiastic fluid replacement may precipitate pulmonary oedema in the very young or the very old. Hyperchloraemic acidosis may develop in the course of treatment since patients have lost a large variety of negatively charged electrolytes, which are replaced with chloride. The kidneys usually correct this spontaneously within a few days.

Subsequent management

Intravenous glucose and insulin are continued until the patient feels able to eat and keep food down. The drip is then taken down and a similar amount of insulin is given as four injections of soluble insulin subcutaneously at meal times and a dose of intermediate-acting insulin at night.

Sliding-scale regimens are unnecessary and may even delay the establishment of stable blood glucose levels.

The mortality of diabetic ketoacidosis is around 5%, and is increased in older patients. Its treatment is incomplete without a careful enquiry into the causes of the episode and advice as to how to avoid its recurrence.

Hyperosmolar hyperglycaemic state

This condition, in which severe hyperglycaemia develops without significant ketosis, is the metabolic emergency characteristic of uncontrolled type 2 diabetes. Patients present in middle or later life, often with previously undiagnosed diabetes. Common precipitating factors include consumption of glucose-rich fluids, concurrent medication such as thiazide diuretics or steroids, and intercurrent illness. The hyperosmolar hyperglycaemic state and ketoacidosis represent two ends of a spectrum rather than two distinct disorders ([Box 20.4](#)). The biochemical differences may partly be explained as follows:

- **Age.** The extreme dehydration characteristic of hyperosmolar hyperglycaemic state may be related to age. Old people experience thirst less acutely, and more

Box 20.4 Electrolyte changes in diabetic ketoacidosis and the hyperosmolar hyperglycaemic state

Examples of blood values

	Severe ketoacidosis	Hyperosmolar hyperglycaemic state
Na^+ (mmol/L)	140	155
K^+ (mmol/L)	5	5
Cl^- (mmol/L)	100	110
HCO_3^- (mmol/L)	5	25
Urea (mmol/L)	8	15
Glucose (mmol/L)	30	50
Arterial pH	7.0	7.35

The normal range of osmolality is 285–300 mOsm/kg. It can be measured directly, or can be calculated approximately from the formula:

$$\text{Osmolality} = 2(\text{Na}^+ + \text{K}^+) + \text{glucose} + \text{urea}.$$

For instance, in the example of severe ketoacidosis given above:

$$\text{Osmolality} = 2(140 + 5) + 30 + 8 = 328 \text{ mOsm/kg}$$

and in the example of the hyperosmolar hyperglycaemic state:

$$\text{Osmolality} = 2(155 + 5) + 50 + 15 = 385 \text{ mOsm/kg}.$$

The normal anion gap is <17 . It is calculated as $(\text{Na}^+ + \text{K}^+) - (\text{Cl}^- + \text{HCO}_3^-)$. In the example of ketoacidosis the anion gap is 40, and in the example of the hyperosmolar hyperglycaemic state, the anion gap is 25. Mild hyperchloraemic acidosis may develop in the course of therapy. This will be shown by a rising plasma chloride and persistence of a low bicarbonate even though the anion gap has returned to normal.

readily become dehydrated. In addition, the mild renal impairment associated with age results in increased urinary losses of fluid and electrolytes.

- **The degree of insulin deficiency.** This is less severe in the hyperosmolar hyperglycaemic state. Endogenous insulin levels are sufficient to inhibit hepatic ketogenesis, but insufficient to inhibit hepatic glucose production.

Clinical features

The characteristic clinical features on presentation are dehydration and stupor or coma. Impairment of consciousness is directly related to the degree of hyperosmolality. Evidence of underlying illness such as pneumonia or pyelonephritis may be present, and the hyperosmolar state may predispose to stroke, myocardial infarction or arterial insufficiency in the lower limbs.

Investigations and treatment

These are (with some exceptions) according to the guidelines for ketoacidosis. The plasma osmolality is usually extremely high. It can be measured directly or calculated as $(2(\text{Na}^+ + \text{K}^+) + \text{glucose} + \text{urea})$, all in mmol/L. Many patients are extremely sensitive to insulin, and the glucose concentration may plummet. The resultant change in osmolality may cause cerebral damage. It is sometimes useful to infuse insulin at a rate of 3 U/hour for the first 2–3 hours, increasing to 6 U/hour if glucose is falling too slowly. The standard fluid for replacement is 0.9% saline. Avoid 0.45% saline, since rapid dilution of the blood may cause more cerebral damage than a few hours of exposure to hypernatraemia. Low-molecular-weight heparin should be given to counter the increased risk of thromboembolic complications associated with this condition.

Prognosis

The reported mortality ranges as high as 20–30%, mainly because of the more advanced age of the patients and the frequency of intercurrent illness. Unlike ketoacidosis, the hyperosmolar hyperglycaemia state is not an absolute indication for subsequent insulin therapy, and survivors may do well on diet and oral agents.

Lactic acidosis

Lactic acidosis may occur in diabetic patients on biguanide therapy. The risk in patients taking metformin is extremely low provided that the therapeutic dose is not exceeded and the drug is withheld in patients with advanced hepatic or renal dysfunction.

Patients present in severe metabolic acidosis with a large anion gap (normally <17 mmol/L), usually without significant hyperglycaemia or ketosis. Treatment is by rehydration and infusion of isotonic 1.26% bicarbonate. The mortality is in excess of 50%.

COMPLICATIONS OF DIABETES

People with diabetes still have a considerably reduced life expectancy. The major cause of death in treated patients is due to cardiovascular problems (60–70%) followed by renal failure (10%) and infections (6%). There is no doubt that the duration and degree of hyperglycaemia play a major role in the production of complications. Better diabetic control can reduce the rate of progression of both nephropathy and retinopathy and the DCCT showed a 60% reduction in developing complications over 9 years when the HbA_{1c} was kept at around 7% in type 1 diabetes.

Pathophysiology

The mechanisms leading to damage are ill-defined. The following are consequences of hyperglycaemia and may play a role:

- **Non-enzymatic glycosylation** of a wide variety of proteins, e.g. haemoglobin, collagen, LDL and tubulin in peripheral nerves. This leads to an accumulation of advanced glycosylated end-products causing injury and inflammation via stimulation of pro-inflammatory factors, e.g. complement, cytokines.
- **Polyol pathway.** The metabolism of glucose by increased intracellular aldose reductase leads to accumulation of sorbitol and fructose. This causes changes in vascular permeability, cell proliferation and capillary structure via stimulation of protein kinase C and TGF- β .
- **Abnormal microvascular blood flow** impairs supply of nutrients and oxygen. Microvascular occlusion is due to vasoconstrictors, e.g. endothelins and thrombogenesis, and leads to endothelial damage.
- **Other factors** include the formation of reactive oxygen species and growth factors stimulation (TGF- β) and vascular endothelial growth factor (VEGF). These growth factors are released by ischaemic tissues and cause endothelial cells to proliferate.
- **Haemodynamic changes**, e.g. in kidney (see p. 1025).

It has been proposed that all of the above mechanisms stem from a single hyperglycaemia-induced process of overproduction of superoxide by the mitochondrial electron chain. This paradigm offers an integrated explanation of how complications of diabetes develop.

Macrovascular complications (Table 20.10)

Diabetes is a risk factor for the development of atherosclerosis. This risk is related to that of the background population. For example, people with diabetes in Japan are less likely than European patients to develop atherosclerosis, but more likely to develop it than non-diabetic Japanese.

- Stroke is twice as likely.
- Myocardial infarction is 3–5 times as likely, and women with diabetes lose their premenopausal protection from coronary artery disease.
- Amputation of a foot for gangrene is 50 times as likely.

Several large trials have shown that intensive glucose-lowering treatment of diabetes has a relatively minor effect upon cardiovascular risk. Since the effect of other cardiovascular risk factors is enhanced in diabetes, it is vital to tackle all cardiovascular risk factors together in diabetes, and not just to focus on glucose levels.

- **Hypertension.** The UKPDS demonstrated that aggressive treatment of hypertension produces a marked reduction in adverse cardiovascular outcomes,

Table 20.10 Diabetic risk factors for macrovascular complications

Duration
Increasing age
Systolic hypertension
Hyperinsulinaemia due to insulin resistance associated with obesity and the metabolic syndrome
Hyperlipidaemia, particularly hypertriglyceridaemia/low HDL
Proteinuria (including microalbuminuria)
Other factors are the same as for the general population

both microvascular and macrovascular. To achieve the target for blood pressure (Table 20.8), the UKPDS found that one-third of patients needed three or more antihypertensive drugs in combination, and two-thirds of treated patients needed two or more.

- **Smoking:** the avoidable risk factor (see p. 806). Never give up efforts to help diabetic patients stop smoking.
- **Lipid abnormalities.** Clinical trials suggest that there is no 'safe' cut-off for serum cholesterol. The lowest achievable level seems best to aim for, and in practice this means that almost all people with type 2 diabetes will be treated with a statin.
- **Low-dose aspirin** can reduce macrovascular risk, but is associated with a morbidity and mortality from bleeding. The benefits of aspirin outweigh the bleeding risk when the risk of a cardiovascular end-point is >30% in the next 10 years. This risk is reached in patients aged under 45 with three strong additional cardiovascular risk factors, aged 45–54 with three additional risk factors, aged 54–65 with two additional risk factors or aged over 65 with just one additional risk factor.
- **ACE inhibitors/angiotensin II receptor antagonists.** Treating people with diabetes and at least one other major cardiovascular risk factor with an ACE inhibitor produces a 25–35% lowering of the risk of heart attack, stroke, overt nephropathy or cardiovascular death. Angiotensin II receptor antagonists are sometimes preferred initially and are also used for those intolerant to ACE inhibitors.

Microvascular complications

In contrast to macrovascular disease, which is prevalent in the West as a whole, microvascular disease is specific to diabetes. Small blood vessels throughout the body are affected but the disease process is of particular danger in three sites:

- Retina
- Renal glomerulus
- Nerve sheaths.

Diabetic retinopathy, nephropathy and neuropathy tend to manifest 10–20 years after diagnosis in young patients, but may present earlier in older patients, probably because these have had unrecognized diabetes for months or even years prior to diagnosis. Genetic factors appear to contribute to the susceptibility to microvascular disease. Diabetic siblings of diabetic patients with renal and eye disease have a three- to five-fold increased risk of the same complication in both type 1 and type 2 patients. There are racial differences in the overall prevalence of nephropathy. In the USA, prevalence is: Pima American Indians > Hispanic/Mexican > US black > US white patients.

Diabetic eye disease

At least 90% of young patients with type 1 diabetes will develop retinal changes, but these only progress to sight-threatening retinopathy in a minority. Some 30–50% will require laser photocoagulation to prevent or limit progression to proliferative retinopathy, and good control of blood pressure is essential. Diabetes is still the commonest cause of blindness in under 65 year olds. It affects the eye in a variety of ways:

- **Diabetic retinopathy** is damage to the retina and iris caused by diabetes, which can lead to blindness.

- **Cataract** is denaturation of the protein and other components of the lens of the eye which render it opaque.
- **External ocular palsies** (p. 1081). The sixth and the third nerve are the most commonly affected. Third nerve palsy is not associated with pain. These nerve palsies usually recover spontaneously within a period of 3–6 months.

Natural history

Cataracts

Cataract develops earlier in people with diabetes than in the general population. Sustained very poor diabetes control with a degree of ketosis can cause an acute cataract (snowflake cataract), which comes on rapidly. Fluctuations in blood glucose concentration can cause refractive variability, as a result of osmotic changes within the lens (the absorption of water into the lens causes temporary hypermetropia). This presents as fluctuating difficulty in reading. It resolves with better metabolic control of the diabetes.

Diabetic retinopathy

Diabetic retinopathy (Fig. 20.13) is the most commonly diagnosed diabetes-related complication. Its prevalence increases with the duration of diabetes (Fig. 20.14). Some 20% of people with type 1 diabetes will have retinal changes after 10 years, rising to >95% after 20 years (see Table 20.11); 20–30% of people with type 2 diabetes have retinopathy at diagnosis. The metabolic consequences of poorly-controlled diabetes cause intramural pericyte death, and thickening of the basement membrane in the small blood vessels of the retina. This leads initially to incompetence and increased permeability of the vascular walls, and later to occlusion of the vessels (capillary closure). This process has somewhat different consequences in the peripheral retina and in the macular area.

Peripheral retina

Damage to the wall of small vessels causes *microaneurysms* (small red dots) within the retina. When vessel walls are breached *superficial (blot) haemorrhages* occur in the ganglion cell and outer plexiform layers. Damaged blood vessels leak fluid into the retina. The fluid is cleared into the retinal veins leaving behind protein and lipid deposits causing *hard exudates*. These are eventually cleared by macrophages.

Micro-infarcts within the retina due to occluded vessels cause *cotton wool spots*. The spot itself is due to the accumulation of axoplasmic debris. This debris is removed by macrophages. As this occurs, there may be white dots at the site of the previous cotton wool spot (*cytoid bodies*). Damage to the walls of veins causes their calibre to vary (*venous beading*), and elongation to occur causing *venous loops*. Blockage of blood vessels leads to areas of capillary non-perfusion. Ischaemia in these areas causes the release of vascular growth factors such as VEGF (vascular endothelial growth factor). These factors cause new blood vessels to grow in the retina (*neovascularization*). Some of these new blood vessels are inside the retina and are helpful. These new intraretinal vessels, and other vessels whose walls are damaged and dilated, give the appearance of *intraretinal microvascular abnormalities (IRMAs)*.

Other new vessels emerge through the retina and lie on its surface, usually at the margin of an area of capillary closure. The normal shearing stresses that occur within the eye can cause these poorly supported new vessels to bleed. Small haemorrhages give rise to *pre-retinal haemorrhages* (boat-shaped haemorrhages). With further bleeding

Figure 20.13 Features of diabetic eye disease.

(a) The normal macula (centre) and optic disc (to left). (b) Microaneurysms (small circles) and blot haemorrhage (larger circle) – early background retinopathy. (c) Hard exudates (circled) and single cotton wool spot (arrowed) in addition to multiple blot haemorrhages in background retinopathy. (d) Intra-retinal microvascular abnormalities (IRMA) – pre-proliferative retinopathy (circled). (e) Venous loop (circled) also indicates pre-proliferative change. (f) Fronds of new vessels on the disc and elsewhere (proliferative). (g) Pre-retinal haemorrhage in proliferative disease. (h) Hard exudates within a disc-width of the macula (maculopathy). (i) Cortical and (j) central cataracts can be seen against the red reflex with the ophthalmoscope.

vitreous haemorrhage occurs with consequent sudden loss of vision. Later collagen tissue grows along the margins of the new vessels and giving rise to *fibrotic bands*. These bands may contract and pull on the retina causing further haemorrhage and *retinal detachment*. Sometimes vessels may be induced to grow on the pupil margin (*rubeosis*) and in the angle of the anterior chamber of the eye giving rise to rapid increase in intraocular pressure (*rubeotic glaucoma*). These features of retinopathy in the peripheral retina are grouped, according to the risk of visual loss, into three stages (Table 20.11).

Figure 20.14 Prevalence of retinopathy in relation to duration of the disease in patients with type 1 diabetes mellitus diagnosed under the age of 33 years. Almost all eventually develop background change and 60% progress to proliferative retinopathy. (Data from Archives of Ophthalmology 1984; 102:520.)

Macular area

Fluid from leaking vessels is cleared poorly in the macular area due to its anatomy differing from the rest of the retina. Above a certain rate of formation, clearance fails and macular oedema occurs. This distorts and thickens the retina at the macula. If sustained, this distortion causes loss of central vision. Macular oedema is not visible with the ophthalmoscope or with retinal photography. For this reason surrogate markers for the presence of macular oedema are used (Table 20.11). Capillary occlusion in the macular area will also cause loss of central vision.

Examination

Bedside examination of the eye. *Visual acuity* should be checked using both a pinhole and the patient's distance spectacles. The *ocular movements* are assessed to detect any ocular motor palsies. The *iris* is examined for rubeosis and then the pupils dilated with 1% tropicamide. About 20 minutes later the eye is examined for the presence of a cataract by looking at the lens with a +10.00 lens in the ophthalmoscope and viewing the lens against the red reflex. The *retina* is then examined systematically looking at the disc, then all four quadrants, and finally the macula. The macula is examined last because this induces the greatest discomfort, and pupillary constriction.

Eye screening

Screening for sight-threatening eye disease with universal access is seen as offering the best hope of displacing diabetes as the commonest cause of blindness in those under 65 years of age. The National Screening Committee in the UK has helped establish digital photography-based screening across the country, based on a national set of standards. All people with diabetes, over the age of 12 are offered annual measurement of their acuity, and photographs of their retina. Box 20.5 shows standardized criteria for screening schemes; these are regularly inspected.

Management of diabetic eye disease (Table 20.11)

Cataract

Extraction and intraocular lens implantation is indicated if the cataract is causing visual disability to the patient or is giving rise to inability to view the retina adequately. Cataract extraction is straightforward if there is no retinopathy present. Pre-existing retinopathy may worsen after cataract extraction.

Retinopathy

The DCCT and UKPDS show that the risk of developing diabetic eye disease, and the risk of established retinopathy

Table 20.11 Grading of pathological changes in the retina in diabetic retinopathy: the action needed

Retinopathy grade	Retinal abnormality (cause)	Action needed
Peripheral retina		
Background (R1)	Dot haemorrhages (capillary microaneurysms) (usually appear first) Blot haemorrhages (leakage of blood into deeper retinal layers) Hard exudates (exudation of plasma rich in lipids and protein)	Annual screening only
Pre-proliferative (R2)	Cotton wool spots/Cytoid bodies Venous beading/loops Intraretinal microvascular abnormalities – IRMAs	Non-urgent referral to an ophthalmologist
Proliferative (R3)	Multiple deep round haemorrhages New blood vessel formation/neovascularization Preretinal or subhyaloid haemorrhage	Urgent referral to an ophthalmologist
Advanced retinopathy	Vitreous haemorrhage Retinal fibrosis Traction retinal detachment	Urgent referral to an ophthalmologist – but much vision already lost
Central retina		
Maculopathy (M1)	Hard exudates within one disc-width of macula Lines or circles of hard exudates within 2 disc-widths of macula Microaneurysms or retinal haemorrhages within 1 disc-width of macula if associated with an unexplained visual acuity 6/12 or worse	Referral to an ophthalmologist soon

Note: Hard exudates have a bright yellowish-white colour and are often irregular in outline with a sharply defined margin. Cotton-wool spots are greyish-white, have indistinct margins and a dull matt surface, unlike the glossy appearance of hard exudates. R, retinopathy; M, maculopathy.

Box 20.5 Criteria for a successful local screening scheme for sight-threatening diabetic retinopathy

Clearly defined geographical area for the screening programme	Single collated list of all people with diabetes in the area over the age of 12
Adequate number of people with diabetes for viability (>12 000)	Equipment to obtain adequate disc and macula centred images of each eye
An identified screening programme manager	Single image grading centre
An identified clinical screening lead	Process to manage people with poor quality images
An identified hospital eye service for diagnosis and laser treatment	Clear route of referral for treatment, and for feedback from treatment centre to screening unit
Computer software capable of supporting call/recall of patients and image grading	Accreditation of screening staff
Centralized appointment administration	Annual reporting of service performance

developing further, can be reduced by tight metabolic control of both diabetes and blood pressure. Development or progression of retinopathy may be accelerated by rapid improvement in glycaemic control, pregnancy and in those with nephropathy, and these groups need frequent monitoring. Fluorescein angiography (a fluorescent dye is injected into an arm vein and photographed in transit through the retinal vessels) is used to define the extent of the potentially sight-threatening diabetic retinopathy. Ocular coherence tomography (OCT) is used to image the content of the layers of the retina at the macula, and in particular to measure retinal thickness. It can detect macular oedema and other macular abnormalities.

Treatment of proliferative retinopathy

New vessels are an indication for laser photocoagulation therapy. New vessels on the disc carry the worst prognosis and warrant urgent laser therapy. The laser should be directed

at the new vessels and, in addition, to the associated areas of capillary non-perfusion (ischaemia). If the proliferative retinopathy has progressed to new vessels developing on the optic disc then a technique known as *panretinal photocoagulation (PRP)* is carried out. This involves multiple laser burns to the peripheral retina, especially in the areas of capillary non-perfusion. Rubeosis is also treated with panretinal photocoagulation. If some bleeding has occurred but there is a good view then laser treatment should be applied. Vitreoretinal surgery is used if bleeding is recurrent and preventing laser therapy. It is also used to try to salvage some vision after vitreous haemorrhage and to treat fibrotic traction retinal detachment in advanced retinopathy.

Treatment of maculopathy

Extrafoveal exudates can be watched. However, if they are beginning to encroach on the fovea then the centre of any rings of exudates, should be treated by laser photocoagulation. If oedema has spread into the centre of the macula, then a technique known as grid photocoagulation is used, where a number of laser burns are scattered around the macula. This limits deterioration in vision, and on occasion results in some visual improvement. Ischaemic maculopathy is not treatable, and leads to central visual loss.

The future

Anti-VEGF drugs, such as bevacizumab and ranibizumab (see p. 1064) are being used to control diabetic retinopathy and diabetic maculopathy, particularly that which involves the centre of the macula and is causing sight loss. Recent studies have shown benefit over laser for this type of maculopathy.

The diabetic kidney

The kidney may be damaged by diabetes in three main ways:

- Glomerular damage
- Ischaemia resulting from hypertrophy of afferent and efferent arterioles
- Ascending infection.

Diabetic nephropathy

Epidemiology

Clinical nephropathy secondary to glomerular disease usually manifests 15–25 years after diagnosis of diabetes and affects 25–35% of patients diagnosed under the age of 30 years. It is the leading cause of premature death in young diabetic patients. Older patients also develop nephropathy, but the proportion affected is smaller. The incidence of end-stage kidney disease has fallen in recent decades, probably due to better control of blood glucose and blood pressure, but this benefit has been cancelled out by the rising incidence of both types of diabetes.

Pathophysiology

The earliest functional abnormality in the diabetic kidney is renal hypertrophy associated with a raised glomerular filtration rate. This appears soon after diagnosis and is related to poor glycaemic control. As the kidney becomes damaged by diabetes, the afferent arteriole (leading to the glomerulus) becomes vasodilated to a greater extent than the efferent glomerular arteriole. This increases the intraglomerular filtration pressure, further damaging the glomerular capillaries. This increased intraglomerular pressure also leads to increased local shearing forces which are thought to contribute to mesangial cell hypertrophy and increased secretion of extracellular mesangial matrix material. This process eventually leads to glomerular sclerosis. The initial structural lesion in the glomerulus is thickening of the basement membrane. Associated changes result in disruption of the protein cross-linkages which normally make the membrane an effective filter. In consequence, there is a progressive leak of large molecules (particularly protein) into the urine.

Albuminuria

The earliest evidence of this is 'microalbuminuria' – amounts of urinary albumin so small as to be undetectable by standard dipsticks (see p. 309). Microalbuminuria may be tested for by radioimmunoassay or by using special dipsticks. It is a predictive marker of progression to nephropathy in type 1 diabetes, and of increased cardiovascular risk in type 2 diabetes. Microalbuminuria may, after some years, progress to intermittent albuminuria followed by persistent proteinuria. Light-microscopic changes of glomerulosclerosis become manifest; both diffuse and nodular glomerulosclerosis can occur. The latter is sometimes known as the Kimmelstiel–Wilson lesion. At the later stage of glomerulosclerosis, the glomerulus is replaced by hyaline material.

At the stage of persistent proteinuria, the plasma creatinine is normal but the average patient is only some 5–10 years from end-stage kidney disease. The proteinuria may become so heavy as to induce a transient nephrotic syndrome, with peripheral oedema and hypoalbuminaemia.

Patients with nephropathy typically show a normochromic normocytic anaemia and a raised erythrocyte sedimentation rate (ESR). Hypertension is a common development and may itself damage the kidney still further. A rise in plasma creatinine is a late feature that progresses inevitably to renal failure, although the rate of progression may vary widely between individuals.

The natural history of this process is shown in Figure 20.15.

Ischaemic lesions

Arteriolar lesions, with hypertrophy and hyalinization of the vessels, can occur in patients with diabetes. The

Figure 20.15 Schematic representation of the natural history of nephropathy. The typical onset is 15 years after diagnosis. Intermittent proteinuria leads to persistent proteinuria. In time, the plasma creatinine rises as the glomerular filtration rate falls.

appearances are similar to those of hypertensive disease and lead to ischaemic damage to the kidneys.

Infective lesions

Urinary tract infections are relatively more common in women with diabetes, but not in men. Ascending infection may occur because of bladder stasis resulting from autonomic neuropathy, and infections more easily become established in damaged renal tissue. Autopsy material frequently reveals interstitial changes suggestive of infection, but ischaemia may produce similar changes and the true frequency of pyelonephritis in diabetes is uncertain. Untreated infections in diabetics can result in renal papillary necrosis, in which renal papillae are shed in the urine, but this complication is now very rare.

Diagnosis

The urine of all diabetic patients should be checked regularly (at least annually) for the presence of protein. Many centres also screen younger patients for microalbuminuria since there is evidence that meticulous glycaemic control and early antihypertensive treatment, particularly with ACE inhibitors and angiotensin 2 blockers, may delay the onset of frank proteinuria. The albumin creatinine ratio (ACR) (tested on a mid-stream first morning urine sample) is <2.5 in healthy men, <3.5 mg/mmol in healthy women. Once proteinuria is present, other possible causes should be considered (see below), but once these are excluded, a presumptive diagnosis of diabetic nephropathy can be made. For practical purposes this implies inevitable progression to end-stage kidney disease, although the time course can be markedly slowed by early aggressive antihypertensive therapy. Clinical suspicion of a non-diabetic cause of nephropathy may be provoked by an atypical history, the absence of diabetic retinopathy (usually but not invariably present with diabetic nephropathy) and the presence of red-cell casts in the urine. Renal biopsy should be considered in such cases, but is rarely necessary or helpful. A 24-hour urine collection is often performed to quantify protein loss. Regular measurement is made of the plasma creatinine level with estimated glomerular filtration rate (eGFR).

Management

The management of diabetic nephropathy is similar to that of other causes of chronic kidney disease, with the following provisos:

- Aggressive treatment of blood pressure with a target below 130/80 mmHg has been shown to slow the rate of deterioration of renal failure considerably. Angiotensin-converting enzyme inhibitors or an angiotensin receptor II antagonist are the drugs of choice (see Chapter 8). These drugs should also be used in normotensive patients with persistent microalbuminuria. Reduction in albuminuria occurs with this treatment.
- Oral hypoglycaemic agents partially excreted via the kidney (e.g. glibenclamide and metformin) should be avoided.
- Insulin sensitivity increases and drastic reductions in insulin dosage may be needed.
- Associated diabetic retinopathy tends to progress rapidly, and frequent ophthalmic supervision is essential.

Management of end-stage disease is made more difficult by the fact that patients often have other complications of diabetes such as blindness, autonomic neuropathy or peripheral vascular disease. Vascular shunts tend to calcify rapidly and hence chronic ambulatory peritoneal dialysis may be preferable to haemodialysis. The failure rate of renal transplants is somewhat higher than in non-diabetic patients. A segmental pancreatic or islet graft is sometimes performed under cover of the immunosuppression needed for the renal graft, and this has been shown to improve survival as well as offering freedom from insulin injections.

Diabetic neuropathy

Diabetes can damage peripheral nervous tissue in a number of ways. The vascular hypothesis postulates occlusion of the vasa nervorum as the prime cause. This seems likely in isolated mononeuropathies, but the diffuse symmetrical nature of the common forms of neuropathy implies a metabolic cause. Since hyperglycaemia leads to increased formation of sorbitol and fructose in Schwann cells, accumulation of these sugars may disrupt function and structure.

The earliest functional change in diabetic nerves is delayed nerve conduction velocity; the earliest histological change is segmental demyelination, caused by damage to Schwann cells. In the early stages axons are preserved, implying prospects of recovery, but at a later stage irreversible axonal degeneration develops.

The following varieties of neuropathy occur (Fig. 20.16):

- Symmetrical mainly sensory polyneuropathy (distal)
- Acute painful neuropathy
- Mononeuropathy and mononeuritis multiplex
 - cranial nerve lesions
 - isolated peripheral nerve lesions
- Diabetic amyotrophy (asymmetrical motor diabetic neuropathy)
- Autonomic neuropathy.

Symmetrical mainly sensory polyneuropathy

This is often unrecognized by the patient in its early stages. Early clinical signs are loss of vibration sense, pain sensation (deep before superficial) and temperature sensation in the feet. At later stages patients may complain of a feeling of 'walking on cotton wool' and can lose their balance when washing the face or walking in the dark owing to impaired proprioception. Involvement of the hands is much less common and should prompt a search for non-diabetic causes. Complications include unrecognized trauma, beginning as blistering due to an ill-fitting shoe or a hot-water bottle, and leading to ulceration.

Sequelae of neuropathy. Involvement of motor nerves to the small muscles of the feet gives rise to interosseous wasting. Unbalanced traction by the long flexor muscles leads to a characteristic shape of the foot, with a high arch and clawing of the toes, which in turn leads to abnormal distribution of pressure on walking, resulting in callus formation under the first metatarsal head or on the tips of the toes and perforating neuropathic ulceration. *Neuropathic arthropathy* (Charcot's joints) may sometimes develop in the ankle. The hands show small-muscle wasting as well as sensory changes, but these signs and symptoms must be differentiated from those of the carpal tunnel syndrome, which occurs with increased frequency in diabetes and may be amenable to surgery.

Acute painful neuropathy

A diffuse, painful neuropathy is less common. The patient describes burning or crawling pains in the feet, shins and anterior thighs. These symptoms are typically worse at night, and pressure from bedclothes may be intolerable. It may present at diagnosis or develop after sudden improvement in glycaemic control (e.g. when insulin is started). It usually remits spontaneously after 3–12 months if good control is maintained. A more chronic form, developing later in the course of the disease, is sometimes resistant to almost all forms of therapy. Neurological assessment is difficult because of the hyperaesthesia experienced by the patient, but muscle wasting is not a feature and objective signs can be minimal.

Management is firstly to explore for non-diabetic causes (see p. 1146). Explanation and reassurance about the high likelihood of remission within months may be all that is needed. Duloxetine (NICE recommend as first-line therapy), tricyclics, gabapentin or pregabalin, mexiletine, valproate and carbamazepine all reduce the perception of neuritic pain somewhat, but usually not as much as patients hope for. Transepidermal nerve stimulation (TENS) benefits some patients. Topical capsaicin-containing creams help occasionally. A few report that acupuncture has helped.

Mononeuritis and mononeuritis multiplex (multiple mononeuropathy)

Any nerve in the body can be involved in diabetic mononeuritis; the onset is typically abrupt and sometimes painful. Radiculopathy (i.e. involvement of a spinal root) may also occur.

Isolated palsies of nerves to the external eye muscles, especially the third and sixth nerves, are more common in diabetes. A characteristic feature of diabetic third nerve lesions is that pupillary reflexes are retained owing to sparing of pupillomotor fibres. Full spontaneous recovery is the rule for most episodes of mononeuritis over 3–6 months. Lesions are more likely to occur at common sites for external pressure palsies or nerve entrapment (e.g. the median nerve in the carpal tunnel, see p. 1074).

Diabetic amyotrophy

This condition is usually seen in older men with diabetes. Presentation is with painful wasting, usually asymmetrical, of the quadriceps muscles or occasionally in the shoulders. The wasting may be very marked and knee reflexes are diminished or absent. The affected area is often extremely tender. Extensor plantar responses sometimes develop and CSF protein content is elevated. Diabetic amyotrophy is usually associated with periods of poor glycaemic control and may be present at diagnosis. It often resolves in time with careful metabolic control of the diabetes.

Autonomic neuropathy

Asymptomatic autonomic disturbances can be demonstrated on testing in many patients (Box 20.6), but symptomatic autonomic neuropathy is rare. It affects both the sympathetic and parasympathetic nervous systems and can cause disabling postural hypotension.

The cardiovascular system

Vagal neuropathy results in tachycardia at rest and loss of sinus arrhythmia. At a later stage, the heart may become denervated (resembling a transplanted heart). Cardiovascular reflexes such as the Valsalva manoeuvre are impaired. Postural hypotension occurs owing to loss of sympathetic

<i>R–R, time between R and next R on ECG; HR, heart rate.</i>		

tone to peripheral arterioles. A warm foot with a bounding pulse is sometimes seen in a polyneuropathy as a result of peripheral vasodilatation.

Gastrointestinal tract

Vagal damage can lead to gastroparesis, often asymptomatic, but sometimes leading to intractable vomiting. Implantable devices which stimulate gastric emptying, and injections of botulinum toxin into the pylorus (to partly paralyse the sphincter), have each shown benefit in cases of this previously intractable problem. Autonomic diarrhoea characteristically occurs at night accompanied by urgency and incontinence. Diarrhoea and steatorrhoea may occur owing to small bowel bacterial overgrowth; treatment is with antibiotics such as tetracycline.

Bladder involvement

Loss of tone, incomplete emptying and stasis (predisposing to infection) can occur, and may ultimately result in an atonic, painless, distended bladder. Treatment is with intermittent self-catheterization, permanent catheterization if that fails and prophylactic antibiotic therapy for those prone to recurrent infection.

Male erectile dysfunction

This is common. The first manifestation is incomplete erection which may in time progress to total failure; retrograde ejaculation also occurs in patients with autonomic neuropathy. Erectile dysfunction in diabetes has many causes including anxiety, depression, alcohol excess, drugs (e.g. thiazides and beta-blockers), primary or secondary gonadal failure, hypothyroidism and inadequate vascular supply owing to atheroma in pudendal arteries. The history and examination should focus on these possible causes. Blood is taken for LH, FSH, testosterone, prolactin and thyroid function. Treatment should ideally include sympathetic counselling of both partners.

Phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, vardenafil, avanafil), which enhance the effects of nitric oxide on smooth muscle and increase penile blood flow, are used in those who do not take nitrates for angina. Some 60% of patients can be expected to benefit from this therapy.

Alternatives for those who fail to improve with a phosphodiesterase inhibitor, who dislike the side-effects (headache and a green tinge to vision the next day) or those in whom it is contraindicated, are:

- Apomorphine 2 or 3 mg sublingually 20 min before sexual activity
- Alprostadil (prostaglandin E1 preparation) given as a small pellet inserted with a device into the urethra (125 µg initially with a maximum of 500 µg). If the

- Vacuum devices.

The diabetic foot

A total of 10–15% of diabetic patients develop foot ulcers at some stage in their lives. Diabetic foot problems are responsible for nearly 50% of all diabetes-related hospital admissions. Many diabetic limb amputations could be delayed or prevented by more effective patient education and medical supervision. Ischaemia, infection and neuropathy combine to produce tissue necrosis. Although all these factors may co-exist, the ischaemic and the neuropathic foot (Table 20.12) can be distinguished. In rural India, foot ulcers are commonly due to neuropathic and infective causes rather than vascular causes.

Management

Many diabetic foot problems are avoidable, so patients need to learn the principles of foot care (Table 20.13). Older patients should visit a chiropodist/podiatrist regularly and should not cut their own toenails. Once tissue damage has occurred in the form of ulceration or gangrene, the aim is preservation of viable tissue. The four main threats to the skin and subcutaneous tissues are:

- **Infection.** This can take hold rapidly in a diabetic foot. Early antibiotic treatment is essential, with antibiotic therapy adjusted in the light of culture results. The organisms grown from the skin surface may not be the organism causing deeper infection. Collections of pus are drained and excision of infected bone is needed if osteomyelitis develops and does not respond to

appropriate antibiotic therapy. Regular X-rays of the foot are needed to check on progress.

- **Ischaemia.** The blood flow to the feet is assessed clinically and with Doppler ultrasound. Femoral angiography is used to localize areas of occlusion amenable to bypass surgery or angioplasty. Relatively few patients fall into this category.
- **Abnormal pressure.** An ulcerated site must be kept non-weight-bearing. Resting the affected leg may need to be supplemented with special deep shoes and insoles to move pressure away from critical sites, or by removable or non-removable casts of the leg. After healing, special shoes and insoles are likely to continue to be needed to protect the feet and prevent abnormal pressure repeating damage to a healed area. In neuropathic feet particularly, sharp surgical debridement by a chiropodist is necessary to prevent callus distorting the local wound architecture and causing damage through abnormal pressure on normal skin nearby.
- **Wound environment.** Dressings are used to absorb or remove exudate, maintain moisture, and protect the wound from contaminating agents, and should be easily removable. Expensive new dressings containing growth factors and other biologically active agents may have a role to play in future, but their place is still being assessed.

Good liaison between physician, chiropodist/podiatrist and surgeon is essential if periods in hospital are to be used efficiently. When irreversible arterial insufficiency is present, it is often quicker and kinder to opt for an early major amputation rather than subject the patient to a debilitating sequence of conservative procedures.

Infections

There is no evidence that diabetic patients with good glycaemic control are more prone to infection than normal subjects. However, poorly-controlled diabetes entails increased susceptibility to the following infections:

- **Skin**
 - staphylococcal infections (boils, abscesses, carbuncles)
 - mucocutaneous candidiasis
- **Gastrointestinal tract**
 - periodontal disease
 - rectal and ischiorectal abscess formation (when control very poor)
- **Urinary tract**
 - urinary tract infections (in women)
 - pyelonephritis
 - perinephric abscess
- **Lungs**
 - staphylococcal and pneumococcal pneumonia
 - Gram-negative bacterial pneumonia
 - tuberculosis
- **Bone**
 - spontaneous staphylococcal spinal osteomyelitis.

One reason why poor control leads to infection is that chemotaxis and phagocytosis by polymorphonuclear leucocytes are impaired because at high blood glucose concentrations neutrophil superoxide generation is impaired.

Conversely, infections may lead to loss of glycaemic control, and are a common cause of ketoacidosis. Insulin-treated patients need to increase their dose by up to 25% in the face of infection, and non-insulin-treated patients may need insulin cover while the infection lasts. Patients should

Table 20.12 Distinguishing features between ischaemia and neuropathy in the diabetic foot

Inspect feet daily Moisturize dry skin Seek early advice for any damage Check shoes inside and out for sharp bodies/areas before wearing Use lace-up shoes with plenty of room for the toes Keep feet away from sources of heat (hot sand, hot-water bottles, radiators, fires) Check the bath temperature before stepping in Regular podiatrist care
--

be told never to omit their insulin dose, even if they are nauseated and unable to eat; instead they should test their blood glucose frequently and seek urgent medical advice. Diabetic patients should receive pneumococcal vaccine and yearly influenza vaccine.

Diabetes and cancer

Certain types of cancer are more common in type 2 diabetes. The risk of carcinoma of the uterus and of the pancreas is approximately doubled, and there is a 20–50% increase in the risk of colorectal and breast cancer. These associations appear to be mediated by obesity, which confers similar levels of risk in the absence of hyperglycaemia, although there is also an element of reverse causation with carcinoma of the pancreas, which can precipitate or cause diabetes. Metformin-treated patients have been reported to have a lower cancer risk than those on other therapies, and this agent is under investigation for possible anti-tumour properties.

Skin and joints

Joint contractures in the hands are a common consequence of childhood diabetes. The sign may be demonstrated by asking the patient to join the hands as if in prayer; the metacarpophalangeal and interphalangeal joints cannot be opposed. Thickened, waxy skin can be noted on the backs of the fingers. These features may be due to glycosylation of collagen and are not progressive (see also p. 1220). The condition is sometimes referred to as diabetic cheiroarthropathy.

Osteopenia in the extremities is also described in type 1 diabetes but rarely leads to clinical consequences.

NOTES ON SPECIAL SITUATIONS IN DIABETES

Surgery

Smooth control of diabetes minimizes the risk of infection and balances the catabolic response to anaesthesia and surgery. The procedure for insulin-treated patients is simple:

- Long-acting and/or intermediate insulin should be stopped the day before surgery, with soluble insulin substituted.
- Whenever possible, diabetic patients should be first on the morning theatre list.
- An infusion of glucose, insulin and potassium is given during surgery. The insulin can be mixed into the glucose solution or administered separately by syringe pump. A standard combination is 16 U of soluble insulin with 10 mmol of KCl in 500 mL of 10% glucose, infused at 100 mL/hour.
- Postoperatively, the infusion is maintained until the patient is able to eat. Other fluids needed in the perioperative period must be given through a separate intravenous line and must not interrupt the glucose/insulin/potassium infusion. Glucose levels are checked every 2–4 hours and potassium levels are monitored. The amount of insulin and potassium in each infusion bag is adjusted either upwards or downwards according to the results of regular monitoring of the blood glucose and serum potassium concentrations.

The same approach is used in the emergency situation, with the exception that a separate variable-rate insulin infusion may be needed to bring blood glucose under control before surgery.

Non-insulin-treated patients should stop medication 2 days before the operation. Patients with mild hyperglycaemia (fasting blood glucose below 8 mmol/L) can be treated as non-diabetic. Those with higher levels are treated with soluble insulin prior to surgery, and with glucose, insulin and potassium during and after the procedure, as for insulin-treated patients.

Pregnancy in established diabetes

Pregnancy in diabetes was in the past associated with high fetal mortality, which has been dramatically reduced by meticulous metabolic control of the diabetes and careful obstetric management. Despite this, the rates of congenital malformation and perinatal mortality remain several times higher than in the non-diabetic population. Type 2 diabetes is now much more prevalent in the maternal population as a result of the changing natural history of this condition.

Metabolic control of diabetes in pregnancy

Congenital malformations are associated with poor glucose control in the early weeks of pregnancy, and good control should therefore be in place before conception wherever possible. The mother should perform daily home blood glucose profiles, recording blood tests before and 2 hours after meals. The renal threshold for glucose falls in pregnancy, and urine tests are therefore of little value. Insulin requirements rise progressively, and intensified insulin regimens are generally used. The aim is to maintain blood glucose and fructosamine (or HbA_{1c}) levels as close to the normal range as can be tolerated. Oral antidiabetic therapy should be avoided, except for metformin which is recognized to be safe in pregnancy.

General management

The patient is seen at intervals of 2 weeks or less at a clinic managed jointly by physician and obstetrician. Circumstances permitting, the aim should be outpatient management with a spontaneous vaginal delivery at term. Retinopathy and nephropathy may deteriorate during pregnancy. Digital photographic eye screening and urine testing for protein should be undertaken at booking, at 28 weeks and before delivery.

Obstetric problems associated with diabetes

Congenital malformations associated with maternal diabetes affect cardiac and skeletal development, of which the caudal regression syndrome is an example. Poorly-controlled diabetes later in gestation is associated with stillbirth, mechanical problems in the birth canal owing to fetal macrosomia, hydramnios and pre-eclampsia. Ketoacidosis in pregnancy carries a 50% fetal mortality, but maternal hypoglycaemia, although highly undesirable, is relatively well tolerated by the fetus.

Neonatal problems

Maternal diabetes, especially when poorly controlled, is associated with fetal macrosomia. The infant of a diabetic mother is more susceptible to hyaline membrane disease than non-diabetic infants of similar maturity. In addition, neonatal hypoglycaemia may occur. The mechanism is as follows: maternal glucose crosses the placenta, but insulin does not; the fetal islets hypersecrete to combat maternal hyperglycaemia, and a rebound to hypoglycaemic levels occurs when the umbilical cord is severed. These complications are due to hyperglycaemia in the third trimester.

Gestational diabetes

This term refers to glucose intolerance that develops or is first recognized in the course of pregnancy; it is typically asymptomatic and usually remits following delivery. Gestational diabetes has been estimated to complicate about 7% of all pregnancies, with wide variation due to differences between populations and diagnostic criteria. Women with a previous history of gestational diabetes, older or overweight women, those with a history of large for gestational age babies and women from certain ethnic groups are at particular risk, but many affected women are not in any of these categories. For this reason some advocate screening of all pregnant women on the basis of random plasma glucose testing in each trimester and by oral glucose tolerance testing if the glucose concentration is, for example, 7 mmol/L or more. The Hyperglycemia and Adverse Pregnancy Outcomes (HAPO) study found that the risk of adverse outcomes increased as a function of maternal glucose levels at 24–28 weeks of pregnancy, even when these were within the normal reference range. This has added to the controversy concerning the appropriate cut-off levels for screening and intervention, since the benefits of intervention are marginal at lower glucose levels, while labelling a mother as diabetic may have unwanted consequences such as a higher rate of caesarean section.

Those who meet the diagnostic criteria for diabetes at first presentation are treated with insulin. Treatment for the remainder is with diet in the first instance, although most patients require insulin cover at some stage during pregnancy (target levels: fasting <4.9 mmol/L; postprandial <6.5 mmol/L). Insulin does not cross the placenta. Many oral agents cross the placenta and are usually avoided because of the potential risk to the fetus, although metformin has been used with success when healthcare facilities are limited.

Gestational diabetes has been associated with all the obstetric and neonatal problems described above for pre-existing diabetes, except that there is no increase in the rate of congenital abnormalities. Gestational diabetes typically remits after delivery but signals an increased risk of type 2 diabetes in later life; maintaining a low bodyweight and keeping physically active reduce this risk.

Not all diabetes presenting in pregnancy is gestational. True type 1 diabetes may develop, and swift diagnosis is essential to prevent the development of ketoacidosis. Hospital admission is required if the patient is symptomatic, or has ketonuria or a markedly elevated blood glucose level.

Unstable diabetes

This term is used to describe patients with recurrent ketoacidosis and/or recurrent hypoglycaemic coma. Of these, the largest group is made up of those who experience recurrent severe hypoglycaemia.

Recurrent severe hypoglycaemia

This affects 1–3% of insulin-dependent patients. Most are adults who have had diabetes for >10 years. By this stage, endogenous insulin secretion is negligible in the great majority of patients. Pancreatic α cells are still present in undiminished numbers, but the glucagon response to hypoglycaemia is virtually absent. Long-term patients are thus subject to fluctuating hyperinsulinaemia owing to erratic absorption of insulin from injection sites, and lack a major component of the hormonal defence against hypoglycaemia. In this situation adrenaline (epinephrine) secretion becomes vital, but this too may become impaired in the course of diabetes. Loss of adrenaline (epinephrine) secretion has

been attributed to autonomic neuropathy, but this is unlikely to be the sole cause; central adaptation to recurrent hypoglycaemia may also be a factor.

The following factors may also predispose to recurrent hypoglycaemia:

- **Overtreatment with insulin.** Frequent biochemical hypoglycaemia lowers the glucose level at which symptoms develop. Symptoms often reappear when overall glucose control is relaxed.
- **An unrecognized low renal threshold for glucose.** Attempts to render the urine sugar-free will inevitably produce hypoglycaemia.
- **Excessive insulin doses.** A common error is to increase the dose when a patient needs more frequent injections to overcome a problem of timing.
- **Endocrine causes.** These include pituitary insufficiency, adrenal insufficiency and premenstrual insulin sensitivity.
- **Alimentary causes.** These include exocrine pancreatic failure and diabetic gastroparesis.
- **Chronic kidney disease.** Clearance of insulin is diminished.
- **Patient causes.** Patients may be unintelligent, uncooperative or may manipulate their therapy.

Recurrent ketoacidosis

This usually occurs in adolescents or young adults, particularly girls. Metabolic decompensation may develop very rapidly. A combination of chaotic food intake and insulin omission, whether conscious or unconscious, is now regarded as the primary cause of this problem. It almost always occurs in the context of considerable psychosocial problems, particularly eating disorders. This area needs careful and sympathetic exploration in any patient with recurrent ketoacidosis. It is perhaps not surprising that in an illness where much of one's life is spent thinking of and controlling food intake, 30% of women with diabetes have had some features of an eating disorder at some time. Other causes include:

- **Iatrogenic.** Inappropriate insulin combinations may be a cause of swinging glycaemic control. For example, a once-daily regimen may cause hypoglycaemia during the afternoon or evening and pre-breakfast hyperglycaemia due to insulin deficiency.
- **Intercurrent illness.** Unsuspected infections, including urinary tract infections and tuberculosis, may be present. Thyrotoxicosis can also manifest as unstable glycaemic control.

HYPOGLYCAEMIA IN THE NON-DIABETIC

Hypoglycaemia develops when hepatic glucose output falls below the rate of glucose uptake by peripheral tissues. Hepatic glucose output may be reduced by:

- The inhibition of hepatic glycogenolysis and gluconeogenesis by insulin
- Depletion of hepatic glycogen reserves by malnutrition, fasting, exercise or advanced liver disease
- Impaired gluconeogenesis (e.g. following alcohol ingestion).

In the first of these categories, insulin levels are raised, the liver contains adequate glycogen stores and the hypoglycaemia can be reversed by injection of glucagon. In the other

two situations, insulin levels are low and glucagon is ineffective. Peripheral glucose uptake is accelerated by high insulin levels and by exercise, but these conditions are normally balanced by increased hepatic glucose output.

The most common symptoms and signs of hypoglycaemia are neurological. The brain consumes about 50% of the total glucose produced by the liver. This high energy requirement is needed to generate ATP used to maintain the potential difference across axonal membranes.

Insulinomas

Insulinomas are pancreatic islet cell tumours that secrete insulin. Most are sporadic but some patients have multiple tumours arising from neural crest tissue (multiple endocrine neoplasia). Some 95% of these tumours are benign. The classic presentation is with fasting hypoglycaemia, but early symptoms may also develop in the late morning or afternoon. Recurrent hypoglycaemia is often present for months or years before the diagnosis is made, and the symptoms may be atypical or even bizarre; the presenting features in one series are given in Table 20.14. Common misdiagnoses include psychiatric disorders, particularly pseudodementia in elderly people, epilepsy and cerebrovascular disease. Whipple's triad remains the basis of clinical diagnosis. This is satisfied when:

- Symptoms are associated with fasting or exercise
- Hypoglycaemia is confirmed during these episodes
- Glucose relieves the symptoms.

A fourth criterion – demonstration of inappropriately high insulin levels during hypoglycaemia – may usefully be added to these.

The diagnosis is confirmed by the demonstration of hypoglycaemia in association with inappropriate and excessive insulin secretion. Hypoglycaemia is demonstrated by:

- Measurement of overnight fasting (16 hours) glucose and insulin levels on three occasions. About 90% of patients with insulinomas will have low glucose and non-suppressed (normal or elevated) insulin levels.
- A prolonged 72-hour supervised fast if overnight testing is inconclusive and symptoms persist.

Autonomous insulin secretion is demonstrated by lack of the normal feedback suppression during hypoglycaemia. This may be shown by measuring insulin, C-peptide or proinsulin during a spontaneous episode of hypoglycaemia.

Treatment of insulinoma

The most effective therapy is surgical excision of the tumour, but insulinomas are often very small and difficult to localize. Many techniques can be used to attempt to localize insulinomas. Sensitivity and specificity vary between centres and between operators. These include highly selective angiography, contrast-enhanced high-resolution CT scanning, scanning with radiolabelled somatostatin (some insulinomas express somatostatin receptors) and endoscopic and intra-operative ultrasound scanning. Venous sampling for the detection of 'hot spots' of high insulin concentration in the various intra-abdominal veins is still used occasionally.

Medical treatment with diazoxide is useful when the insulinoma is malignant, in patients in whom a tumour cannot be located and in elderly patients with mild symptoms. Symptoms may also remit on treatment with a somatostatin analogue (octreotide or lanreotide).

Hypoglycaemia with other tumours

Hypoglycaemia may develop in the course of advanced neoplasia and cachexia, and has been described in association with many tumour types. Certain massive tumours, especially sarcomas, may produce hypoglycaemia owing to the secretion of insulin-like growth factor-1. True ectopic insulin secretion is extremely rare.

Postprandial hypoglycaemia

If frequent venous blood glucose samples are taken following a prolonged glucose tolerance test, about one in four subjects will have at least one value below 3 mmol/L. The arteriovenous glucose difference is quite marked during this phase, so that very few are truly hypoglycaemic in terms of arterial (or capillary) blood glucose content. Failure to appreciate this simple fact led some authorities to believe that postprandial (or reactive) hypoglycaemia was a potential 'organic' explanation for a variety of complaints that might otherwise have been considered psychosomatic. An epidemic of false 'hypoglycaemia' followed, particularly in the USA. Later work showed a poor correlation between symptoms and biochemical hypoglycaemia. Even so, a number of otherwise normal people occasionally become pale, weak and sweaty at times when meals are due, and report benefit from advice to take regular snacks between meals.

True postprandial hypoglycaemia may develop in the presence of alcohol, which 'primes' the cells to produce an exaggerated insulin response to carbohydrate. The person who substitutes alcoholic beverages for lunch is particularly at risk. Postprandial hypoglycaemia sometimes occurs after gastric surgery, owing to rapid gastric emptying and mismatching of nutrient absorption and insulin secretion. This is referred to as 'dumping' but it is now rarely encountered (see p. 251).

Hepatic and renal causes of hypoglycaemia

The liver can maintain a normal glucose output despite extensive damage, and hepatic hypoglycaemia is uncommon. It is particularly a problem with fulminant hepatic failure.

The kidney has a subsidiary role in glucose production (via gluconeogenesis in the renal cortex), and hypoglycaemia is sometimes a problem in terminal renal failure.

Hereditary fructose intolerance occurs in 1 in 20 000 live births and can cause hypoglycaemia (see p. 1040).

Endocrine causes of hypoglycaemia

Deficiencies of hormones antagonistic to insulin are rare but well-recognized causes of hypoglycaemia. These include hypopituitarism, isolated adrenocorticotrophic hormone (ACTH) deficiency and Addison's disease.

Drug-induced hypoglycaemia

Many drugs have been reported to produce isolated cases of hypoglycaemia, but usually only when other predisposing factors are present:

- Sulfonylureas may be used in the treatment of diabetes or may be taken by non-diabetics in suicide attempts.
- Quinine may produce severe hypoglycaemia in the course of treatment for falciparum malaria.
- Salicylates may cause hypoglycaemia; usually accidental ingestion by children.
- Propranolol can induce hypoglycaemia in the presence of strenuous exercise or starvation.
- Pentamidine used in the treatment of resistant pneumocystis pneumonia (see p. 188).

Alcohol-induced hypoglycaemia

Alcohol inhibits gluconeogenesis. Alcohol-induced hypoglycaemia occurs in poorly-nourished chronic alcoholics, binge drinkers and in children who have taken relatively small

amounts of alcohol, since they have a diminished hepatic glycogen reserve. They present with coma and hypothermia (hypothermia is a feature of hypoglycaemia, due to the suppression of central thermoregulation, particularly the shivering response: children manifest hypothermia more frequently due to their high surface area to body mass ratio).

Factitious hypoglycaemia

This is a relatively common variant of self-induced disease and is more common than an insulinoma. Hypoglycaemia is produced by surreptitious self-administration of insulin or sulfonylureas. Many patients in this category have been extensively investigated for an insulinoma. Measurement of C-peptide levels during hypoglycaemia should identify patients who are injecting insulin; sulfonylurea abuse can be detected by chromatography of plasma or urine.

DISORDERS OF LIPID METABOLISM

Lipid physiology

Lipids are insoluble in water, and are transported in the bloodstream as macromolecular complexes. In these complexes, lipids (principally triglyceride, cholesterol and cholesterol esters) are surrounded by a stabilizing coat of phospholipid. Proteins (called apoproteins) embedded into the surface of these 'lipoprotein' particles exert a stabilizing function and allow the particles to be recognized by receptors in the liver and the peripheral tissues. The structure of a chylomicron (one type of lipoprotein particle) is illustrated in Figure 20.17.

Five principal types of lipoprotein particles are found in the blood (Fig. 20.18). They are structurally different and can be separated in the laboratory by their density and electrophoretic mobility. The larger particles give postprandial plasma its cloudy appearance. More than half of all patients aged under 60 with angiographically confirmed coronary artery disease have a lipoprotein disorder.

The genes for all the major apoproteins and that for the low-density lipoprotein (LDL) receptor have been isolated, sequenced and their chromosomal sites mapped. Production of abnormal apoproteins is known to produce, or predispose to, several types of lipid disorder, and it is likely that others will be discovered.

Chylomicrons

Chylomicrons (Fig. 20.18) are synthesized in the small intestine postprandially, passing initially into the intestinal

Figure 20.17 Schematic diagram of a chylomicron particle (75–1200 nm) showing apoproteins lying in the surface membrane.

lymphatic drainage, then along the thoracic duct into the bloodstream. They contain triglyceride and a small amount of cholesterol and its ester, and provide the main mechanism for transporting the digestion products of dietary fat to the liver and peripheral tissues. Each newly formed chylomicron contains several different apoproteins (B-48, A-I, A-II), and acquires apoproteins C-II and E by transfer from high-density lipoprotein (HDL) particles in the bloodstream. Apoprotein C-II binds to specific receptors in adipose tissue and skeletal muscle and the liver, where the endothelial enzyme, lipoprotein lipase, hydrolyses most of the triglyceride into fatty acids

Figure 20.18 Schematic representation of the sites of origin, interaction between, and fate of, the major lipoprotein particles.

which are used as an energy source or stored. The remaining chylomicron remnant particle, which contains the bulk of the original cholesterol, is taken up by the liver. Apoprotein E on the particle's surface binds with liver clearance receptors.

Very-low-density lipoprotein (VLDL) particles

These are synthesized continuously in the liver and contain most of the body's endogenously synthesized triglyceride and a smaller quantity of cholesterol. They are the body's main source of energy during prolonged fasting. Apoprotein B-100 is an essential component of VLDL. Apoproteins C-II and E are incorporated later into VLDL by transfer from HDL particles. As they pass round the circulation, VLDL particles bind through apoprotein C-II allowing triglyceride to be progressively removed by lipoprotein lipase in the capillary endothelium. This leaves a particle, now depleted of triglyceride and apoprotein C-II, called an intermediate-density lipoprotein (IDL) particle.

Intermediate-density lipoprotein (IDL) particles

These have apoprotein B-100 and apoprotein E molecules on the particle surface. Most IDL particles bind to liver LDL receptors through the apoprotein E molecule and are then catabolized. Some IDL particles have further triglyceride removed (by the enzyme hepatic lipase), producing LDL particles.

Low-density lipoprotein (LDL) particles

LDL particles are the main carrier of cholesterol, and deliver it both to the liver and to peripheral cells. The surface of the LDL particle contains apoprotein B-100, and also apoprotein E. The apoprotein B-100 is the principal ligand for the LDL clearance receptor. This receptor lies within coated pits on the surface of the hepatocyte. Once bound to the receptor, the coated pit invaginates and fuses with liposomes which destroy the LDL particle (Fig. 20.19). The number of hepatic LDL clearance receptors regulates the circulating LDL concentration, which is also influenced by controlling the

activity of the rate-limiting enzyme in the cholesterol synthetic pathway, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase.

LDL particles can deposit lipid into the walls of the peripheral vasculature. Not all the cholesterol synthesized by the liver is packaged immediately into lipoprotein particles. Some is oxidized into bile salts. Both bile salts and cholesterol are excreted in the bile: both are then reabsorbed through the terminal ileum and recirculated (enterohepatic circulation).

LDL particles become Lp(a) lipoproteins as a result of the linkage of apoprotein (a) to apoprotein B-100 with a single disulphide bond. Raised levels of Lp(a) lipoprotein are a risk factor for cardiovascular disease.

High-density lipoprotein (HDL) particles

Nascent HDL particles are produced in both the liver and intestine. They are disc shaped, seemingly inert and contain apoprotein A-I. They are transmuted into mature particles by the acquisition of phospholipids, and the E and C apoproteins from chylomicrons and VLDL particles in the circulation. The more mature HDL particles take up cholesterol from cells in the peripheral tissues aided by cholesterol-efflux regulatory protein – a product of the ATP-binding cassette transporter 1 gene (ABC1 gene). As it is taken up, the enzyme lecithin cholesterol acyltransferase (LCAT), activated by the apoprotein A on the particle's surface, esterifies the sequestered cholesterol. The HDL particle transports cholesterol away from the periphery and may transfer it indirectly to other particles such as VLDL in the circulation or deliver its cholesterol directly to the liver (reverse cholesterol transport) and steroid-synthetic tissues (ovaries, testes, adrenal cortex).

This direct delivery takes place through scavenger-receptor B1. In experimental animals the absence of scavenger-receptor B1 dramatically accelerates the development of atheroma, and genetically programmed overproduction suppresses atheroma formation.

Measurement

When a laboratory measures fasting serum lipids, the majority of the total cholesterol concentration consists of LDL particles with a 20–30% contribution from HDL particles. The triglyceride concentration largely reflects the circulating number of VLDL particles, since chylomicrons are not normally present in the fasted state. If the patient is not fasted, the total triglyceride concentration will be raised owing to the additional presence of triglyceride-rich chylomicrons.

Epidemiology and lipids

LDL and total cholesterol

Population studies have repeatedly demonstrated a strong association between both total and LDL cholesterol concentration and coronary heart risk. There is a strong link between mean fat consumption, mean serum cholesterol concentration and the prevalence of coronary heart disease between countries. The exception is France where the cardiovascular risk is only moderate – perhaps owing to high alcohol consumption. Studies of migrants, particularly of Japanese men migrating to Hawaii, have shown that as diet changes, and cholesterol concentrations rise, so does the cardiovascular risk. Such studies show the role of the environment rather than the genetic make-up of a population.

The Multiple Risk Factor Intervention Trial (MRFIT) screened one-third of a million American men for various cardiovascular risk factors and then followed them for 6 years. Data from this study have shown that although cardiovascular risk rises

Figure 20.19 Receptor-mediated endocytosis. LDL receptors are formed in the endoplasmic reticulum and transported via the Golgi apparatus to the surface of a hepatocyte. LDLs bind to these receptors, are internalized and taken up by the endosome. The receptor is recycled back to the surface, while the LDL is broken down by the lysosomes, freeing cholesterol needed for membrane synthesis.

Figure 20.20 The Multiple Risk Factor Intervention Trial. Relationship between levels of serum cholesterol and risks of fatal coronary artery disease in a longitudinal study of >361 000 men screened for entry into the trial. (Data from Stamler J, Wentworth D, Neaton JD. Is relationship between serum cholesterol and risk of death from coronary heart disease continuous and graded? Findings in 356 222 primary screenees of the Multiple Risk Factor Intervention Trial (MRFIT). JAMA 1986; 256:2823.)

progressively as total cholesterol concentration increases (Fig. 20.20), the risk increase is modest for individuals with no other cardiovascular risk factors. With each additional risk factor the effect produced by the same difference in cholesterol concentration becomes greatly magnified. The Framingham Study has reproduced these findings in a separate population.

HDL cholesterol

Epidemiological studies have shown that higher HDL concentrations protect against cardiovascular disease. Raising HDL by pharmacological means does not, however, necessarily reduce cardiovascular risk. HDL also has effects on the function of platelets and of the haemo-static cascade. These properties may favourably influence thrombogenesis.

VLDL particles (triglycerides)

There is a relatively weak independent link between raised concentrations of (triglyceride-rich) VLDL particles and cardiovascular risk. Very raised triglyceride concentrations (>6 mmol/L) cause a greatly increased risk of acute pancreatitis and retinal vein thrombosis. Hypertriglyceridaemia tends to occur in association with a reduced HDL concentration. Much of the cardiovascular risk associated with 'hypertriglyceridaemia' turns out on multivariate analysis to be due to the associated low HDL levels and not to the hypertriglyceridaemia itself.

Chylomicrons

Excess chylomicrons do not confer an excess cardiovascular risk, but raise the total plasma triglyceride concentration.

HYPERLIPIDAEMIA

Hyperlipidaemia results from genetic predisposition interacting with an individual's diet.

Secondary hyperlipidaemia

If a lipid disorder has been detected it is vital to carry out a clinical history, examination and simple special investigations

Table 20.15 Causes of secondary hyperlipidaemia

Hypothyroidism
Diabetes mellitus (when poorly controlled)
Obesity
Renal impairment
Nephrotic syndrome
Dysglobulinaemia
Hepatic dysfunction
Alcohol in susceptible individuals
Drugs:
Oral contraceptives in susceptible individuals
Retinoids, thiazide diuretics, corticosteroids, op'DDD (used in the treatment of Cushing's syndrome), sirolimus (and other immunosuppressive agents)

to detect causes of secondary hyperlipidaemia (Table 20.15), which may need treatment in their own right. Hypothyroidism, diabetes, renal disease and abnormal liver function can all raise plasma lipid levels.

Classification, clinical features and investigation of primary hyperlipidaemias

We have used the functional/genetic classification which has the advantage that the genetic disorders may be grouped by the results of simple lipid biochemistry into causes of:

- Disorders of VLDL and chylomicrons – hypertriglyceridaemia alone
- Disorders of LDL – hypercholesterolaemia alone
- Disorders of HDL
- Combined hyperlipidaemia.

Disorders of VLDL and chylomicrons – hypertriglyceridaemia alone

The majority of cases appear to be due to multiple genes acting together to produce a modest excess of circulating concentration of VLDL particles, such cases being termed polygenic hypertriglyceridaemia.

In a proportion of cases, there will be a family history of a lipid disorder or its effects (e.g. pancreatitis). Such cases are often classified as familial hypertriglyceridaemia. The defect underlying the majority of such cases is not understood. Apoprotein A5 deficiency underlies some cases. The main clinical feature is a history of attacks of pancreatitis or retinal vein thrombosis in some individuals.

Lipoprotein lipase deficiency and apoprotein C-II deficiency

These are rare diseases which produce greatly elevated triglyceride concentrations owing to the persistence of chylomicrons (and not VLDL particles) in the circulation. The chylomicrons persist because the triglyceride within cannot be metabolized if the enzyme lipoprotein lipase is defective, or because the triglycerides cannot gain access to the normal enzyme owing to deficiency of the apoprotein C-II on their surface. Patients present in childhood with eruptive xanthomas, lipaemia retinalis and retinal vein thrombosis, pancreatitis and hepatosplenomegaly. If not identified in childhood, it can present in adults with gross hypertriglyceridaemia resistant to simple measures. The presence of chylomicrons floating like cream on top of fasting plasma suggests this diagnosis. It is confirmed by plasma electrophoresis or ultracentrifugation. An abnormality of apoprotein C can be deduced if the hypertriglyceridaemia improves temporarily after infusing fresh frozen plasma, and lipoprotein lipase deficiency is likely if it does not.

Disorders of LDL – hypercholesterolaemia alone

Heterozygous familial hypercholesterolaemia is an autosomal dominant monogenic disorder present in 1 in 500 of the normal population. The average primary care physician would therefore be expected to have four such patients, but because of clustering within families the prevalence varies. There is an increased prevalence in some racial groups (e.g. French Canadians, Finns, South Africans). Surprisingly, most individuals with this disorder remain undetected. Patients may have no physical signs, in which case the diagnosis is made on the presence of very high plasma cholesterol concentrations which are unresponsive to dietary modification and are associated with a typical family history of early cardiovascular disease. Diagnosis can more easily be made if typical clinical features are present. These include xanthomatous thickening of the Achilles tendons and xanthomas over the extensor tendons of the fingers. Xanthelasma may be present, but is not diagnostic of familial hypercholesterolaemia.

The genetic defect is the underproduction or malproduction of the LDL cholesterol clearance receptor in the liver (Table 20.16). Over 150 different mutations in the LDL receptor have been described to date. Fifty per cent of men with the disease will die by the age of 60, most from coronary artery disease, if untreated.

Homozygous familial hypercholesterolaemia is very rare indeed. Affected children have no LDL receptors in the liver. They have a hugely elevated LDL cholesterol concentration, and massive deposition of lipid in arterial walls, the aorta and the skin. The natural history is for death from ischaemic heart disease in late childhood or adolescence. Repeated plasmapheresis has been used to remove LDL cholesterol with some success. Liver transplantation is a 'cure'. Plasma lipids normalize and xanthomas regress after transplantation, but the number of patients having undergone this procedure is small.

Mutations in the apoprotein B-100 gene cause another relatively common single gene disorder. Since LDL particles bind to their clearance receptor in the liver through apoprotein B-100, this defect also results in high LDL concentrations in the blood, and a clinical picture which closely resembles classical heterozygous familial hypercholesterolaemia. The two disorders can be distinguished clearly only by genetic tests. The approach to treatment is the same.

Polygenic hypercholesterolaemia is a term used to lump together patients with raised serum cholesterol concentrations, but without one of the monogenic disorders above.

They exist in the right-hand tail of the normal distribution of cholesterol concentration. The precise nature of the polygenic variation in plasma cholesterol concentration remains unknown. Variations in the apoprotein E gene (chromosome 19), and in sterol-regulatory element-binding protein (SREBP)-2 gene, are involved in some individuals in this heterogeneous group.

Disorders of HDL (very low HDL, low total cholesterol)

Tangier disease is an autosomal recessive disorder characterized by a low HDL cholesterol concentration. Cholesterol accumulates in reticuloendothelial tissue and arteries causing enlarged orange-coloured tonsils and hepatosplenomegaly. Cardiovascular disease, corneal opacities and a polyneuropathy also occur. It is due to a gene mutation (ABC1 gene, see HDL physiology above and Table 20.16) which normally promotes cholesterol uptake from cells by HDL particles.

Other mutations in this gene have been found in a few families with autosomal dominant HDL deficiency. It is as yet unknown whether abnormalities of this gene contribute to the low HDL cholesterol concentrations commonly seen in cardiovascular disease patients.

Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)

The most common patient group is a polygenic combined hyperlipidaemia. Patients have an increased cardiovascular risk due to both high LDL concentrations and suppression of HDL by the hypertriglyceridaemia.

Familial combined hyperlipidaemia

This is relatively common, affecting 1 in 200 of the general population. The genetic basis for the disorder has not yet been characterized. It is diagnosed by finding raised cholesterol and triglyceride concentrations in association with a typical family history. There are no typical physical signs.

Remnant hyperlipidaemia

This is a rare (1 in 5000) cause of combined hyperlipidaemia. It is due to accumulation of LDL remnant particles and is associated with an extremely high risk of cardiovascular disease. It may be suspected in a patient with raised total cholesterol and triglyceride concentrations by finding xanthomas in the palmar creases (diagnostic) and the presence of tuberous xanthomas, typically over the knees and elbows

Table 20.16 The genetic defects underlying some lipoprotein disorders

Disorder	Affected gene	Chromosome	Frequency
Common disorders			
Heterozygous familial hypercholesterolaemia	LDL receptor	19	1:500
Familial defective apoprotein B	Apo B-100	2	1:700
Hypobetalipoproteinaemia	Apo B-100	2	1:1000
Familial combined hyperlipidaemia	As yet unknown	As yet unknown	1:200
Familial hypertriglyceridaemia	As yet unknown	As yet unknown	1:200
Some rarer disorders			
Homozygous familial hypercholesterolaemia	LDL receptor	19	1:1000 000
Lipoprotein lipase deficiency	As yet unknown	8	1:1000 000 (homozygous)
Apoprotein C-II deficiency	Apo C-II	19	40 cases
Tangier disease	ATP-binding cassette	9	Very rare
Lecithin cholesterol acyltransferase deficiency	LCAT	16	Very rare
Apoprotein A1 deficiency	Apo A1	1	Very rare

Figure 20.21 Tuberous xanthomas behind the elbow, and lipid deposits in the hand creases in a patient with remnant hyperlipidaemia.

(Fig. 20.21). Remnant hyperlipidaemia is almost always due to the inheritance of a variant of the apoprotein E allele (apoprotein E2) together with an aggravating factor such as another primary hyperlipidaemia. When suspected clinically the diagnosis can be confirmed using ultracentrifugation of plasma, or phenotyping apoprotein E.

Therapies available to treat hyperlipidaemia

The lipid-lowering diet

Studies have shown that dieticians helping patients to adjust their own diet to meet the nutritional targets set out below produce a better lipid-lowering effect than does the issuing of standard diet sheets and advice from a doctor. The main elements of a lipid-lowering diet are similar to those for people with diabetes (Table 20.5). Additional specific measures are to:

- reduce consumption of liver, offal and fish roes to reduce dietary cholesterol
- reduce alcohol consumption, since this may worsen primary lipid disorders at doses that would not affect normal individuals
- include foods containing plant stanols in the diet. Plant stanols reduce the absorption of cholesterol from the intestine by competing for space in the micelles that deliver lipid to the mucosal cells of the gut. They are largely unabsorbed and excreted in the stool. Increasing the amount of plant stanol in the diet 10-fold by using a margarine (e.g. Benecol) containing added stanol esters lowers LDL cholesterol by approximately 0.35–0.5 mmol/L. A reduction in the risk of heart disease of about 25% would be expected if this reduction in LDL cholesterol was applied to a population.

Drugs

The classes of drugs used to treat hyperlipidaemia are described in Table 20.17. How they are used is set out in Table 20.18. Statins are the most widely used lipid-lowering agents. Generalized muscular aches are the commonest adverse effect, occasionally leading to a frank myopathy. These adverse events occur more frequently in people with a SNP in a gene region coding for a liver-specific organic anion transporter protein (SoLute Carrier Organic anion transporter IBI – SLCO1B1), which leads to a decreased hepatic uptake of the statin and higher statin levels in the serum.

Other specific issues in the management of hyperlipidaemias

Screening

Most patients with hyperlipidaemia are asymptomatic and have no clinical signs. Many are discovered during the screening of high-risk individuals. Whose lipids should be measured?

There are great doubts as to whether blanket screening of plasma lipids is warranted. Selective screening of people at high risk of cardiovascular disease should be undertaken:

- A family history of coronary heart disease (especially below 50 years of age)
- A family history of lipid disorders
- The presence of a xanthoma
- The presence of xanthelasma or corneal arcus before the age of 40 years
- Obesity
- Diabetes mellitus
- Hypertension
- Acute pancreatitis
- Those undergoing renal replacement therapy.

Where one family member is known to have a monogenic disorder such as familial hypercholesterolaemia (1 in 500 of the population), siblings and children must have their plasma lipid concentrations measured. It is also worth screening the prospective partners of any patients with this heterozygous monogenic lipid disorder because of the small risk of producing children homozygous for the condition.

Acute severe illnesses such as myocardial infarction can derange plasma lipid concentrations for up to 3 months. Plasma lipid concentrations should be measured either within 48 hours of an acute myocardial infarction (before derangement has had time to occur) or 3 months later.

Serum cholesterol concentration does not change significantly after a meal and as a screening test a random blood sample is sufficient. If the total cholesterol concentration is raised, HDL cholesterol, triglyceride and LDL cholesterol concentrations should be quantitated on a fasting sample. If a test for hypertriglyceridaemia is needed, a fasting blood sample is mandatory.

Treatment of hypertriglyceridaemia

A serum triglyceride concentration below 2.0 mmol/L is normal. In the range 2.0–6.0 mmol/L, no specific intervention will be needed unless there are coincident cardiovascular risk factors, and in particular a strong family history of early cardiovascular death. In general, patients should be advised that they have a minor lipid problem, offered advice on weight reduction if obese, and advice on correcting other cardiovascular risk factors.

If the triglyceride concentration is above 6.0 mmol/L, there is a risk of pancreatitis and retinal vein thrombosis. Patients should be advised to reduce their weight if overweight and start a formal lipid-lowering diet (see below). A proportion of individuals with hypertriglyceridaemia have livers which respond to even moderate degrees of alcohol intake by allowing accumulation or excess production of VLDL particles. If hypertriglyceridaemia persists, lipid measurements should be repeated before and after a 3-week interval of complete abstinence from alcohol. If a considerable improvement results, lifelong abstinence may prove necessary. Other drugs, including thiazides, oestrogens and glucocorticoids, can have a similar effect to alcohol in susceptible patients.

Table 20.17 Drugs used in the management of hyperlipidaemia

Drug	Mechanism of action	Contraindications and adverse reactions	Expected therapeutic effect	Long-term safety
Statins e.g. Simvastatin Pravastatin Fluvastatin Atorvastatin Rosuvastatin	Inhibit the rate-limiting step in cholesterol synthesis (HMG CoA reductase)	<i>Contraindications:</i> Active liver disease, pregnancy, lactation <i>Adverse effects:</i> Constant aches/muscle stiffness, derangement of liver biochemistry, diarrhoea, myopathy. Raised ciclosporin level in blood	30–60% reduction in LDL cholesterol Modest triglyceride lowering Tiny effect on HDL cholesterol Atorvastatin and particularly rosuvastatin have the most potent cholesterol-lowering effects	Simvastatin, Atorvastatin and Pravastatin have good long-term safety in large-scale trials and in clinical practice. Avoid if possible in women of childbearing age
Cholesterol absorption inhibitors e.g. Ezetimibe	Inhibition of gut absorption of cholesterol from food and also from bile. Mechanism of this inhibition is unclear	<i>Contraindications:</i> Lactation <i>Adverse effects:</i> Occasional diarrhoea, abdominal discomfort	Reduce LDL cholesterol by additional 10–15% if given with a statin. Triglyceride concentrations reduced by 10%. Increase HDL cholesterol by 5%	Mostly act in gut and little is absorbed. Short/medium-term safety good. Long-term safety unknown
Bile acid sequestrants e.g. Cholestyramine Colestipol Colesevelam	Bind bile acids in the gut preventing enterohepatic circulation. Liver makes more bile acids from cholesterol, depleting the cholesterol pool	<i>Adverse effects:</i> Gastrointestinal side-effects predominate. Palatability is a problem <i>Counselling:</i> Other drugs bind to resins and should be taken 1 h before or 4 h afterwards	8–15% reduction in LDL Little or no effect on HDL cholesterol 5–15% rise in triglyceride concentration	Not systemically absorbed. Safety profile is good. Appear safe in women of childbearing age. Fat-soluble vitamin supplements may be required in children, pregnancy and breast-feeding
Fibric acid derivatives e.g. Gemfibrozil Bezafibrate Ciprofibrate Fenofibrate	Activate peroxisome proliferator-activated nuclear receptors (esp. PPAR- α). This has protean effects on lipid metabolism	<i>Contraindications:</i> Severe hepatic or renal impairment, gall bladder disease, pregnancy <i>Adverse effects:</i> Reversible myositis, nausea, predispose to gallstones, nonspecific malaise, impotence	Reduction of LDL cholesterol by 10–15% and triglycerides by 25–35% HDL cholesterol concentrations increase by 10–50% (newer agents often have greater beneficial effect on HDL)	No knowledge of effect on developing fetus. Avoid in women of childbearing age. Long-term safety appears good
Nicotinic acid (NA) derivatives e.g. Modified-release nicotinic acid (also used with laropiprant, which stops flushing); Acipimox	Unclear. Probably inhibit lipid synthesis in the liver by reducing free fatty acid concentrations through an inhibitory effect on lipolysis in fat tissue	<i>Contraindications:</i> Pregnancy, breast-feeding <i>Adverse effects:</i> Value limited by frequent side-effects: headache, flushing, dizziness, nausea, malaise, itching, abnormal liver biochemistry. Glucose intolerance, hyperuricaemia, dyspepsia, hyperpigmentation may occur	Reduce LDL cholesterol by 5–10% Reduce triglycerides by 15–20% HDL cholesterol increased by 10–20%	Medium-term safety but marred by the adverse effects listed. Modified-release preparation or combination with laropiprant reduces side-effect incidence
Fatty acid compounds e.g. Omega-3 acid ethyl esters; omega-3 marine triglycerides	Reduce hepatic VLDL secretion	Occasional nausea and belching	Reduce triglycerides in severe hypertriglyceridaemia No favourable change in other lipids, and may aggravate hypercholesterolaemia in a few patients	Long-term safety is not yet known but seems unlikely to be poor
Cholesteryl ester transfer protein inhibitor e.g. Anacetrapib Torcetrapib	Under development	Unknown	LDL-C similar to statins and increase in HDL-C	Unknown

Table 20.18 Classes of drugs used to treat hyperlipidaemia

	Hypertriglyceridaemia (predominantly)	Combined hyperlipidaemia	Hypercholesterolaemia (predominantly)
First-line agents	Fibric acid derivative	Fibric acid derivative	Statin – simvastatin 40 mg initially. Atorvastatin 80 mg for greater cholesterol lowering (Cholesterol binding resin instead if pregnancy possible)
Additional/alternative agents	Fish oil capsules Nicotinic acid derivatives	Statin may be required in addition to lower cholesterol adequately (monitor carefully for muscle aches, CK rise or worsening liver function) Ezetimibe (to lower cholesterol further) Nicotinic acid derivative (to lower cholesterol and triglycerides further)	Ezetimibe if statin not tolerated or greater cholesterol lowering needed Cholesterol binding resin Nicotinic acid derivative

If the triglyceride concentration remains above 6.0 mmol/L, despite the above measures, drug therapy is warranted (Table 20.18). The severe hypertriglyceridaemia associated with the rare disorders of lipoprotein lipase deficiency and apoprotein C-II deficiency may require restriction of dietary fat to 10–20% of total energy intake and the use of special preparations of medium-chain triglycerides in cooking in place of oil or fat. Medium-chain triglycerides are not absorbed via chylomicrons (see p. 260).

Treatment of hypercholesterolaemia (without hypertriglyceridaemia)

Familial hypercholesterolaemia

Individuals often require treatment with diet and more than one cholesterol-lowering drug. The cholesterol absorption inhibitor ezetimibe is a logical addition to a statin and has a low side-effect profile (Tables 20.17 and 20.18). Bile acid sequestrants are an alternative to ezetimibe, but there are problems with tolerability. Concurrent therapy with statins and fibrates, particularly fenofibrate, can be used in severe cases. Checking for muscle symptoms and measuring creatine kinase is necessary.

Primary prevention for people with risk factors

Lipid-lowering therapy using a statin, or alternatives as above is used in asymptomatic individuals irrespective of the total or LDL cholesterol level in type 2 diabetes alone or with two or more of: positive family history of cardiovascular disease, albuminuria, hypertension, smoking.

Primary prevention for people without risk factors

In the absence of risk factors, lipid-lowering therapy should be used in asymptomatic men with LDL cholesterol levels persistently above 6.5 mmol/L despite dietary change. The situation for women is less clear.

Secondary prevention

As a generality, statin treatment is warranted for any patient with known macrovascular disease (coronary artery disease, TIA or stroke, peripheral vascular disease), irrespective of the total or LDL cholesterol level (treatment target is total cholesterol under 4.0, LDL under 2 mmol/L). If a statin is not tolerated, combinations of other agents are tried (Table 20.18).

Risk prevention tables

An array of risk prediction tables (see p. 669) are available to allow quantification of the risk of a patient having a cardiovascular event within the next 10 years. Some advocate the use of these risk tables as a guide to treatment, e.g. if the 10-year risk reaches the 15% or the 30% level. The authors

side with those who have reservations over their use. Such risk analyses are a useful approach in helping to decide whether to use treatments such as aspirin. Aspirin probably has no effect until the day an atherosclerotic plaque ruptures, when it may then prevent thrombosis leading to a heart attack or stroke. Furthermore, it has a significant associated morbidity and mortality (from bleeding). At a 10-year cardiovascular risk level of 15% the benefit:risk ratio for aspirin becomes favourable. At the 30% level the benefits are clear.

By contrast, the use of lipid-lowering agents, if initially tolerated, has a low associated morbidity and mortality. These agents probably reduce the rate of atheroma accumulation over a period of decades. When a patient is young, the chance that atheroma will be bad enough to cause a heart attack or stroke within the next 10 years will be small, even if atheroma is accumulating at a swift rate. The level of cardiovascular risk will only rise to the 15% or 30% level when the patient gets older. Yet it seems bizarre not to treat the gradual accumulation of atheroma when the patient is young with a low 10-year risk, and then to start treatment when age causes the 10-year risk levels to rise to a particular threshold, if all other factors are the same. In choosing whether or not to prescribe, we prefer to consider, 'will he/she live long enough to collect some pension and see his/her grandchildren?', rather than, 'will he/she have a heart attack or stroke within the next 10 years?' The answers to these two questions are very different.

Combined hyperlipidaemia (hypercholesterolaemia and hypertriglyceridaemia)

Treatment is the same for all varieties of combined hyperlipidaemia. For any given cholesterol concentration the hypertriglyceridaemia found in the combined hyperlipidaemias increases the cardiovascular risk considerably. Treatment is aimed at reducing serum cholesterol below 4.0 mmol/L and triglycerides below 2.0 mmol/L. Therapy is with diet in the first instance and with drugs if an adequate response has not occurred. Fibrates are the treatment of choice since these reduce both cholesterol and triglyceride concentrations, and also have the benefit of raising cardioprotective HDL concentrations. Combination with other agents is often needed (Table 20.18).

Other lipid disorders

Hypolipidaemia

Low lipid levels can be found in severe protein-energy malnutrition. They are also seen occasionally with severe malabsorption and in intestinal lymphangiectasia.

Hypobetalipoproteinaemia (Table 20.16) is a benign familial condition which is being increasingly recognized. The cholesterol levels are in the range 1–3.5 mmol/L.

Abetalipoproteinaemia

This is described on page 270.

INBORN ERRORS OF CARBOHYDRATE METABOLISM

Glycogen storage disease

All mammalian cells can manufacture glycogen, but the main sites of its production are the liver and muscle. Glycogen is

a high-molecular-weight glucose polymer made up of 1–4 linked glucose units, with a 1–6 branch point every 4–10 residues. In glycogen storage disease there is either an abnormality in the molecular structure or an increase in glycogen concentration owing to a specific enzyme defect. Almost all these conditions are autosomal recessive in inheritance and present in infancy, except for McArdle's disease, which presents in adults.

Table 20.19 shows the classification and clinical features of some of these diseases.

Galactosaemia

Galactose is normally converted to glucose. However, a deficiency of the enzyme *galactose-1-phosphate*

Inborn errors of carbohydrate metabolism

^aTissue obtained is used for the biochemical assay of the enzyme. % = percentage of total number of cases in USA and Europe.

uridyl-transferase or, less commonly, *uridine diphosphate galactase-4-epimerase*, results in accumulation of galactose-1-phosphate in the blood. The transferase deficiency, inherited as an autosomal recessive, is due in 70% of patients to a glutamine to arginine missense mutation in Q188R. Galactose ingestion (i.e. milk) leads to inanition, failure to thrive, vomiting, hepatomegaly and jaundice, diabetes, cataracts and developmental delay. A lactose-free diet stops the acute toxicity but poor growth and problems with speech and mental development still occur with the transferase deficiency. A newborn screening programme to detect galactosaemia is used in parts of the USA and other countries.

Prenatal diagnosis and diagnosis of the carrier state are possible by measurement of red cell galactose-1-phosphate activity. DNA analysis is available for common mutations.

Galactokinase deficiency also results in galactosaemia and early cataract formation.

Defects of fructose metabolism

Absorbed fructose is chiefly metabolized in the liver to lactic acid or glucose. Three defects of metabolism in the liver and intestine occur; all are inherited as autosomal recessive traits:

- **Fructosuria** is due to fructokinase deficiency. It is a benign asymptomatic condition.
- **Hereditary fructose intolerance** is due to fructose-1-phosphate aldolase deficiency. Fructose-1-phosphate accumulates after fructose ingestion, inhibiting both glycogenolysis and gluconeogenesis, resulting in symptoms of severe hypoglycaemia. Hepatomegaly and renal tubular defects occur but are reversible on a fructose- and sucrose-free diet. Intelligence is normal and there is an absence of dental caries.
- **Hereditary fructose-1,6-diphosphatase deficiency** leads to a failure of gluconeogenesis. Infants present with hypoglycaemia, ketosis and lactic acidosis. Dietary control can lead to normal growth.

INBORN ERRORS OF AMINO ACID METABOLISM

Inborn errors of amino acid metabolism are chiefly inherited as autosomal recessive conditions. The major ones are shown in Table 20.20.

Amino acid transport defects

Amino acids are filtered by the glomerulus, but 95% of the filtered load is reabsorbed in the proximal convoluted tubule by an active transport mechanism. Aminoaciduria results from:

- abnormally high plasma amino acid levels (e.g. phenylketonuria)
 - any inherited disorder that damages the tubules secondarily (e.g. galactosaemia)
 - tubular reabsorptive defects, either generalized (e.g. Fanconi's syndrome) or specific (e.g. cystinuria).
- Amino acid transport defects can be congenital or acquired.

Generalized aminoacidurias

Fanconi's syndrome

This occurs in a juvenile form (De Toni-Fanconi-Debré syndrome); in adult life it is often acquired through, for

example, heavy metal poisoning, drugs or some renal diseases. There is a generalized defective proximal tubular reabsorption of: most amino acids, glucose, urate, phosphate, resulting in hypophosphataemic rickets and bicarbonate, with failure to transport hydrogen ions, causing a renal tubular acidosis that then produces a hyperchloraemic acidosis (see p. 664).

Other abnormalities include potassium depletion, primary or secondary to the acidosis, polyuria, increased excretion of immunoglobulins and other low-molecular-weight proteins.

Various combinations of the above abnormalities have been described.

The juvenile form begins at the age of 6–9 months, with failure to thrive, vomiting and thirst. The clinical features are as a result of fluid and electrolyte loss and the characteristic vitamin D-resistant rickets.

In the adult, the disease is similar to the juvenile form, but osteomalacia is a major feature.

Treatment of the bone disease is with large doses of vitamin D (e.g. 1–2 mg of 1 α -hydroxycholecalciferol with regular blood calcium monitoring). Fluid and electrolyte loss needs to be corrected.

Specific aminoacidurias

Cystinuria

There is a defective tubular reabsorption and jejunal absorption of cystine and the dibasic amino acids, lysine, ornithine and arginine. Cystinuria is either a completely or incompletely autosomal recessive disorder with mutations in two genes, *SLC3A1* and *SLC7A9*. Cystine absorption from the jejunum is impaired but, nevertheless, cystine in peptide form can be absorbed. Cystinuria leads to urinary stones and is responsible for approximately 1–2% of all urinary calculi. The disease often starts in childhood, although most cases present in adult life.

Treatment is described on page 603.

The condition cystinosis must not be confused with cystinuria. Cystinosis is characterized by the accumulation of cystine in different organs leading to organ dysfunction, e.g. photophobia and ocular problems, chronic kidney disease. Treatment is with cysteamine.

Hartnup's disease

There is defective tubular reabsorption and jejunal absorption of most neutral amino acids but not their peptides. The resulting tryptophan malabsorption produces nicotinamide deficiency (see p. 210). Patients can be asymptomatic, but others develop evidence of pellagra (p. 210). Treatment is with nicotinamide.

Other aminoacidurias

Tryptophan malabsorption syndrome (blue diaper syndrome), familial iminoglycinuria and methionine malabsorption syndrome have all been described.

LYSOSOMAL STORAGE DISEASES

Lysosomal storage diseases are due to inborn errors of metabolism which are mainly inherited in an autosomal recessive manner (see Table 20.19).

Table 20.20 The major inborn errors of amino acid metabolism

Disease	Enzyme defect	Incidence	Biochemical and clinical features	Treatment	Prognosis
Albinism	Tyrosinase	1 in 13 000	Amelanosis: whitish hair, pink-white skin, grey-blue eyes Nystagmus, photophobia, strabismus	Symptomatic	Good
Alkaptonuria	Homogentisic acid oxidase	1 in 100 000	Homogentisic acid polymerizes to produce a brown-black product that is deposited in cartilage and other tissues (ochronosis)	None	Good
Homocystinuria Type I	Cystathionine synthase	1 in 20 000	Homocystine is excreted in urine Learning difficulties Marfan-like syndrome Thrombotic episodes Survivors have learning difficulties	Diet: low in methionine cystine supplemented Pyridoxine Betaine	Many die as neonates
Type II	Methylene tetrahydrofolate reductase				
Phenylketonuria	Phenylalanine hydroxylase	1 in 20 000	Brain damage with learning difficulties and epilepsy Phenylpyruvate and its derivatives excreted in urine	Diet low in phenylalanine in first few months of life prevents damage	Good but some intellectual impairment
Histidinaemia	Histidase	Very rare	Learning difficulties	–	–
'Maple syrup' disease	Branched-chain ketoacid dehydrogenase	Very rare	Failure to thrive Fits, neonatal acidosis and severe cerebral degeneration Valine, isoleucine and their derivatives are excreted in urine A milder form is seen	–	Early death
Oxalosis (hyperoxaluria)	Alanine: glyoxylate aminotransferase	Very rare	Nephrocalcinosis, renal stones, renal failure due to deposition of calcium oxalate Prenatal and early diagnosis now possible	–	Liver transplantation ? Gene therapy

There are many other enzyme defects producing, e.g. alaninaemia, ammonaemia, argininaemia, citrullinaemia, isovaleric acidaemia, lysinaemia, ornithinaemia or tyrosinaemia.

Glucosylceramide lipidoses: Gaucher's disease

This is the most prevalent lysosomal storage disease and is due to a deficiency in glucocerebrosidase, a specialized lysosomal acid β -glucosidase. This results in accumulation of glucosylceramide in the lysosomes of the reticuloendothelial system, particularly the liver, bone marrow and spleen. Over 200 mutations have been characterized in the glucocerebrosidase gene (1g21), the most common being a single base change (N370S) causing the substitution of arginine for serine; this is seen in 70% of Jewish patients. The typical Gaucher cell, a glucocerebroside-containing reticuloendothelial histiocyte, is found in the bone marrow, producing many cytokines such as CD14.

There are three clinical types, the most common presenting in childhood or adult life with an insidious onset of hepatosplenomegaly (**Type 1**). There is a high incidence in Ashkenazi Jews (1 in 3000 births), and patients have a characteristic pigmentation on exposed parts, particularly the

forehead and hands. The clinical spectrum is variable, with patients developing anaemia, evidence of hypersplenism and pathological fractures that are due to bone involvement. Nevertheless, many have a normal life-span.

The diagnosis is made on finding reduced glucocerebrosidase in leucocytes. Mutational analysis will confirm the diagnosis. Plasma chitotriosidase (an enzyme secreted by activated macrophages) is grossly elevated in Gaucher's disease and other lysosomal disorders: it is used to monitor enzyme replacement therapy.

Acute Gaucher's disease (**Type 2**) presents in infancy with rapid onset of hepatosplenomegaly, with neurological involvement owing to the presence of Gaucher cells in the brain. The outlook is very poor.

Type 3 presents in childhood or adolescence with a variable progression of hepatosplenomegaly, neurodegeneration and bone disease. Again, the outlook is poor.

Some patients with non-neuropathic (**Type 1**) Gaucher's disease show considerable improvement with infusion of human recombinant glucocerebrosidase (imiglucerase – a

SIGNIFICANT WEBSITE

Information on genetic testing: www.genetests.org

human recombinant enzyme). Velaglucerase alfa is also used. Oral miglustat (an inhibitor of glucosylceramide synthase) is used for mild to moderate type 1 Gaucher's disease.

Sphingomyelin cholesterol lipidoses: Niemann–Pick disease

The disease is due to a deficiency of lysosomal sphingomyelinase which results in the accumulation of sphingomyelin cholesterol and glycosphingolipids in the reticuloendothelial macrophages of many organs, particularly the liver, spleen, bone marrow and lymph nodes. The disease usually presents within the first 6 months of life with mental retardation and hepatosplenomegaly; a particular type (11c) presents in adults with dementia. The gene frequency is 1:100 in Ashkenazi Jews, the diagnosis being made in the group by targeted mutation analysis. Typical foam cells are found in the marrow, lymph nodes, liver and spleen.

The mucopolysaccharidoses (MPSs)

This is a group of disorders caused by the deficiency of lysosomal enzymes (e.g. α -L-iduronidase) required for the catabolism of glycosaminoglycans (mucopolysaccharides).

The catabolism of dermatan sulphate, heparan sulphate, keratin sulphate or chondroitin sulphate may be affected either singularly or together.

Accumulation of glycosaminoglycans in the lysosomes of various tissues results in the disease. Ten forms of MPS have been described; all are chronic but progressive, and a wide spectrum of clinical severity can be seen within a single enzyme defect. The MPS types show many clinical features though in variable amounts, with dysostosis, abnormal facies, poor vision and hearing and joint dysmobility (either stiff or hypermobile) being frequently seen. Mental retardation is present in, e.g. Hurler (MPS IH) and San Filippo A (MPS IIIA) types, but normal intelligence and life-span are seen in Scheie (MPS IS). L-arionidase infusion reduces lysosomal storage, resulting in clinical improvement.

The GM2 gangliosidoses

In these conditions there is accumulation of GM2 gangliosides in the central nervous system and peripheral nerves. It is particularly common (1 in 2000) in Ashkenazi Jews. Tay–Sachs disease is the severest form, where there is a progressive degeneration of all cerebral function, with fits, epilepsy, dementia and blindness, and death usually occurs before 2 years of age. The macula has a characteristic cherry spot appearance.

Fabry's disease

This X-linked recessive condition involves the glycosphingolipid pathway. There is a deficiency of lysosomal hydrolase (α -galactosidase A). This enzyme is encoded by the gene on the Xq22.1 region of the X chromosome. Many mutations have been described and genetic analysis is used in the diagnosis, causing an accumulation of globotriaosylceramide with terminal α -galactosyl moieties in the lysosomes of various tissues including the liver, kidney, blood vessels and the ganglion cells of the nervous system. The patients present with peripheral nerve involvement, gastrointestinal symptoms/abdominal pain, diarrhoea and early satiety, but eventually most patients have a cardiomyopathy, strokes and kidney disease in adult life. An absent or very low level of α -gal A in leucocytes confirms the diagnosis. Genetic testing is available. Treatment is with agalsidase α - β infusions.

Diagnosis

Many of the sphingolipidoses can be diagnosed by demonstrating the enzyme deficiency, usually in peripheral blood leucocytes.

Prenatal diagnosis is possible in a number of the conditions by obtaining specimens of amniotic cells. Carrier states can also be identified, so that sensible genetic counselling can be given.

AMYLOIDOSIS

Amyloidosis is a disorder of protein metabolism in which there is an extracellular deposition of pathological insoluble fibrillar proteins in organs and tissues. Characteristically, the amyloid protein consists of β -pleated sheets that are responsible for its insolubility and resistance to proteolysis.

Amyloidosis can be acquired or inherited. Classification is based on the nature of the precursor plasma proteins (at least 20) that form the fibrillar deposits. The process for the production of these fibrils appears to be multifactorial and differs amongst the various types of amyloid.

AL amyloidosis (immunoglobulin light chain-associated)

This is a plasma cell dyscrasia, related to multiple myeloma, in which clonal plasma cells in the bone marrow produce immunoglobulins that are amyloidogenic. This may be the outcome of destabilization of light chains owing to substitution of particular amino acids into the light chain variable region. There is a clonal dominance of amyloid light (AL) chains – either the dominant κ or γ isotype – which are excreted in the urine (Bence Jones proteins). This type of amyloid is often associated with lymphoproliferative disorders, such as myeloma, Waldenstrom's macroglobulinaemia or non-Hodgkin's lymphoma. It rarely occurs before the age of 40 years.

The clinical features are related to the organs involved. These include the kidneys (presenting with proteinuria and the nephrotic syndrome) and the heart (presenting with heart failure). Autonomic and sensory neuropathies are relatively common, and carpal tunnel syndrome with weakness and paraesthesia of the hands may be an early feature. Sensory neuropathy is common. There is an absence of central nervous system involvement.

On examination, hepatomegaly and rarely splenomegaly, cardiomyopathy, polyneuropathy and bruising may be seen. Macroglossia occurs in about 10% of cases and periorbital purpura in 15%.

Familial amyloidoses (transthyretin-associated, ATTR)

These are autosomally dominant transmitted diseases where the mutant protein forms amyloid fibrils, starting usually in middle age. The most common form is due to a mutant – transthyretin – which is a tetrameric protein with four identical subunits. It is a transport protein for thyroxine and retinol-binding protein and mainly synthesized in the liver. Over 80 amino acid substitutions have been described; for example, a common substitution is that of methionine for valine at position 30 (Met 30) in all racial groups, and alanine for threonine (Ala 60) in the English and Irish. These substitutions destabilize the protein, which precipitates following stimulation, and can cause disorders such as familial amyloidotic polyneuropathy (FAP), cardiomyopathy or the

nephrotic syndrome. Major foci of FAP occur in Portugal, Japan and Sweden.

Other less common variants include mutations of apoprotein A-I, gelsolin, fibrinogen A α and lysozyme.

Clinically, peripheral sensorimotor and autonomic neuropathy are common, with symptoms of autonomic dysfunction, diarrhoea and weight loss. Renal disease is less prevalent than with AL amyloidosis. Macroglossia does not occur. Cardiac problems are usually those of conduction. There may be a family history of unidentified neurological disease.

Other hereditary systemic amyloidoses include other familial amyloid polyneuropathies (e.g. Portuguese, Icelandic, Dutch). There is a familial Creutzfeldt-Jakob disease. In familial Mediterranean fever, renal amyloidosis is a common serious complication.

Reactive systemic (secondary AA) amyloidoses

These are due to amyloid formed from serum amyloid A (SAA), which is an acute phase protein. It is, therefore, related to chronic inflammatory disorders and chronic infection.

Clinical features depend on the nature of the underlying disorder. Chronic inflammatory disorders include rheumatoid arthritis, inflammatory bowel disease and untreated familial Mediterranean fever. In developing countries, it is still associated with infectious diseases such as tuberculosis, bronchiectasis and osteomyelitis. AA amyloidosis often presents with chronic kidney disease, with hepatomegaly and splenomegaly. Macroglossia is not a feature and cardiac involvement is rare. The degree of renal failure correlates with the SAA level in a more favourable outcome in patients with low normal levels.

Other amyloids

Cerebral amyloidosis, Alzheimer's disease and transmissible spongiform encephalopathy

The brain is a common site of amyloid deposition, although it is not directly affected in any form of acquired systemic amyloidosis. Intracerebral and cerebrovascular amyloid deposits are seen in Alzheimer's disease. Most cases are sporadic, but hereditary forms caused by mutations have been reported. In hereditary spongiform encephalopathies several amyloid plaques have been seen.

Amyloid deposits are frequently found in the elderly, particularly cerebral deposits of A β protein. This is also seen in Down's syndrome. Apoprotein E (involved in LDL transport, see p. 1033) interacts directly with β -A β protein in senile plaques and neurofibrillary tangles in the brain. The gene for apoprotein E is on chromosome 19 and may be a susceptibility factor in the aetiology of Alzheimer's disease.

Local amyloidosis

Deposits of amyloid fibrils of various types can be localized to various organs or tissues (e.g. skin, heart and brain).

Dialysis-related amyloidosis

This is due to the β_2 -microglobulin producing amyloid fibrils in chronic dialysis patients (see p. 628). It frequently presents with the carpal tunnel syndrome.

Diagnosis

This is based on clinical suspicion and, if possible, on tissue histology. Amyloid in tissues appears as an amorphous,

homogeneous substance that stains pink with haematoxylin and eosin and stains red with Congo red. It also has a green fluorescence in polarized light. Tissue can be obtained from the rectum, gums or fat pad. The bone marrow may show plasma cells in amyloidosis or a lymphoproliferative disorder. A paraproteinaemia and proteinuria with light chains in the urine may also be seen in AL amyloidosis. In secondary or reactive amyloidosis there will be an underlying disorder. Scintigraphy using ^{125}I -labelled serum amyloid P component is useful for the assessment of AL, ATTR and AA amyloidosis, but it is not widely available and is expensive.

Treatment

This is symptomatic or the treatment of the associated disorder. The nephrotic syndrome and congestive cardiac failure require the relevant therapies. Treatment of any inflammatory source or infection should be instituted. Colchicine may help familial Mediterranean fever. Eprodisate, which interferes with interactions between amyloid proteins and glycosaminoglycans, inhibits polymerization of amyloid fibrils; it slows the fall in renal function in AA amyloidosis. Chemotherapy is with melphalan plus dexamethasone in AL amyloidosis. Stem cell therapy is also used. In ATTR amyloidosis where transthyretin is predominantly synthesized in the liver, liver transplantation (when there would be a disappearance of the mutant protein from the blood) is considered as the definitive therapy.

THE PORPHYRIAS

This heterogeneous group of rare inborn errors of metabolism is caused by abnormalities of enzymes involved in the biosynthesis of haem, resulting in overproduction of the intermediate compounds called 'porphyrins' (Fig. 20.22). The porphyrias show extreme genetic heterogeneity. For example, in acute intermittent porphyria, more than 90 mutations have been identified in the uroporphobilinogen deaminase gene. One mutation has a high prevalence in patients in northern Sweden, suggesting a common ancestor.

Structurally, porphyrins consist of four pyrrole rings. These pyrrole rings are formed from the precursors glycine and succinyl-CoA, which are converted to δ -aminolaevulinic acid (δ -ALA) in a reaction catalysed by the enzyme δ -ALA synthase. Two molecules of δ -ALA condense to form a pyrrole ring.

Porphyrins can be divided into uroporphyrins, coproporphyrins or protoporphyrins depending on the structure of the side-chain. They are termed type I if the structure is symmetrical and type III if it is asymmetrical. Both uroporphyrins and coproporphyrins can be excreted in the urine.

The sequence of enzymatic changes in the production of haem is shown in Figure 20.22. The chief rate-limiting step is the enzyme δ -ALA synthase. This has two isoforms, ALA-N (non-erythroid) and ALA-E (erythroid). ALA-N is under negative feedback by haem but is upregulated by drugs and chemicals; there is no known inherited deficiency and the gene is on 3p21. Conversely ALA-E, encoded by Xp11.21, is unaffected by drugs or haem, and an inherited deficiency causes X-linked sideroblastic anaemia (Fig. 20.22).

Consequently:

- Haem (endogenous or exogenous) produces remission of hepatic porphyria.
- Chemicals and drugs can produce disease.
- Erythropoietic porphyria gives constant symptoms and is affected by sunlight.

Amyloidosis

The porphyrias

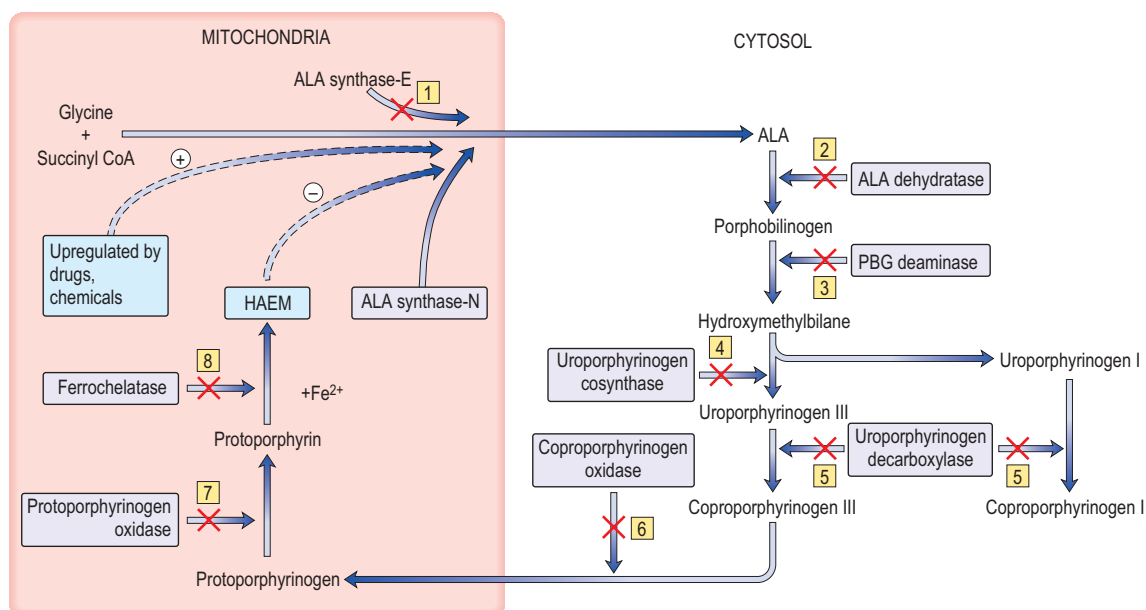

Figure 20.22 Porphyrin metabolism showing the various porphyrias. ALA synthase is the rate-limiting enzyme. Deficiencies of the other seven enzymes (crosses) cause the different porphyrias: **(1)** X-linked sideroblastic anaemia; **(2)** ALA dehydratase porphyria (ADP); **(3)** Acute intermittent porphyria (AIP); **(4)** Congenital erythropoietic porphyria (CEP); **(5)** Porphyrria cutanea tarda (PCT) and hepatoerythropoietic porphyria (HEP); **(6)** Hereditary coproporphyria (HCP); **(7)** Variegate porphyria (VP); **(8)** Erythropoietic protoporphyria (EPP).

Table 20.21 Porphyria: neurovisceral symptoms	
Neuropsychiatric	Visceral
Neuropathy	Abdominal pain
Motor (70%)	Vomiting
Sensory	Constipation
Epilepsy (15%)	Diarrhoea (occasional)
Psychiatric disorders (50%)	Fever (~30%)
Depression	Hypertension (up to 50%)
Anxiety	Tachycardia (up to 80%)
Psychosis	Muscular pain (~50%)

Clinical features

All of the haem intermediates shown in Figure 20.22 are potentially toxic. Three patterns of symptoms occur in the various types of porphyria:

- Neurovisceral (Table 20.21)
- Photosensitive
- Haemolytic anaemia.

The most common types of porphyria are acute intermittent (AIP), porphyria cutanea tarda (PCT) and erythropoietic porphyria (EPP).

Neurovisceral

Acute intermittent porphyria (AIP)

AIP is an autosomal dominant disorder (Fig. 20.22). Presentation is in early adult life, usually around the age of 30 years, and women are affected more than men. It may be precipitated by alcohol and drugs such as barbiturates and oral contraceptives, but a wide range of lipid-soluble drugs have also been incriminated. Acute attacks present with neurovisceral symptoms (Table 20.21). Symptoms of the rare,

autosomal recessive aminolaevulinic acid dehydrogenase porphyria (ADP) are similar.

Investigations

A rapid semi-quantitative spot urine test for porphobilinogen (PBG) is often available.

The urine turns red-brown or red on standing.

- Blood count. This is usually normal, with occasional neutrophil leucocytosis.
- Liver biochemical tests. There is elevated bilirubin and aminotransferases.
- Serum urea is often raised.
- ALA and PBG are raised (24 h collection).
- Erythrocyte PBG deaminase is decreased.

Screening

Family members should be screened to detect latent cases. Urinalysis is not adequate but measurement of erythrocyte porphobilinogen deaminase and ALA synthase is extremely sensitive.

Mixed neurovisceral and photocutaneous Variegate porphyria (VP)

This combines neurovisceral symptoms with those of a cutaneous photosensitive porphyria (Fig. 20.22). A bullous eruption develops on exposure to sunlight owing to the activation of porphyrins deposited in the skin.

Investigation shows an elevated urinary ALA and PBG. Fluorescence emission spectroscopy of plasma differentiates this from other cutaneous porphyrias.

Hereditary coproporphyria (HCP)

This is extremely rare and broadly similar in presentation to variegate porphyria.

Photocutaneous

Porphyria cutanea tarda (cutaneous hepatic porphyria) (PCT)

This condition, which has a genetic predisposition, presents with a bullous eruption on exposure to sunlight; the eruption heals with scarring. Alcohol is the most common aetiological agent but hepatitis C, iron overload or HIV can also precipitate the disease. Evidence of biochemical or clinical liver disease may also be present. Polychlorinated hydrocarbons have been implicated and porphyria cutanea tarda has been seen in association with benign or malignant tumours of the liver.

Hepatoerythropoietic porphyria (HEP, Fig. 20.22) is a rare disease clinically very similar to congenital erythropoietic porphyria presenting in childhood; haemolytic anaemia occurs. The defect of HEP is similar to that of PCT.

The **diagnosis** depends on demonstration of increased levels of urinary uroporphyrin. Histology of the skin shows subepidermal blisters with perivascular deposition of periodic acid–Schiff-staining material. The serum iron and transferrin saturation are often raised. Liver biopsy shows mild iron overload as well as features of alcoholic liver disease.

Congenital erythropoietic porphyria (CEP)

This is extremely rare and is transmitted as an autosomal recessive trait. Its victims show extreme sensitivity to sunlight and develop disfiguring scars. Dystrophy of the nails, blindness due to lenticular scarring, and brownish discoloration of the teeth also occur.

Erythropoietic protoporphyria (EPP)

This is more common than congenital erythropoietic porphyria and is inherited as an autosomal dominant trait. It presents with irritation and a burning pain in the skin on exposure to sunlight. The liver is usually normal but protoporphyrin deposition can occur. Diagnosis is made by fluorescence of the peripheral red blood cells and by increased protoporphyrin in the red cells and stools.

Management of porphyrias

Neurovisceral

Acute. The management of acute episodes is largely supportive. Precipitating factors, e.g. drugs, should be stopped. Analgesics should be given (avoiding drugs that may aggravate an attack). Intravenous carbohydrates, e.g. glucose, inhibit ALA synthase activity. Intravenous haem arginate (human haemin) infusion reduces ALA and PBG excretion by having a negative effect on ALA synthase-N activity (Fig. 20.22) and decreases the duration of an attack; this is useful in a severe attack. Calorie and fluid intake should be maintained.

Prevention in remission period. This is by avoidance of possible precipitating factors, e.g. drugs and alcohol.

Stopping smoking, treatment of infections and stress avoidance are helpful. Surgery can precipitate attacks. A high-carbohydrate diet should be maintained and haemin infusions may also help.

Photocutaneous episodes

Acute attacks following exposure to UV light can only be treated symptomatically. However, venesection, which reduces urinary porphyrin, can be used for PCT in both acute and remission phases. Chloroquine can also aid excretion by forming a water-soluble complex with uroporphyrins. Liver transplantation is used for severe cases.

Prevention is with avoidance of sunlight, and use of zinc-containing sunscreens and protective clothing.

Oral β -carotene, which quenches free radicals, provides effective protection against solar sensitivity in EPP.

DISORDERS OF THE EAR, NOSE AND THROAT

THE EAR

Anatomy and physiology

The ear can be divided into three parts: outer, middle and inner (Fig. 21.1).

The outer ear has a skin-lined tube 2.5 cm long leading down to the tympanic membrane (the ear drum). Its outer third is cartilaginous and contains hair, sebaceous and ceruminous glands, but the walls of the inner two-thirds are bony. The outer ear is self-cleaning as the skin is migratory and there are no indications to use cotton wool buds. Wax should only be seen in the outer third.

The middle ear is an air-containing cavity derived from the branchial clefts. It communicates with the mastoid air cells superiorly, and the Eustachian tube connects it to the nasopharynx medially. The Eustachian tube ventilates the middle ear and maintains equal air pressure across the tympanic membrane. It is normally closed but opens via the action of the palatal muscles to allow air entry when swallowing or yawning. A defect in this mechanism, such as with a cleft palate, will prevent air entering the middle ear cleft which may then fill with fluid. Lying within the middle ear cavity are the three ossicles (malleus, incus and stapes) that transmit sound from the tympanic membrane to the inner ear. On the medial wall of the cavity is the horizontal segment of the facial nerve, which can be damaged during surgery or by direct extension of infection in the middle ear.

The inner ear contains the cochlea for hearing and the vestibule and semicircular canals for balance. There is a

semicircular canal arranged in each body plane and these are stimulated by rotatory movement. The facial, cochlear and vestibular nerves emerge from the inner ear and run through the internal acoustic meatus to the brainstem (see Fig. 22.7, p. 1076).

Physiology of hearing

The ossicles, in the middle ear, transmit sound waves from the tympanic membrane to the cochlea. They amplify the waves by about 18-fold to compensate for the loss of sound waves moving from the air-filled middle ear to the fluid-filled cochlea. Hair cells in the basilar membrane of the cochlea detect the vibrations and transduce these into nerve impulses which pass to the cochlear nucleus and then eventually to the superior olivary nuclei of both sides; thus lesions central to the cochlear nucleus do not cause unilateral hearing loss.

If the ossicles are diseased, sound can also reach the cochlea by vibration of the temporal bone (bone conduction).

Examination

The pinna and postauricular region should first be examined for scars or swellings. An auroscope is used to examine the external ear canal whilst the pinna is retracted backwards and upwards to straighten the canal. Look for wax, discharge or foreign bodies. The tympanic membrane should always be seen with a light reflex anteroinferiorly. Previous repeated infections may cause a thickened, whitish drum but fluid in

Weber test.

the middle ear may show as dullness of the drum. Perforations are marginal or central.

Common disorders

The discharging ear (otorrhoea)

Discharge from the ear is usually due to infection of the outer or middle ear.

Otitis externa

This is a diffuse inflammation of the skin of the ear canal. The cause is bacterial, viral or fungal and the patient usually complains of severe pain. Gentle pulling of the pinna is tender and there may be lymphadenopathy of the preauricular nodes.

Examination often reveals debris in the canal which needs to be removed either by gentle mopping or preferably by suction viewed directly under a microscope. In severe cases the canal may be swollen and a view of the tympanic membrane impossible. Any foreign body seen should be removed with great care by trained personnel.

Treatment is with topical antibiotics in the first instance (drops such as dexamethasone 0.05%, framycetin sulphate 0.5%, gramicidin 0.005% drops or hydrocortisone acetate 1%, gentamicin 0.3%, or a spray such as dexamethasone 0.1%, neomycin sulphate 3250 units). If it does not resolve in 3–4 days then microsuction in an ENT department is necessary.

Otitis media

Otitis media can also present with discharge from the middle ear through a perforation of the tympanic membrane. There are no mucous glands in the external ear canal, however; if the discharge is serous, then middle ear pathology is unlikely.

Treatment for the acute case is initially with non-steroidal anti-inflammatory drugs then, if it is not resolving, with systemic antibiotics.

Cholesteatoma

Cholesteatoma is defined as keratinizing squamous epithelium within the middle ear cleft and can present with foul-smelling otorrhoea. Examination shows a defect in the tympanic membrane full of white cheesy material. Mastoid surgery is required to remove this sac of squamous debris as it can erode local structures such as the facial nerve or even extend intracranially.

Box 21.1 Hearing loss

Hearing loss

Deafness can be conductive or sensorineural and these can be differentiated at the bedside by the Rinne and the Weber tests (Box 21.1) or with pure-tone audiometry. *Conductive hearing loss* has many causes (Table 21.1) but wax is the commonest.

Rinne test

- Normally a tuning fork, 512 Hz, will be heard as louder if held next to the ear (i.e. air conduction) than it will if placed on the mastoid bone (*Rinne positive*).
- If the tuning fork is perceived louder when placed on the mastoid (i.e. via bone conduction), then a defect in the conducting mechanism of the external or middle ear is present (true *Rinne negative*).

Weber test

A tuning fork placed on the forehead or vertex of a patient with normal hearing (or with symmetrical hearing loss) should be perceived centrally by the patient.

Pure tone audiometry

The patient is asked to respond to a series of pure tones presented to each ear, in turn, in a soundproof room. An audiogram is produced (see Fig. 21.2).

Perforated tympanic membrane

This arises from trauma or chronic middle ear disease where recurrent infection results in a permanent defect. Surgical

repair is only indicated if the patient is symptomatic with hearing loss or recurrent discharge.

Otitis media

This is an acute inflammation of the middle ear, causing severe pain (otalgia) and conductive hearing loss. This occurs because fluid accumulation in the middle ear impairs sound conduction to the cochlea. Otitis media is often viral in origin, e.g. following a cold, and will settle within 72 hours without antibacterial treatment. In people with systemic features or after 72 hours, a systemic antibiotic, e.g. amoxicillin, should be given, particularly in the under 2 year olds. Topical therapy is of no value. Complications include infection of the mastoid bone.

Acute otitis media can spread to the mastoid area. If there is tenderness and swelling over the mastoid then an urgent ENT opinion should be obtained.

Secretory otitis media with effusion ('serous otitis media' or 'glue ear')

This is common in children because of Eustachian tube dysfunction. The effusion resolves naturally in the majority of cases but can persist giving hearing loss, and it predisposes to recurrent attacks of acute otitis media. A grommet (tympanostomy tube) is inserted into the tympanic membrane and ventilates the middle ear cavity, i.e. takes over the Eustachian tube's function. Grommets are extruded from the tympanic membrane as it heals (over 6 months to 2 years). Developmental outcomes are not improved by grommet insertions. In most children the middle third of the face grows around the age of 7–14 years and Eustachian tube dysfunction is rare after this.

Otosclerosis

This is usually a hereditary disorder in which new bony deposits occur within the stapes footplate and the cochlea. Characteristically seen in the second and third decades, it is commoner in females and can become worse during pregnancy. The hearing loss may be mixed, and treatment includes a hearing aid or replacement of the fixed stapes with a prosthesis (stapedectomy). The choice of treatment is dependent on the patient. Surgery is an excellent option, with very good success rates in regular stapedectomists' hands, but it always carries a small risk of a complete hearing loss. Hearing aids, whilst safe, require the patient's compliance if they are to afford benefit.

Presbycusis

This is the commonest cause of deafness. It is a degenerative disorder of the cochlea and is typically seen in old age. It can be due to the loss of outer hair cells (sensory), loss of the ganglion cells (neural), strial atrophy (metabolic) or it can be a mixed picture. Ageing itself does not cause outer hair cell loss but environmental noise toxicity over the years is a major factor. The onset is gradual and the higher frequencies are affected most (Fig. 21.2). Speech has two components: low frequencies (vowels) and high frequencies (consonants). When the consonants are lost, speech loses its intelligibility. Increasing the volume merely increases the low frequencies and the characteristic response of 'Don't shout. I'm not deaf!'

A high-frequency-specific hearing aid will do much to ease the frustrations of both the patients and their close contacts.

Figure 21.2 Audiogram showing presbycusis (high frequency loss).

Noise trauma

Cochlear damage can occur, e.g. when shooting without ear protectors or from industrial noise (see p. 935), and characteristically has a loss at 4 kHz.

Acoustic neuroma

This is a slow-growing benign schwannoma of the vestibular nerve (see p. 1076) which can present with progressive sensorineural hearing loss. Any patient with an asymmetric sensorineural hearing loss or sudden sensorineural hearing loss should be investigated, e.g. with an MRI scan.

Vertigo

Vertigo is usually rotatory when it arises from the ear. The presence of otalgia, otorrhoea, tinnitus or hearing loss suggests an otologic aetiology. Vestibular causes can be classified according to the duration of the vertigo. Common causes are summarized below.

- Seconds to minutes – benign paroxysmal positional vertigo
- Minutes to hours – Ménière's disease
- Hours to days – labyrinthine or central pathology.

Benign paroxysmal positional vertigo (BPPV)

BPPV is thought to be due to loose otoliths in the semicircular canals, commonly the posterior canal. Positional vertigo is precipitated by head movements, usually to a particular position, and often occurs when turning in bed or on sitting up. The onset is typically sudden and distressing. The vertigo lasts seconds or minutes and the phenomenon becomes less severe on repeated movements (fatigue). There is no serious underlying cause but it sometimes follows vestibular neuritis (see p. 1079), head injury or ear infection.

Diagnosis

Diagnosis is made on the basis of the history and by the *Hallpike manoeuvre* (Fig 21.3). A positive Hallpike test confirms BPPV, which can be cured in over 90% of cases by the Epley manoeuvre. This involves gentle but specific manipulation and rotation of the patient's head to shift the loose otoliths from the semicircular canals.

DISORDERS OF THE EAR, NOSE AND THROAT

The ear

Secretory otitis media (glue ear). Auroscopic view of the tympanic membrane, which is dull with loss of light reflex.

FURTHER READING

Halmagyi GM. Diagnosis and management of vertigo. *Clin Med* 2005; 5:159–165.

Figure 21.3 Hallpike manoeuvre for diagnosis of benign paroxysmal positional vertigo. This can be done in the outpatient department. **(a)** The patient sits on a couch, his head is turned towards one ear. **(b)** The head is supported by the examiner while the patient lies down so that his head is just below the horizontal. Nystagmus (following a latent interval of a few seconds) is commonly noted when the head has been turned towards the affected ear. This can be repeated with the patient's head turned towards the other ear.

A differential diagnosis is a cerebellar mass, but here positional nystagmus (and vertigo) is immediately apparent (no latent interval) and does not fatigue.

Ménière's disease

This condition is characterized by recurring episodic rotatory vertigo lasting 30 minutes to a few hours; attacks are recurrent over months or years. Classically, it is associated with a low frequency sensorineural hearing loss, feeling of fullness in the affected ear, loss of balance, tinnitus and vomiting. There is a build-up of endolymphatic fluid in the inner ear, although its precise aetiology is still unclear.

Treatment

Vestibular sedatives, e.g. cinnarizine, are used in the acute phase. Preventative measures, such as a low-salt diet, beta-histidine and avoidance of caffeine, are useful. If the disease cannot be controlled, then a chemical labyrinthectomy, perfusing the round window orifice with ototoxic drugs such as gentamicin, is used. Gentamicin destroys the vestibular epithelium; therefore the patient has severe vertigo for around 2 weeks until the body compensates for the lack of vestibular input on that side. The patient will happily trade occasional mild vertigo when the balance system is challenged to the unpredictable, severe and disabling attacks of vertigo of Ménière's disease.

Labyrinthine or central causes of vertigo

(see Table 22.4)

These are managed with vestibular sedatives in the acute phase. Most patients will settle over a few days but continuous true vertigo with nystagmus suggests a central lesion. A patient with a deficit of vestibular function due to viral labyrinthitis or neuronitis should be able to cease vestibular sedatives within 2 weeks; long-term use can give parkinsonian side-effects, delay central compensation and thus prolong the vertigo. Vestibular rehabilitation by a physiotherapist or

Figure 21.4 The anatomy of the nose in longitudinal section. IT, inferior turbinate; MT, middle turbinate; ST, superior turbinate; a, internal ostium; b, respiratory region; c, choanae.

audiological scientist can speed up the compensation process, although most patients will be able to do this themselves with time.

Tinnitus

This is a sensation of a sound when there is no auditory stimulus. It can occur without hearing loss and results from heightened awareness of neural activity in the auditory pathways. Patients describe a hissing or ringing in their ears and this can cause much distress. It usually does not have a serious cause but vascular malformation, e.g. aneurysms, or vascular tumours can be associated. Tinnitus occurs due to awareness of neural activity in the auditory pathways that our brains are made more conscious of.

Treatment

This is difficult. A tinnitus masker (a mechanically produced continuous soft sound) can help. Specialist audiological services are of use and rehabilitate patients well.

THE NOSE

Anatomy and physiology (Fig. 21.4)

The function of the nose is to facilitate smell and respiration:

- Smell is a sensation conveyed by the olfactory epithelium in the roof of the nose. The olfactory epithelium is supplied by the first cranial nerve (see p. 1071).
- The nose also filters, moistens and warms inspired air and in doing so assists the normal process of respiration.

The external portion of the nose consists of two nasal bones attached to the rest of the facial skeleton and to the upper and lower lateral cartilages. The internal nose is divided by a midline septum that comprises both cartilage and bone. This divides the internal nose in two, from the external nostril to the posterior choanae. The posterior choanae are in continuity with the nasopharynx posteriorly.

Lockwood AH. Tinnitus. *New England Journal of Medicine* 2002; 348:1027–1032.

Figure 21.5 (a) Blood supply of Little's area on the septum of the nose. (b) Nasal pack.

The paranasal sinuses open into the lateral wall of the nose and are a system of aerated chambers within the facial skeleton.

The blood supply of the nose is derived from branches of both the internal and external carotid arteries. The internal carotid artery supplies the upper nose via the anterior and posterior ethmoidal arteries. The external carotid artery supplies the posterior and inferior portion of the nose via the superior labial artery, greater palatine artery and sphenopalatine artery. On the anterior nasal septum is an area of confluence of these vessels (Little's area) (Fig. 21.5a).

Examination

The anterior part of the nose can be examined using a nasal speculum and light source. Endoscopes are required to examine the nasal cavity and postnasal space.

Common disorders

Epistaxis

Nose bleeds vary in severity from minor to life-threatening. Little's area (Fig. 21.5a) is a frequent site of nasal haemorrhage. First aid measures should be administered immediately, including external digital compression of the anterior lower portion of the external nose, ice packs and leaning forward. The patient should be asked to avoid swallowing any blood running posteriorly as this causes gastric irritation and then nausea and vomiting.

Not infrequently, small recurrent epistaxes occur and these may require a visit to the emergency clinic for an examination and simple local anaesthetic cautery with a silver nitrate stick. If the bleeding continues profusely then resuscitation in the form of intravenous access, fluid replacement or blood, and oxygen can be administered. If further intervention is necessary, consideration should be given to intranasal cautery of the bleeding vessel, or intranasal packing using a variety of commercially available nasal packs (Fig. 21.5b). In addition to direct treatment of the epistaxis, a cause and appropriate treatment of a cause should be sought (Table 21.2).

Rhinitis

See page 808.

Table 21.2 Aetiology of epistaxis

Local	Idiopathic Trauma – foreign bodies, nose-picking and nasal fractures Iatrogenic – surgery, intranasal steroids Neoplasm – nasal, paranasal sinus and nasopharyngeal tumours
General	Anticoagulants Coagulation disorders Hypertension Osler–Weber–Rendu syndrome (familial haemorrhagic telangiectasia)

Nasal obstruction

Nasal obstruction is a symptom and not a diagnosis. It can significantly affect a patient's quality of life. Causes include:

- **Rhinitis** (see p. 808). If an allergen is identified, then allergen avoidance is the mainstay of treatment. Topical steroids and/or antihistamines can be tried. If severe, then oral antihistamines or referral to an allergy clinic for immunotherapy is warranted.
- **Septal deviation**. Correction of this deviation can be undertaken surgically.
- **Nasal polyps**. This condition occurs with inflammation and oedema of the sinus nasal mucosa. This oedematous mucosa prolapses into the nasal cavity and can cause significant nasal obstruction. In allergic rhinitis (see p. 798) the mucosa lining the nasal septum and inferior turbinates are swollen and a dark red or plum colour. Nasal polyps can be identified as glistening swellings which are not tender. Treatment with intranasal steroids helps but if polyps are large or unresponsive to medical treatment then surgery is necessary.
- **Foreign bodies**. These are usually seen in children who present with unilateral nasal discharge. Clinical examination of the nose with a light source often reveals the foreign body, which requires removal either in clinic or in theatre with a general anaesthetic.
- **Sinonasal malignancy**. This is extremely rare. The diagnosis must be considered if unusual unilateral

Box 21.2 Types of sinusitis

Acute	Symptoms lasting 1 week to 1 month
Recurrent acute	>4 episodes of acute sinusitis per year
Subacute	Symptoms for 1–3 months
Chronic	Symptoms for >3 months

symptoms are seen, including nasal obstruction, epistaxis, pain, epiphora, cheek swelling, paraesthesia of the cheek and proptosis of the orbit.

Sinusitis

Sinusitis is an infection of the paranasal sinuses that either is bacterial (mainly *Streptococcus pneumoniae* and *Haemophilus influenzae*) or is occasionally fungal. It is most commonly associated with an upper respiratory tract infection and can occur with asthma. Symptoms include frontal headache, purulent rhinorrhoea, facial pain with tenderness and fever. It can be confused with a variety of other conditions such as migraine, trigeminal neuralgia and cranial arthritis.

Treatment

Treatment for a bacterial sinusitis includes nasal decongestants, e.g. xylometazoline, broad-spectrum antibiotics, e.g. co-amoxiclav because *H. influenzae* can be resistant to amoxicillin, anti-inflammatory therapy with topical corticosteroids such as fluticasone propionate (nasal spray) to reduce mucosal swelling, and steam inhalations.

If the symptoms of sinusitis are recurrent (Box 21.2) or complications such as orbital cellulitis arise, then an ENT opinion is appropriate and a CT scan of the paranasal sinuses is undertaken. Plain sinus X-rays are now rarely used to image the sinuses.

CT scan of the sinuses or an MRI scan can demonstrate bony landmarks and soft tissue planes.

Functional endoscopic sinus surgery (FESS) is used for ventilation and drainage of the sinuses.

Anosmia

Olfaction is mainly under the control of cranial nerve I, although irritant, unpleasant nasal sensations are carried by cranial nerves V, IX and X. Anosmia is a complete loss of the sense of smell and *hyposmia* is a decreased sense of smell:

- A **conductive deficit** of smell occurs if odorant molecules do not reach the olfactory epithelium high in the nose.
- A **sensorineural loss** of smell is incurred if the neural transmission of smell is affected.
- Some conditions predispose to a mixed (conductive and sensorineural) loss of smell.

The main cause of a loss of smell is nasal obstruction due to upper respiratory infection or nasal polyps. Other causes include sinonasal disease, old age, drug therapy and head injury/trauma. It is difficult to predict the speed and extent of recovery in the latter causes. In many patients anosmia is idiopathic, but before this diagnosis is accepted an assessment of the patient for the possibility of an intranasal tumour or intracranial mass should be undertaken.

Figure 21.6 Normal anatomy of the throat.

Fractured nose

People with a fractured nose present with epistaxis, bruising of the eyes and nasal bridge swelling. Initially, it is often difficult to assess if the bones are deviated, particularly if there is significant swelling. Reduction of the fracture should be undertaken in the first 2 weeks after injury and can be achieved by manipulation. However, if the fracture sets, a more formal rhinoplasty may have to be undertaken at a later stage. The patient should be examined for a head injury and the nose should also be checked for a septal haematoma. This is painful, can cause nasal obstruction, is fluctuant to touch on the nasal septum and requires immediate drainage.

THE THROAT

Anatomy and physiology

The throat can be considered as the oral cavity, the pharynx and the larynx (Fig. 21.6). The oral cavity extends from the lips to the tonsils. The pharynx can be divided into three areas:

- **The nasopharynx:** extending from the posterior nasal openings to the soft palate
- **The oropharynx:** extending from the soft palate to the tip of the epiglottis
- **The hypopharynx:** extending from the tip of the epiglottis to just below the level of the cricoid cartilage where it is continuous with the oesophagus.

Lying within the hypopharynx is the larynx. This consists of cartilaginous, ligamentous and muscular tissue with the primary function of protecting the distal airway. The pharynx is innervated from the pharyngeal plexus.

In the larynx, there are two vocal cords which abduct (open) during inspiration and adduct (close) to protect the airway and for voice production (phonation). The main nerve supply of the vocal cords comes from the recurrent laryngeal nerves (branches of the vagus nerve) which arise in the neck, but on the left side passes down around the aortic arch and then ascends in the tracheo-oesophageal groove to the larynx.

Normal vocal cords in phonation vibrate between 90 (male) and 180 (female) times per second, giving the voice its pitch or frequency. A healthy voice requires full closure of the vocal cords with a smooth, regular pattern of vibration, and any pathology that prevents full closure will result in air escaping between the vocal cords during phonation and a 'breathy' voice.

Septal haematoma.

CT of the sinuses showing an inverting papilloma (P) obstructing the right nostril and mucosal thickening (M) of the right maxillary sinus.

Examination

Good illumination is essential. Look at teeth, gums, tongue, floor of mouth and oral cavity. Tonsils, soft palate and uvula are easily seen, and a gag reflex (see p. 1080) is present. The remainder of the pharynx and larynx can be inspected with a laryngeal mirror or flexible nasendoscope.

Examination of the neck for lymph nodes and other masses is also performed.

Common disorders

Hoarseness (dysphonia)

There are three essential components for voice production: an air source (the lungs); a vibratory source (the vocal cords); and a resonating chamber (the pharynx, the nasal and oral cavities). Although chest and nasal disorders can affect the voice, the majority of hoarseness is due to laryngeal pathology.

Inflammation which increases the 'mass' of the vocal cords will cause the vocal cord frequency to fall, giving a much deeper voice. Thus listening to a patient's voice can often give a diagnosis before the vocal cords are examined.

Nodules

Nodules (always bilateral and commoner in females) and polyps are found on the free edge of the vocal cord preventing full closure and giving a 'breathy, harsh' voice. They are commonly found in professions that rely on their voice for their livelihood, such as teachers, singers and lawyers. They are usually related to poor technique of voice production and can usually be cured with speech therapy. If surgery is needed, great care must be taken to remain in the superficial layers of the vocal cord in order to prevent deep scarring which leaves the voice permanently hoarse.

Reinke's oedema

This is due to a collection of tissue fluid in the subepithelial layer of the vocal cord. The vocal cord has poor lymphatic drainage, predisposing it to oedema. Reinke's oedema is associated with irritation of the vocal cords with smoking, voice abuse, acid reflux and very rarely hypothyroidism. Treatment is to remove the irritation in most cases but surgery to incise the cords and reduce the oedema will also allow the voice to return to its normal pitch.

Acute-onset hoarseness

Hoarseness, in a smoker, is a danger sign. Any patient with a hoarse voice for over 6 weeks should be seen by an ENT surgeon. Other red flag symptoms are also to be enquired about and will require urgent laryngoscopy (**Emergency Box 21.1**). The voice may be deep, harsh and breathy indicating a mass on the vocal cord or it can be weak suggesting a paralysed left vocal cord secondary to mediastinal disease, e.g. bronchial carcinoma.

Early squamous cell carcinoma of the larynx has a good prognosis. Treatment is with carbon dioxide laser resection or radiotherapy. Spread and growth of the tumour can lead to referred otalgia which if significant in its size requires a laryngectomy (removal of the voicebox) with a neck dissection to remove the affected glands in the neck. A patient with a paralysed left vocal cord must have a CT of the neck and chest. Medialization of the paralysed cord to allow contact with the opposite cord can return the voice and give a

Emergency Box 21.1

Table 21.3 Indications for tracheostomy

Upper airway obstruction (real or anticipated)
Long-term ventilation
Bronchial lavage
Incompetent larynx with aspiration

competent larynx. This can be done under local anaesthesia, giving an immediate result whatever the long-term prognosis of the chest pathology.

Stridor

Stridor or noisy breathing can be divided into:

- **Inspiratory:** obstruction is at the level of the vocal cords or above
- **Mixed** (both inspiratory and expiratory): obstruction is in the subglottis or extrathoracic trachea
- **Expiratory:** obstruction is in the intrathoracic trachea or distal airways.

All people with stridor, both paediatric and adult, are potentially at risk of asphyxiation and should be investigated fully. Severe stridor may be an indication for either intubation or a tracheostomy (**Table 21.3**).

Tracheostomy

Tracheostomy tubes are:

- **Cuffed or uncuffed.** A high-volume, low-pressure cuff is used to prevent aspiration and to allow positive-pressure ventilation.
- **Fenestrated or unfenestrated.** A fenestrated cuff has a small hole on the greater curvature of the tube (both outer and inner) allowing air to escape upwards to the vocal cords and therefore the patient can speak. This tube often has a valve which allows air to enter from the stoma but closes on expiration, directing the air through the fenestration.

Most long-term tracheostomy tubes have an inner and outer tube. The inner tube fits inside the outer tube and projects beyond its lower end. A major problem with a tracheostomy tube is crusting of its distal end with dried secretions, and this arrangement allows the inner tube to be removed, cleaned and replaced as frequently as required, without disrupting the outer tube.

When to decannulate a patient is often a difficult issue if laryngeal competence is unclear. Movement of the vocal cords requires an ENT examination but owing to the risk of aspiration, a speech therapist's opinion can also be useful. The tracheostomy tube itself can also give problems due to compression of the oesophagus with a cuffed tube and by preventing the larynx from rising during normal swallowing.

Carcinoma of the right cord.

Table 21.4 Indications for tonsillectomy

Suspected malignancy
Obstructive sleep apnoea due to tonsillar hypertrophy
Recurrent tonsillitis: five attacks a year for at least 2 years
Quinsy in a patient with a history of recurrent tonsillitis

Tonsillitis and pharyngitis

Viral infections of the throat are common and, although many practitioners are under pressure from the patient to give antibiotics, the vast majority are usually self-limiting, settling with bed rest, analgesia and encouraging fluid intake. Fungal infections, usually candidiasis, are uncommon and may indicate an immunocompromised patient or undiagnosed diabetes.

Tonsillitis

Tonsillitis, with a good history of pyrexia, dysphagia, lymphadenopathy and severe malaise, is usually bacterial with β -haemolytic streptococcus the commonest organism.

Glandular fever (see p. 99)

This can also present with tonsillitis. Although clinically the tonsils have a white exudate, there is often a petechial rash on the soft palate and an accompanying lymphadenopathy.

Quinsy

Quinsy is a collection of pus outside the capsule of the tonsil usually located adjacent to its superior pole. The patient often has trismus making examination difficult but the pus pushes the uvula across the midline to the opposite side. The area is usually hyperaemic and smooth but unilateral tonsil ulceration is more likely to be a malignancy. In either case urgent referral to an ENT specialist is essential.

Indications for a tonsillectomy are shown in Table 21.4. This is carried out under a general anaesthetic and current surgical techniques include diathermy dissection, laser excision and coblation (using an ultrasonic dissecting probe). There are strong advocates for each technique and much will depend on the individual surgeon's preference. Some departments now carry out tonsillectomy as a day case procedure as most reactionary bleeding will occur within the first 8 hours postoperatively.

Snoring

Snoring is due to vibration of soft tissue above the level of the larynx. It is a common condition (50% of 50-year-old males will snore to some extent) and can be considered to be related to obstruction of three potential areas: the nose, the palate or/and the hypopharynx (see Fig. 15.26).

The Epworth questionnaire (see Table 15.11) can assist in the discrimination of sleep apnoea from simple snoring. People with a history of habitual, non-positional, heroic (can be heard through a wall) snoring require a full ENT examination and can be investigated by sleep nasendoscopy in which a sedated, snoring patient has a flexible nasendoscope inserted to identify the source of vibration.

Nasal pathology such as polyps can be removed surgically with good results and most patients will benefit from lifestyle changes such as weight loss. Stiffening or shortening the soft

Figure 21.7 Pharyngeal pouch. (a) Position of pharyngeal pouch. (b) Stapling of the party wall between oesophagus and pouch.

palate via surgery, often using a laser, can help for palatal snorers but hypopharyngeal snorers require either a dental prosthesis at night to hold the mandible forward or continuous positive airway pressure (CPAP) via a mask (see p. 818).

Dysphagia

Difficulty in swallowing is a common symptom but can be the presenting feature of carcinoma of the pharynx and therefore requires investigation. Dysphagia (see p. 237) occurs because of any lesion between the throat and stomach. The two conditions described here are the ones usually dealt with by ENT departments. Gastroenterology departments see causes further down the gullet.

A **pharyngeal pouch** is a herniation of mucosa through the fibres of the inferior pharyngeal constrictor muscle (cricopharyngeus) (Fig. 21.7a). An area of weakness known as Killian's dehiscence allows a pulsion diverticulum to form. This will collect food, which may regurgitate into the mouth or even down to the lungs at night with secondary pneumonia. Diagnosis is made with a barium swallow and treatment is surgical, either via an external approach through the neck where the pouch is excised or more commonly endoscopically with stapling of the party wall (Fig. 21.7b).

Foreign bodies in the pharynx can be divided into three general categories: soft food bolus, coins (smooth), bones (sharp). Soft food bolus can be initially treated conservatively with muscle relaxants for 24 hours. Impacted coins should be removed at the earliest opportunity but sharp objects require emergency removal to avoid perforation of the muscle wall.

If the patient perceives the foreign body to be to one side, then it should be above the cricopharyngeus and an ENT examination will locate it; common areas are the tonsillar fossae, base of tongue, posterior pharyngeal wall and valleculae. Radiology will identify coins, and it can be a clinical decision to see whether a coin will pass down to the stomach, in which case no further treatment is required as it will exit naturally. Some departments advocate the use of a metal detector to monitor the position of the coin in the patient, who is usually a child or has a mental disorder. Fish can be divided into those with a bony skeleton (teleosts) and those with a cartilaginous skeleton (elasmobranchs), and therefore radiology is useful only in some cases. Radiology can also

identify air in the cervical oesophagus indicating a radiolucent foreign body lying distally. A soft tissue lateral neck radiograph is the investigation of choice to delineate some of the features above.

Globus pharyngeus

This is a functional disorder and is not a true dysphagia. It is a condition with classic symptoms of an

intermittent sensation of a lump in the throat. This is perceived to be in the midline at the level of the cricoid cartilage and is worse when swallowing saliva; indeed it often disappears when ingesting food or liquids. ENT examination is clear and normal laryngeal mobility can be felt when gently rocking the larynx across the postcricoid tissues. A contrast swallow will show not only the structures below the pharynx but also assess the swallowing dynamically. Any suspicious area will require an endoscopy with biopsy.

DISORDERS OF THE EYE

Pharyngeal pouch shown on barium swallow.

DISORDERS OF THE EYE

Most of the major and common types of eye disease are covered below. However, diabetic eye disease and hypertensive eye disease are discussed elsewhere.

Applied anatomy and physiology

The average length of the human eye is 24 mm. It is essentially made up of two segments:

- The anterior, smaller segment is transparent and coated by the cornea; its radius is approximately 8 mm
- The larger posterior segment is coated by the opaque sclera and is approximately 12 mm in radius.

It is the cornea and the sclera that give the mechanical strength and shape to the exposed surface of the eye.

The cornea occupies the central aspect of the globe and is one of the most richly innervated tissues in the body. This clear, transparent and avascular structure, measuring 12 mm horizontally and 11 mm vertically, provides 78% of the focusing power of the eye. The eyelids prevent the cornea from drying and becoming an irregular surface by distributing the tear film over the surface of the globe with each blink.

Anatomically the cornea is made up of five layers:

- Epithelium
- Bowman's layer (membrane)
- Stroma
- Descemet's membrane
- Endothelium.

The endothelial cells lining the inner surface of the cornea are responsible for maintaining the clarity of the cornea by continuously pumping fluid out of the tissue. Any factor which alters the function of these cells will result in corneal oedema and cause blurred vision.

The sclera is a white opaque structure covering four-fifths of the globe and is continuous with the cornea at the limbus. The six extraocular muscles responsible for eye movements are attached to the sclera and the optic nerve perforates it posteriorly.

The conjunctiva covers the anterior surface of the sclera. This richly vascularized and innervated mucous membrane stretches from the limbus over the anterior sclera (where it is called the bulbar conjunctiva) and is then reflected onto the undersurface of the upper and lower lids (the tarsal conjunctiva). The area of conjunctival reflection under the lids makes up the upper and lower fornix.

The anterior chamber is the space between the cornea and the iris, and is filled with aqueous humour (Fig. 21.8). This fluid is produced by the ciliary body (2 μ L/min) and provides nutrients and oxygen to the avascular cornea. The

outflow of aqueous humour is through the trabecular meshwork and canal of Schlemm adjacent to the limbus. Any factor which impedes its outflow will increase the intraocular pressure. The upper range of normal for intraocular pressure is 21 mmHg.

The uveal tract is made up of the iris anteriorly, the ciliary body and the choroid.

The *iris* is the coloured part of the eye under the transparent cornea. The muscles of the iris diaphragm regulate the size of the pupil, thereby controlling the amount of light entering the eye. The muscles of the *ciliary* body control the accommodation of the lens and the secretory epithelium produces the aqueous humour (see above). The highly vascular *choroid* lines the inner aspect of the sclera and upon this lies the retina.

The lens lies immediately posterior to the pupil and anterior to the vitreous humour. It is a transparent biconvex structure and is responsible for 22% of the refractive power of the eye. By changing its shape it can alter its refractive power and help to focus objects at different distances from the eye. By the fourth decade of life this ability to change shape starts to decline and with time the lens starts to become less transparent and cataracts begin to develop.

The vitreous humour fills the cavity between the retina and the lens.

The retina is a multi-layered structure. The metabolically active region of the retina is represented in Figure 21.9. There are two types of photoreceptors in the retina, rods and cones. There are approximately 6 million cones mainly confined to the *macula* and these are responsible for detailed central vision and colour vision. The peripheral retina has around 125 million rods that are responsible for peripheral vision. The axons of the ganglion cells form the optic nerve (or disc) of the eye (Fig. 21.10).

The blood supply to the eye is via the ophthalmic artery and, in particular, the central retinal artery is responsible for supplying the inner retinal layers. Venous return is through the central retinal and ophthalmic veins. Local lymphatic drainage is to the preauricular and submental nodes.

The sensory innervation of the eye is through the trigeminal (V) nerve. The six extraocular muscles are supplied by different nerves.

- Oculomotor (III) nerve: medial, superior, inferior rectus and inferior oblique
- Trochlear (IV) nerve: superior oblique
- Abducens (VI) nerve: lateral rectus.

The oculomotor (III) nerve also supplies the upper lid and indirectly the pupil (parasympathetic fibres are attached to it). The facial (VII) nerve supplies the orbicularis and other muscles of facial expression.

Figure 21.9 Schematic diagram of the retina.

Figure 21.10 Fundus of the left eye.

History and examination

A careful and detailed history gives most of the facts needed to make a working diagnosis. The eye has limited mechanisms by which it can convey a diseased state. Common symptoms include alteration in visual acuity, redness, pain, discharge and photophobia.

It is essential to adopt a systematic approach to the examination of the eye. Different approaches and instruments are necessary for examination of the lids, anterior and posterior segments as well as extraocular movements. It is vital that an accurate visual acuity is recorded in all people with an eye problem. The Snellen eye chart is the most commonly used, but use of the LogMAR chart (logarithm of the Minimum Angle of Resolution) is increasing, largely due to its necessity in studies or research. Unlike the Snellen and other visual acuity charts, the LogMAR chart has equal graduation between the letters on a line as well as the space between lines. There is also a fixed number of letters, five, on each line. Research done using a logarithmic progression in size of letters on a test chart gives most accurate visual acuity measurement.

Visual acuity

The visual acuity of each eye is recorded in two ways: distance visual acuity and near visual acuity. Distance vision is measured in Snellen letters or, even more commonly, in LogMAR letters or figures of different sizes, constructed to subtend 5' (5 min) of arc at the nodal point to give a value of visual acuity. The recording is given as an expression of the line of letters which can be discerned at a particular distance, usually 6 metres (or 20 feet). For example 6/60, where 6 equals the distance of the chart from the eye in metres and 60 equals the distance at which the letter subtends 5' at the nodal point.

Refractive errors

The eye projects a sharp and focused image onto the retina. Refractive errors refer to any abnormality in the focusing mechanism of the eye and not to any opacity in the system such as a corneal or retinal scar.

The refraction of light in emmetropic (normal), myopic (short-sighted, negative lenses will correct) and hypermetropic (long-sighted, positive lenses will correct) eyes is shown in Figure 21.11.

Figure 21.11 Refraction. (a) Emmetropic (normal). (b) Myopic (short-sighted). (c) Hypermetropic (long-sighted).

Astigmatism is a refractive error of the eye in which there is a different degree of refraction in the different meridians of curvature. It may be myopic in one plane and hypermetropic or emmetropic in the other plane. In this situation the front surface of the eye is more rugby ball shaped than football shaped.

Presbyopia is the term used to describe the normal ageing of the lens and leads to a change in the refractive state of the eye. As the lens ages it becomes less able to alter its curvature and this causes difficulty with near vision, especially reading.

Treatment

Errors of refraction can be corrected by using spectacles or contact lenses. The latter often results in better quality vision, but carries the risk of infection. They may be the only option in some refractive states such as keratoconus, a degenerative disorder of the eye in which structural changes within the cornea cause it to thin and become a more conical shape than its normal gradual curve. A number of surgical techniques can correct these errors of refraction, with varying degrees of accuracy. The most popular method is to use an excimer laser to re-profile the corneal curvature (PRK, LASIK, LASEK). The laser either removes corneal tissue centrally to flatten the cornea in myopia or it removes tissue from the peripheral cornea to steepen it in hypermetropia.

Disorders of the lids

The lids afford protection to the eyes and help to distribute the tear film over the front surface of the globe. Excess tears are drained via the punctae and lacrimal system to the nose (Fig. 21.12). Malposition of the lids, factors which affect blinking or lacrimal drainage, can all cause problems.

Entropion. The lid margin rolls inwards so that the lashes are against the globe (Fig. 21.13a). The lashes act as a foreign body and cause irritation, leading to a red eye which can mimic conjunctivitis. Occasionally the constant rubbing of lashes against the cornea causes an abrasion. The commonest cause is ageing and surgery is usually required.

Figure 21.12 Photograph of the right eye.

Ectropion. The lid margin rolls outwards and is not apposed to the globe. As a result the lacrimal puncta is not in the correct anatomical position to drain tears and patients usually complain of a watery eye. Underlying factors include age, VII nerve palsy and cicatricial skin conditions. Surgery is usually required.

Dacryocystitis. Patients who have inflammation of the lacrimal sac usually present with a painful lump at the side of the nose adjacent to the lower lid (Fig. 21.13b). This should be treated with oral broad-spectrum antibiotics such as cefalexin, and patients should be watched carefully for signs of cellulitis. All patients should be referred to the ophthalmologist as some have an underlying mucocele or dilated sac, and will require surgery.

Blepharitis. This is an extremely common condition where inflammation of the lid margins may involve the lashes and lash follicles (Fig. 21.14a) resulting in styes, or inflammation and blockage of meibomian glands (Fig. 21.14b) leading to chalazion (Fig. 21.14c). Common underlying causes of blepharitis include meibomian gland dysfunction, seborrhoea and *Staphylococcus aureus* infection. Patients can be asymptomatic or complain of itchy, burning eyes because of tear film instability resulting from meibomian gland dysfunction. *Staphylococcus aureus* is frequently responsible for chronic blepharo-conjunctivitis and some patients may develop keratitis in the cornea (Fig. 21.15).

Treatment of blepharitis. Lid hygiene is the mainstay of treatment as it helps to reduce the bacterial load and unblock meibomian glands. A short course of topical chloramphenicol or fusidic acid is useful in chronic cases but in severe cases or cases where acne rosacea is suspected, oral doxycycline may be required. Some patients are left with a lump once the acute inflammatory phase has subsided. Most of these patients find the lump, or chalazion, cosmetically unacceptable and require incision and curettage. People with keratitis should be referred to the ophthalmologist for topical steroids.

Conjunctivitis

The commonest cause of a red eye, inflammation of the conjunctiva can arise from a number of causes, with viral, bacterial and allergic being the commonest. Common features in all types include soreness, redness and discharge, and in general the visual acuity is good. History should include the speed of onset of the inflammation, the colour and consistency of the discharge, whether the eye is itchy, and if there has been a recent history of a cold or sore throat. In the neonate it is vital to exclude gonococcal or chlamydial conjunctivitis associated with maternal sexually transmitted infection. The differential diagnosis of conjunctivitis is shown in Table 21.5.

Figure 21.13 Disorders of the eyelid. (a) Lid entropion. The lower lid appears inverted. (b) Acute dacryocystitis showing a lump on the side of the nose.

Bacterial conjunctivitis

Bacterial conjunctivitis is uncommon, making up 5% of all cases of conjunctivitis. In the vast majority of patients it causes a sore or gritty eye in the presence of good vision. Bacterial conjunctivitis is invariably bilateral and should be suspected when conjunctival inflammation is associated with a purulent discharge.

Clinical features

Gonococcal conjunctivitis should be suspected when the onset of symptoms is rapid, the discharge is copious, and ocular inflammation includes chemosis (conjunctival oedema) and lid oedema. Gonococci are a cause of conjunctivitis giving rise to a palpable preauricular node. Less acute or subacute purulent conjunctivitis with moderate discharge can be attributed to organisms such as *Haemophilus influenzae* and *Streptococcus pneumoniae*. Chronic conjunctivitis is usually associated with mild conjunctival injection and scant purulent discharge. Common organisms include *Staphylococcus aureus* and *Moraxella lacunata*.

Treatment

Prompt treatment with oral and topical penicillin is given in gonococcal conjunctivitis to ensure a reduced rate of corneal perforation. A Gram-stain of the conjunctival swab can quickly confirm the presence of diplococci. Gonococcal conjunctivitis is a notifiable disease in the UK. Empirical treatment for both subacute and chronic conjunctivitis involves a topical broad-spectrum antibiotic such as chloramphenicol.

Swabs should be taken if these cases do not respond to this initial treatment. Antibiotic resistance is increasing.

Chlamydial conjunctivitis

Chlamydia trachomatis (see p. 164) is seen in developed countries as a sexually transmitted infection that is most prevalent in sexually active adolescents and young adults. Direct or indirect contact with genital secretions is the usual route of infections but shared eye cosmetics can also be involved. Neonatal chlamydial conjunctivitis is a notifiable disease in the UK and should be suspected in newborns with a red eye. Mothers should be asked about sexually transmitted infections.

Trachoma caused by the same organism, but not usually sexually transmitted, is found mainly in the tropics and the Middle East and is a very common cause of blindness in the world (see p. 133). Chronic conjunctival inflammation causes progressive scarring, trichiasis, entropion and subsequent corneal scarring which leads to severe visual impairment or blindness from corneal opacification or ulceration.

Clinical features

The onset of symptoms is slow, and patients may complain of mild discomfort for weeks. In these cases the red eye is associated with a scanty mucopurulent discharge and a palpable preauricular lymph node. In chronic cases it is not unusual to see superior corneal vascularization. In neonates the onset of the red eye is typically around 2 weeks after birth, whereas gonococcal conjunctivitis occurs within days of birth. Conjunctival swabs should be taken and a nucleic acid amplification test (NAAT) performed (p. 163) prior to commencement of treatment.

Treatment

Topical erythromycin twice daily is commenced and patients referred to the genitourinary physician. Neonates should be started on topical erythromycin and referred to the paediatrician as there may be associated otitis media or pneumonitis.

Viral conjunctivitis

Adenoviral conjunctivitis

This is highly contagious and can cause epidemics in communities. Transmission is through direct or indirect contact with infected individuals. The onset of symptoms may be preceded by a cold or flu-like symptoms. Inflammation is commonly associated with chemosis, lid oedema and a palpable preauricular lymph node. Some patients develop a membrane on the tarsal conjunctiva (Fig. 21.16) and haemorrhage on the bulbar conjunctiva. Viral conjunctivitis can cause deterioration in visual acuity owing to corneal involvement (focal areas of inflammation). In 50% of the patients the conjunctivitis is unilateral.

Treatment

The condition is largely self-limiting in the majority of cases. Lubricants together with a cold compress can be soothing for patients. Strict hygiene and keeping towels separate from the rest of the household goes a long way towards reducing the spread of the infection. In people with corneal involvement or intense conjunctival inflammation, topical steroids are indicated.

Herpes simplex conjunctivitis

Primary ocular herpes simplex conjunctivitis is typically unilateral. It usually causes a palpable preauricular lymph node and cutaneous vesicles develop on the eyelids and the skin around the eyes in the majority of patients. Over 50% of these patients develop a dendritic corneal ulcer (Fig. 21.17). The organism responsible for this condition is the herpes simplex virus (HSV), which is usually HSV-1 but HSV-2 can give rise to ocular infection.

Treatment

Primary ocular HSV infection is self-limiting but most clinicians choose to treat it with topical aciclovir in order to limit the risk of corneal epithelial involvement.

Figure 21.16 (a,b) Viral conjunctivitis; (b) with pseudomembrane on lower lid.

Figure 21.17 Dendritic ulcers on the cornea. (a) Stained with fluorescein. (b) Stained with fluorescein and viewed with blue light.

Molluscum contagiosum conjunctivitis

This is typically unilateral and produces a red eye that generally goes unrecognized and comes to the forefront because patients fail to improve and the cornea starts to become involved. On close inspection, pearly umbilicated nodules, filled with the DNA poxvirus, can be seen on the lid margin.

Treatment

This includes curetting the central portion of the lesion, freezing the centre or completely excising the lesion. If the corneal involvement is severe or the eye is very inflamed, a short course of topical steroids such as prednisolone 0.5% or dexamethasone 0.1% is helpful.

Phthiriasis palpebrarum

Phthiriasis palpebrarum is an eyelid infestation caused by *Phthirus pubis*, or crab lice. Infestation of the cilia and eyelid is rare. It leads to blepharitis with marked conjunctival inflammation, preauricular lymphadenopathy, and rarely secondary infection at the site of lice bite.

Treatment

Mechanical removal of the lice with fine forceps, physostigmine 1.25% and pilocarpine gel 4% are all effective treatments.

Allergic conjunctivitis

There are five main types of allergic conjunctivitis: seasonal, perennial, vernal, atopic and giant papillary. Both seasonal and perennial allergic conjunctivitis are acute allergic conjunctival disorders. Symptoms include itching and pink to reddish eyes. These two eye conditions are mediated by mast cells and can be easily treated with cold compresses, eyewashes with tear substitutes, and avoidance of allergens. The last three are difficult to treat, chronic and can be sight-threatening. They should be referred to an ophthalmologist.

Seasonal/perennial conjunctivitis

Seasonal allergic conjunctivitis and perennial conjunctivitis, affecting 20% of the general population in the UK, is an allergic reaction to grass, pollen and fungal spores and occurs mainly in spring and summer. Perennial allergic conjunctivitis occurs all year round but peaks in the autumn and includes allergens such as house-dust mites.

The main symptoms include itching, redness, soreness, watering and a stringy discharge. Occasionally the conjunctiva may become so hyperaemic that chemosis results. This is usually associated with swollen lids.

Treatment

Reducing the allergen load (reducing dust, p. 825) is helpful. Medical treatment includes the use of antihistamine drops such as azelastine and emedastine together with topical mast cell-stabilizing agents such as sodium cromoglicate and nedocromil. Olopatadine (twice daily) has dual action and is very effective. Corticosteroid drops should be avoided. Oral antihistamines help the itching.

Corneal disorders

Trauma

Corneal abrasions

Trauma resulting in the removal of a focal area of epithelium on the cornea is very common. Abrasions usually occur

Phthiriasis palpebrarum. The lice (L) and the nits (eggs) can be seen on the lid margins (E, empty egg).

Figure 21.18 Linear corneal abrasion. (a) Stained with fluorescein. (b) Stained with fluorescein and viewed with blue light.

Figure 21.19 Foreign bodies. (a) Corneal. (b) Subtarsal.

when the eye is accidentally poked with a finger, a foreign body (FB) flies into the eye or something brushes against the eye.

Clinical features

Symptoms include severe pain, due to exposure of the corneal nerve endings, lacrimation and inability to open the eye (blepharospasm). Blinking and eye movement can aggravate the pain and foreign body sensation. The visual acuity is usually reduced. Most cases will need topical anaesthetic drops such as oxybuprocaine or tetracaine to be administered before it is possible to examine the eye. The cornea should be inspected with a blue light after instillation of fluorescein drops. The orange dye will stain the area of the abrasion. Under blue light the abrasion lights up as green. Occasionally FBs can lodge on the undersurface of the upper lid and give rise to linear vertical abrasions. Eversion of the upper lid is necessary in all cases of abrasions (Fig. 21.18).

Treatment

Treatment consists of a broad-spectrum topical antibiotic such as chloramphenicol drops or ointment four times a day for 5 days. The role of padding is controversial but common practice is to pad the affected eye for 24 hours once chloramphenicol ointment has been applied to the eye.

Corneal foreign body

Occasionally when something flies into the eye it gets stuck on the cornea (Fig. 21.19a). It may be associated with lacrimation and photophobia. Examination is best attempted following instillation of a topical anaesthetic and should include everting the upper lid (Fig. 21.19b). Corneal foreign bodies can usually be seen directly with a white light.

Treatment

The corneal FB should be removed and the patient given a topical antibiotic such as chloramphenicol four times a day for 5 days or fusidic acid twice a day for 5 days.

Figure 21.20 Blunt trauma. Hyphaema and globe rupture with iris prolapse.

High-velocity trauma

In cases of high-velocity trauma corneal perforation or intraocular FB should be suspected. Examination may show a corneal laceration with or without the FB embedded in the cornea. The FB may be present on the iris or in the lens or vitreous. Other clues of a penetrating injury include a large subconjunctival haemorrhage, a flat anterior chamber with low intraocular pressure, or the presence of blood in the anterior chamber (hyphaema). Urgent referral to the ophthalmologist is mandatory, ensuring that no drops are instilled into the eye and that a plastic shield has been placed over the eye to minimize further risk of trauma.

Blunt trauma usually results in periorbital bruising and gross lid oedema, which can make examination to exclude perforating injury difficult. These patients should be referred to the ophthalmologist for a detailed ocular examination to exclude a perforation, retinal detachment or a traumatic hyphaema (Fig. 21.20).

Keratitis

This is a general term to describe corneal inflammation. Common causes include herpes simplex virus, contact lens-associated infection and blepharitis. Symptoms include the sensation of a foreign body or pain (depending on the size and depth of the ulcer), photophobia and lacrimation. Vision is reduced if the ulcer affects the visual axis.

Herpes simplex keratitis

Corneal epithelial cells infected with the virus eventually undergo lysis and form an ulcer which is typically dendritic in shape (Fig. 21.17). The ulcer stains with fluorescein and can be observed easily with a blue light. Topical immunosuppression, e.g. steroid drops, or systemic immunosuppression, e.g. AIDS, can lead to the centrifugal spread of the virus such that the ulcer increases in area and is referred to as a geographic ulcer. Recurrent attacks of HSV keratitis can be triggered by ultraviolet light, stress and menstruation. All these factors are responsible for activating the virus, which normally lies dormant in the ganglion of the Vth nerve.

Treatment

Aciclovir ointment five times a day for 2 weeks is usually very effective.

Contact lens-related keratitis

A small number of contact lens wearers develop infective corneal ulcers which are potentially sight-threatening (Fig. 21.21). The organisms usually responsible include Gram-positive and Gram-negative bacteria. Patients should be referred to an ophthalmologist for scraping of the ulcer and commencement of antibiotic treatment.

Corneal dystrophy

Fuchs' corneal dystrophy is a genetically associated degenerative disorder leading to corneal oedema and vision loss.

Figure 21.21 Contact lens-related keratitis. (a) Corneal ulcer. (b) Severe keratitis with a corneal abscess and a hypopyon.

Figure 21.22 Cataracts. (a) Early cataract. (b) White mature cataract. (c) Artificial intraocular lens following phacoemulsification.

The gene is *TCF4*. It affects both eyes, is commoner in females, and is of gradual onset leading to blindness in the 40–60 age group. There is an accumulation of deposits (guttæ) in the cornea with thickening of Descemet's membrane. Treatment is by corneal transplantation.

Cataracts

Cataract (Fig. 21.22a,b) is by far the commonest cause of preventable blindness in the world with an effective surgical treatment. In the UK, approximately 250 000 cataract operations are performed each year, making it the commonest surgical procedure.

Aetiology

Age-related opacification of the lens (cataract) is the commonest cause of visual impairment with 30% of people over 65 years having visual acuities below that required for driving (Snellen acuity less than 6/12). The common causes of cataracts are summarized in Table 21.6.

In young patients, familial or congenital causes should be excluded. Any history of ocular inflammation is noted. Cataracts diagnosed in infants demand urgent referral to the ophthalmologist in order to minimize the subsequent development of amblyopia.

Clinical features

Gradual painless deterioration of vision is the commonest symptom. Other symptoms are dependent upon the type of cataract, for example a posterior capsular type would lead

Figure 21.23 (a) Normal optic disc and (b) glaucomatous optic disc. The central cup is enlarged and deepened.

Table 21.6 Cataracts: aetiology

Congenital	Maternal infection Familial
Age	Elderly

Traumatic	Post-intraocular surgery
Inflammatory	Uveitis
Disease associated	Down's syndrome Dystrophia myotonica Lowe's syndrome

to glare and problems with night driving. Early changes in the lens are correctable by spectacles but eventually the opacification needs surgical intervention.

Investigations

Blood glucose, serum calcium and liver biochemistry should be measured to diagnose metabolic disorders.

Treatment

Small incision extracapsular or phacoemulsification cataract extraction with the insertion of an intraocular lens is the treatment of choice (Fig. 21.22c).

Glaucoma

This is a group of diseases in which the pressure inside the eye is sufficiently elevated to cause optic nerve damage and result in visual field defects (Fig. 21.23). Normal intraocular pressure (IOP) is 10–21 mmHg. Some types of glaucoma can result in an IOP exceeding 70 mmHg. Glaucoma is the second commonest cause of blindness worldwide and the third commonest cause of blind registration in the UK.

Primary open-angle glaucoma (POAG)

This is the commonest form of glaucoma. High intraocular pressures result from reduced outflow of aqueous humour through the trabecular meshwork. Common risk factors include age (0.02% of 40-year-olds versus 10% of 80-year-olds), race (black Africans are at five times greater risk than whites), positive family history and myopia.

POAG causes a gradual, insidious, painless loss of peripheral visual field. It is initially asymptomatic and the central vision remains good until the end-stage of the disease. Usually glaucoma is identified during a routine ophthalmic

Quigley MA. Glaucoma. *Lancet* 2011; 377: 1367–1377.

examination. Diagnosis is only made if the IOP is measured. The optic disc is inspected and shows an enlarged cup with a thin neuroretinal rim. Visual fields are performed and show a normal blind spot with scotomas.

Treatment

Treatment aims to reduce the IOP, either by reducing aqueous production or by increasing aqueous drainage:

- Beta-blockers such as timolol, carteolol and levobunolol reduce aqueous production and are the commonest prescribed topical agents. These drugs are contraindicated in people with chronic obstructive pulmonary disease, asthma or heart block.
- Prostaglandin analogues such as latanoprost and travoprost, increase aqueous outflow and are also used (alone or in combination with beta-blockers) for POAG as they can reduce IOP by 30%.
- Carbonic anhydrase inhibitors such as acetazolamide reduce aqueous production and are available in both topical and oral form. In its oral form acetazolamide is the most potent drug for reducing ocular pressure. It should not be used in patients who have a sulphonamide allergy.

Acute angle-closure glaucoma (AACG)

This is an ophthalmic emergency. There is a sudden rise in intraocular pressure to levels greater than 50 mmHg. This occurs due to reduced aqueous drainage as a result of the ageing lens pushing the iris forward against the trabecular meshwork. People most at risk of developing AACG are those with shallow anterior chambers such as hypermetropes and women. The attack is more likely to occur under reduced light conditions when the pupil is dilated.

Red eye and other signs and symptoms

AACG causes sudden onset of a red painful eye and blurred vision. Patients become unwell with nausea and vomiting and complain of headache and severe ocular pain. The eye is injected, tender and feels hard. The cornea is hazy and the pupil is semi-dilated (Fig. 21.24). Table 21.7 shows the

Figure 21.24 Acute angle-closure glaucoma.

differential diagnosis of the acute red eye. Emergency Box 21.2 shows features that require urgent referral to an ophthalmologist.

Treatment

Prompt treatment is required to preserve sight and includes:

- Intravenous acetazolamide 500 mg (provided there are no contraindications) to reduce IOP, and
- Instillation of pilocarpine 4% drops to constrict the pupil to improve aqueous outflow and prevent iris adhesion to the trabecular meshwork.

Other topical drops such as beta-blockers and prostaglandin analogues can also be instilled if available, provided there are no contraindications. Analgesia and antiemetics are given as required.

Patients must be referred to an ophthalmologist immediately so that reduction in IOP can be monitored and other agents such as oral glycerol or i.v. mannitol can be administered to non-responding patients. Definitive treatment involves making a hole in the periphery of the iris of both eyes either by laser or surgically.

Uveitis

Uveitis is inflammation of the uveal tract, which includes the iris, ciliary body and choroid. Inflammation confined to the anterior segment of the eye (in front of the iris) is referred to as iritis or anterior uveitis, that involving the ciliary body is referred to as intermediate uveitis whilst inflammation of the choroid is termed posterior uveitis. If all three regions are involved then the term panuveitis is used. For posterior uveitis, referral to an ophthalmologist is required.

The most common symptoms of uveitis are blurred vision, pain, redness, photophobia and floaters. Each symptom is

Emergency Box 21.2**Red Flags for a red eye**

The following symptoms require urgent referral:

- Severe pain
- Photophobia
- Reduced vision, particularly if sudden
- Coloured halos around point of light in a patient's vision
- Proptosis
- Smaller pupil in affected eye

+

On medical assessment:

- High intraocular pressure
- Corneal epithelial disruption
- Shallow anterior chamber depth
- Ciliary flush

Table 21.7 Differential diagnosis of the acute red eye

Cause	Conjunctival injection	Unilateral or bilateral	Pain	Photophobia	Vision	Pupil	Intraocular pressure
Conjunctivitis	Diffuse	Bilateral (often unilateral initially)	Gritty	Occasionally with adenovirus	Normal	Normal	Normal
Keratitis	Diffuse	Unilateral	Gritty	Yes	Reduced	Normal	Normal
Anterior uveitis	Circumcorneal	Unilateral	Painful	Yes	Reduced	Constricted	Normal or raised
Acute glaucoma	Diffuse	Unilateral	Severe pain	Mild	Reduced	Mid-dilated	Raised

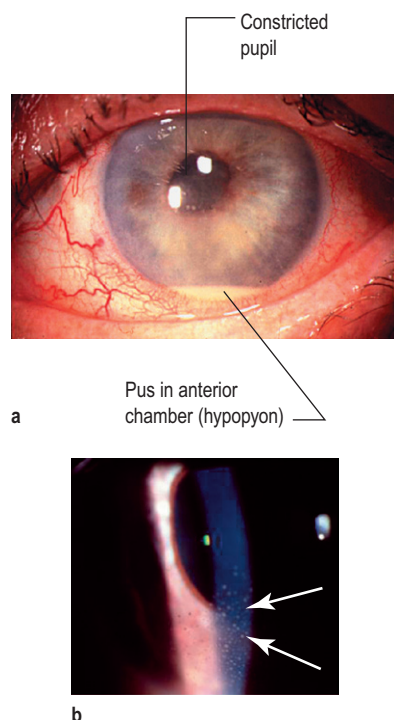

Figure 21.25 Anterior uveitis. (a) Acute with hypopyon. **(b)** Showing keratic precipitates on the corneal endothelium.

determined by the location of the inflammation such that photophobia and pain are common features of iritis whilst floaters are commonly seen with posterior uveitis.

Uveitis is commonly encountered with ankylosing spondylitis and positive HLA-B27 (see p. 527), arthritis, inflammatory bowel disease, sarcoid, tuberculosis, syphilis, toxoplasmosis, Behçet's syndrome, lymphoma and viruses such as herpes, cytomegalovirus and HIV infection. In a number of patients no cause is found (idiopathic uveitis).

Anterior uveitis (iritis)

The classic presentation entails a triad of eye symptoms: redness, pain and photophobia. Vision can be normal or blurred depending on the degree of inflammation. The eye can be generally red or the injection can be localized to the limbus. The anterior chamber shows features consistent with inflammation including cells, keratic precipitates (KP) on the corneal endothelium, fibrin or hypopyon (pus), and the pupil may have adhered to the lens (posterior synechiae) (Fig. 21.25). The IOP may be normal or raised either due to cells clogging up the trabecular meshwork or posterior synechiae causing aqueous to build up behind the iris and force the iris against the trabecular meshwork and so reduce aqueous drainage.

Treatment

This consists of reducing inflammation with the use of topical steroids such as dexamethasone 0.1% and dilating the pupil with cyclopentolate 1% to prevent formation of posterior synechiae. Dilatation also allows fundoscopy to exclude posterior segment involvement. If the IOP is raised, this is treated with topical beta-blockers, prostaglandin analogues, or oral or i.v. acetazolamide. Referral should be made to the ophthalmologist.

Figure 21.26 Central retinal vein occlusion.

Figure 21.27 Central retinal artery occlusion.

Disorders of the retina

Central retinal vein occlusion (CRVO)

This usually leads to profound sudden painless loss of vision with thrombosis of the central retinal vein at or posterior to the lamina cribrosa where the optic nerve exits the globe. The thrombus causes obstruction to the outflow of blood leading to a rise in intravascular pressure. This results in dilated veins, retinal haemorrhage, cotton wool spots, and abnormal leakage of fluid from vessels resulting in retinal oedema (Fig. 21.26). In severe cases, an afferent papillary defect is present and this suggests the ischaemic variant.

Predisposing factors include increasing age, hypertension and cardiovascular disease, diabetes, glaucoma, and in the younger age group, blood dyscrasias and vasculitis.

Treatment

Treatment of any underlying medical condition is mandatory. Referral to an ophthalmologist is essential to monitor the eye, as some patients can develop retinal ischaemia with resulting neovascularization of the retina and iris. Panretinal photocoagulation should be commenced if there is neovascularization, and intravitreal steroid or anti-vascular endothelial growth factor (anti-VEGF) therapy is also used if there is macular oedema. Patients who develop iris neovascularization, rubeosis, are at risk of developing rubeotic glaucoma.

Central retinal artery occlusion (CRAO)

This results in sudden painless severe loss of vision. Retinal arterial occlusion results in infarction of the inner two-thirds of the retina. The arteries become narrow and the retina becomes opaque and oedematous. A cherry red spot is seen at the fovea because the choroidal vasculature shows up through the thinnest part of the retina (Fig. 21.27). An afferent papillary defect is usually present.

Arteriosclerosis-related thrombosis is the most common cause of CRAO. Emboli from atheromas and diseased heart valves are other causes. Giant cell arteritis (see p. 543) must be excluded.

Treatment

CRAO is an ophthalmic emergency since studies have shown that irreversible retinal damage occurs after 90 minutes of onset. Ocular massage and 500 mg i.v. acetazolamide help to reduce ocular pressure and may help in dislodging the emboli. Breathing into a paper bag allows a build-up of carbon dioxide which acts as a vasodilator and so helps

in dislodging the emboli. Other options include making a corneal paracentesis to drain off some aqueous humour, thereby reducing the intraocular pressure.

People with CRAO should have a thorough medical evaluation to determine the aetiology of the emboli or thrombus. Some patients may present with transient loss of vision or amaurosis fugax (see p. 1098). All people with CRAO and amaurosis fugax should be started on oral aspirin if it is not medically contraindicated.

Retinal detachment

This causes a painless progressive visual field loss. The shadow corresponds to the area of detached retina. If the detachment affects the macula, central vision will be lost. Following a tear in the retina, fluid collects in the potential space between the sensory retina and the pigment epithelium (Fig. 21.28). Patients usually report a sudden onset of floaters often associated with flashes of light (photopsia) prior to the detachment. These patients should be referred to an ophthalmologist for a detailed fundal examination.

Retinitis pigmentosa

This is a common chronic inherited degenerative disease of the retina which can be primary or part of a syndrome and leads to blindness. There is constriction of the peripheral vision leading to tunnel vision and progressive loss of night vision.

Ophthalmoscopy shows bone spicule deposits and attenuated retinal vessels. Several genes are implicated.

There is no treatment but high-dose vitamin A supplementation may slow progression. Gene therapy is being investigated.

Age-related macular degeneration (AMD)

This is the commonest cause of visual impairment in patients over 50 years in the western world, and blind registration in this age group. It affects 10% of people over 65 years and

30% over 80 years. Mutations in various genes have been reported; fibulin 5, complement factor H, Arg 80 Gly variant of complement C3.

The cause is unknown but suggested risk factors include increasing age, smoking, hypertension, hypercholesterolaemia and ultraviolet exposure.

There are two types:

- **Non-exudative (dry) macular degeneration** describes a painless and progressive loss of central vision. With age, lipofuscin deposits (drusen) are found between the retinal pigment epithelium (RPE) and Bruch's membrane (see Fig. 21.9 and Fig. 21.29a). Drusen may be hard or soft and there may be focal RPE detachment. Not all people with these changes will be affected visually but some develop distortion and blurring of their central vision. Extensive atrophy of RPE can occur (geographic atrophy).
- **Exudative (wet) AMD** (10% of cases) occurs with the development of abnormal subfoveal choroidal neovascularization in the region of the macula and causes severe central visual loss (Fig. 21.29b).

Treatment

The Age-Related Eye Disease Study (AREDS) has shown that vitamins C and E, β -carotene, zinc and copper slow progression of the disease. People with central distortion or with frank macular pathology should be referred urgently to the ophthalmologist for assessment of treatment.

Antivascular endothelial growth factors (anti-VEGF), such as ranibizumab and bevacizumab, are given by intravitreal injections with great success, although the latter is more expensive. The treatment course should be commenced as a matter of urgency as vision is maintained in up to 95% of patients and improves in approximately a third. Monthly monitoring with optical coherence tomography (OCT) is recommended (Fig. 21.30). Laser treatment and photodynamic therapy with verteporfin were the treatment of choice in the past for the treatment of wet AMD, but now have limited roles.

Emergency Box 21.3

The initial history and examination in the patient presenting with sudden loss of vision

RAPD, relative afferent papillary defect. (After: Pane A, Simcock P. Practical Ophthalmology. Edinburgh: Elsevier Churchill Livingstone; 2005.)

Box 21.3 Loss of vision: summary

Painless loss of vision	Painful loss of vision
Cataract	Acute angle-closure glaucoma
Open-angle glaucoma	Giant cell arteritis
Retinal detachment	Optic neuritis
Central retinal vein occlusion	Uveitis
Central retinal artery occlusion	Scleritis
Diabetic retinopathy	Keratitis
Vitreous haemorrhage	Shingles
Posterior uveitis	Orbital cellulitis
Age-related macular degeneration	Trauma
Optic nerve compression	
Cerebral vascular disease	

Severe visual loss is possible and low-vision aids, such as magnifying glasses, may help to improve a patient's independence.

Visual loss

Every patient with unexplained sudden visual loss requires ophthalmic referral. The initial history and examination are summarized in Emergency Box 21.3.

The common causes of blindness are similar across the world (Box 21.3). In developing countries, trachoma due to *Chlamydia trachomatis* (see p. 164) is also a major cause, accounting for 10% of global blindness, as is onchocerciasis (river blindness, due to *Onchocerca volvulus* – see p. 154), which accounts for blindness in about 1 million people, although this is decreasing with treatment. In leprosy, 70% of patients have ocular involvement, and blindness occurs in 5–10% of these. Ocular involvement is common in cerebral malaria (see p. 144), although loss of vision is rare.

HIV infection can produce uveitis but the major problem is severe opportunistic infection of the eye when the CD4 count falls (see p. 178) and HAART is not available.

Vitamin A deficiency and xerophthalmia affects millions each year; the WHO classification of xerophthalmia by ocular signs is shown in Table 5.10 (see p. 206).

WHO lists the commonest causes of blindness across the world as cataract, glaucoma, acute macular degeneration, corneal opacity, diabetic retinopathy and infections from bacteria or parasites.

THE IMPACT OF NEUROLOGICAL DISEASE

Neurology is a large and diverse subject which covers many conditions that require long-term coordinated care and have serious effects on the daily lives of patients and their families.

Neurology includes conditions as diverse as cognitive disorders involving higher level mental functioning through to disorders of peripheral nerve and skeletal muscle. It is a specialty requiring good clinical skills and examination technique which cannot be replaced with investigations or imaging techniques alone (Table 22.1).

**Box 22.1 Common gait abnormalities**

- Spasticity/hemiparesis
- Parkinson's disease
- Cerebellar ataxia
- Position sense loss (stamping)
- Distal weakness (slapping)
- Proximal weakness (waddling)
- Apraxia of gait

COMMON SYMPTOMS AND SIGNS

Pattern recognition in neurology – interpretation of history, symptoms and examination – is very reliable. Practical experience is vital. There are three critical questions in formulating a clinical diagnosis:

- What is/are the site(s) of the lesion(s)?
- What is the likely pathology?
- Does a recognizable disease fit this pattern?

Difficulty walking and falls

Change in walking pattern is a common complaint (Box 22.1). Arthritis and muscle pain make walking painful and slow (antalgic gait). The *pattern* of gait is valuable diagnostically.

Spasticity and hemiparesis

Spasticity (p. 1082), more pronounced in extensor muscles, with or without weakness, causes stiff and jerky walking. Toes of shoes become scuffed, catching level ground. Pace shortens; a narrow base is maintained. Clonus – involuntary extensor rhythmic leg jerking – may occur.

In a hemiparesis when spasticity is unilateral and weakness marked, the stiff, weak leg is circumducted and drags.

Parkinson's disease: shuffling gait

There is muscular rigidity (p. 1118) throughout extensors and flexors. Power is preserved; the pace shortens, and slows to a shuffle; its base remains narrow. A stoop and diminished arm swinging become apparent. Gait becomes festinant

(hurried) with short rapid steps. There is difficulty turning quickly and initiating movement, sometimes with falls. *Retropulsion* means small backward steps, taken involuntarily when a patient is halted.

Cerebellar ataxia: broad-based gait

In lateral cerebellar lobe disease (p. 1083) stance becomes broad-based, unstable and tremulous. Ataxia describes this incoordination. When walking, the person tends to veer to the side of the affected cerebellar lobe.

In disease of midline structures (cerebellar vermis), the trunk becomes unsteady without limb ataxia, with a tendency to fall backwards or sideways – truncal ataxia.

Sensory ataxia: stamping gait

Peripheral sensory lesions (e.g. polyneuropathy, p. 1145) cause ataxia because of loss of *proprioception* (position sense). Broad-based, high-stepping, stamping gait develops. This form of ataxia is exacerbated by removal of sensory input (e.g. vision) and worse in the dark. Romberg's test, first described in sensory ataxia of tabes dorsalis (p. 1129), becomes positive.

Lower limb weakness: slapping and waddling gaits

When weakness is distal, each foot must be lifted over obstacles. When ankle dorsiflexors are weak, e.g. in a common peroneal nerve palsy (p. 1144), the sole returns to the ground with an audible *slap*.

Weakness of proximal lower limb muscles (e.g. polymyositis, muscular dystrophy) causes difficulty rising from sitting. Walking becomes a *waddle*, the pelvis being poorly supported by each leg.

Gait apraxia

With frontal lobe disease (e.g. tumour, hydrocephalus, infarction), acquired *walking skills* become disorganized. Leg movement is normal when sitting or lying but initiation and organization of walking fail. Shuffling small steps (*marche à petits pas*), gait ignition failure or undue hesitancy may predominate. Urinary incontinence and dementia are often present.

Falls

Falls in the elderly are a major cause of hospital admission, e.g. following fractures. Often no precise cause can be found. A multidisciplinary approach is essential, e.g. reviewing risk factors such as rugs, stairs, footwear and home circumstances.

Dizziness, vertigo and blackouts

Dizziness covers many complaints, from a vague feeling of unsteadiness to severe, acute vertigo. It is frequently used to describe light-headedness, panic, anxiety, palpitations and chronic ill-health. The real nature of this symptom must be determined.

Vertigo (p. 1078) means the illusion of movement, a sensation of rotation or tipping. The patient feels the surroundings are spinning or moving. This is distressing and often accompanied by nausea or vomiting.

Blackout, like dizziness, is simply descriptive, implying either altered consciousness, visual disturbance or falling. Epilepsy (p. 1112) and syncope are mentioned in detail (p. 1116); hypoglycaemia and anaemia must be considered. Commonly no sinister cause is found. A careful history is essential.

 - Reflexes
4. **Lower limbs**
 - Power
 - Tone
 - Reflexes
 - Plantar responses
5. **Sensation**
 - Ask the patient

Collapse is a vague term, but often used. Avoid it.

No serious disease is found in many patients (>20%) referred with symptoms suggestive of possible neurological conditions.

Fatigue is common: when it is an isolated symptom, neurological disease is rarely discovered. There is a borderland (sometimes contentious) between neurology and psychiatry.

Examination and formulation

Following a short or detailed examination, relevant findings are summarized in a brief formulation – the basis for investigation, transfer of information and management (Practical Boxes 22.1, 22.2 and Table 22.2).

FUNCTIONAL NEUROANATOMY**The neurone and synapse**

The neurone is the functional unit of the entire nervous system (Fig. 22.1). Its cell body and axon terminate in a synapse. Size and type of each group of neurones vary. A thoracic spinal cord α -motor neurone has an axonal length of >1 metre and innervates between several hundred and 2000 muscle fibres in one leg – a motor unit. By contrast, some spinal or intracerebral interneurons have axons under 100 μ m long, terminating on one neuronal cell body.

Neurotransmitters

Neurotransmitters are excitatory (acetylcholine, noradrenaline, adrenaline, 5-hydroxytryptamine, dopamine, glutamate and aspartate) or inhibitory (γ -aminobutyric acid (GABA), histamine and glycine). Neuropeptides, e.g. vasopressin, ACTH, substance P and opioid peptides, as well as the purines (ATP and AMP) are both excitatory and inhibitory.

Synaptic transmission is mediated by neurotransmitters released by action potentials passing down an axon. Neurotransmitters activate postsynaptic receptors and are removed

**Practical Box 22.2****10-part neurological examination**

1. **State of consciousness, arousal, appearance**
 2. **Mental state, attitude, insight** (see Box 22.5, p. 1069)

 - Wasting and fasciculation
 - Posture of arms: drift, rebound, tremor
 - Tone: spasticity, clonus, extrapyramidal rigidity
 - Power: 0–5 scale (Table 22.2)
 - Tendon reflexes: + or ++ normal; +++ pathological; 0 = absent with reinforcement
 - Thorax and abdomen:*
 - Respiration
 - Thoracic and abdominal muscles
 - Abdominal reflexes
 - Cremasteric reflexes
 - Lower limbs:*
 - Wasting and fasciculation
 - Tone, power and tendon reflexes
 - Plantar responses
 9. **Coordination and fine movements**
 10. **Sensory system**
 - First: is feeling in limbs, face and trunk normal?
 - Posterior columns:*
 - Vibration (128 Hz tuning fork)
 - Joint position
 - Light touch
 - 2-point discrimination (normal: 0.5 cm finger tips, 2 cm soles)
 - Spinothalamic tracts:*
 - Pain: use a split orange-stick or a sterile pin
 - Temperature: warm and cold objects
- If sensation is abnormal, chart areas involved*

Table 22.2 Six grades of muscle power

Grade	Definition
5	Normal power
4	Active movement against gravity and resistance
3	Active movement against gravity
2	Active movement with gravity eliminated
1	Flicker of contraction
0	No contraction

by transporter proteins. The neurotransmitter-receptor reaction increases ionic permeability and propagates a further action potential. Axonal electrical activity and synaptic chemical release is the basis of neurological function.

Clinical features of focal brain lesions: general mechanisms

The symptoms and signs suggest the area of the brain that is malfunctioning (e.g. aphasia – the left frontal lobe, hemiparesis – internal capsule or a Bell's palsy – VIIth cranial (facial) nerve).

Focal lesions of the cortex, and lesions throughout the nervous system, cause symptoms and signs by two processes:

The impact of neurological disease**Common symptoms and signs****Functional neuroanatomy****FURTHER READING**

Clarke C. The language of neurology – symptoms, signs and basic investigations. In: Clarke C, Howard R, Rossor M et al. (eds) *Neurology: A Queen Square Textbook*. Oxford: Blackwell; 2009.

Figure 22.1 The functional unit: neurone and neurotransmitters. (a) The action potential, i.e. nerve impulse, travels down the axon. Microtubules carry neurotransmitters to nerve endings. (b) Action potential I depolarizes the synaptic membrane, opening voltage-gated calcium channels. (c) Influx of calcium ions cause vesicles to fuse with the membrane allowing neurotransmitter binding to receptors (i) and activation of secondary messengers that modulate gene transcription and also open ligand-gated channels (ii). This allows ions to enter, depolarize the membrane and initiate action potential II.

- **Suppression or destruction of neurones** and surrounding structures (Fig. 22.2). This is the commonest process – part of the system simply fails to work.
- **Synchronous discharge of neurones** by irritative lesions (Fig. 22.3), e.g. cortical lesions, causes epilepsy, either partial or generalized.

Localization within the cerebral cortex

This subject causes unnecessary difficulty. Work on neuronal networks, functional imaging and plasticity questions the traditional views of highly specific localization of cortical function. The following paragraphs summarize areas of clinical relevance.

The dominant hemisphere (usually left)

The concept of cerebral dominance arose from a simple observation: right-handed stroke patients with acquired language disorders had destructive lesions within the left hemisphere. Right-handed (and 70% of left-handed) people have language function on the left.

More specifically, destructive lesions within the left fronto-temporo-parietal region cause disorders of communication:

- Spoken language – *aphasia*, also called *dysphasia*
- Writing – *agraphia*
- Reading – acquired *alexia*.

Site of lesion	Disorder	R	L
Frontal, either	Intellectual impairment Personality change Urinary incontinence Monoparesis or hemiparesis		
Frontal, left	Broca's aphasia		
Temporo-parietal, left	Acalculia Alexia Agraphia Wernicke's aphasia Right-left disorientation Homonymous field defect		
Temporal, right	Confusional states Failure to recognize faces Homonymous field defect		
Parietal, either	Contralateral sensory loss or neglect Agraphaesthesia Homonymous field defect		
Parietal, right	Dressing apraxia Failure to recognize faces		
Parietal, left	Limb apraxia		
Occipital/occipitoparietal	Visual field defects Visuospatial defects Disturbances of visual recognition		

Figure 22.2 Principal features of destructive cortical lesions in a right-handed individual.

Developmental dyslexia describes delayed, disorganized reading and writing ability in children, usually with normal intelligence.

Aphasia

Aphasia is loss of or defective language from damage to the speech centres within the left hemisphere. Numerous varieties have been described.

Broca's (expressive, anterior) aphasia

Damage in the left frontal lobe causes reduced speech fluency with relatively preserved comprehension. The patient makes great efforts to initiate language, which becomes reduced to a few disjointed words with failure to construct sentences. Patients who recover say they knew what they wanted to say, but could not get the words out.

Wernicke's (receptive, posterior) aphasia

Left temporo-parietal damage leaves fluency of language but words are muddled. This varies from insertion of a few incorrect or non-existent words into speech to a profuse outpouring of jargon (i.e. rubbish with wholly non-existent words).

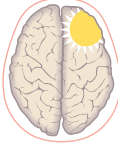

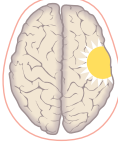

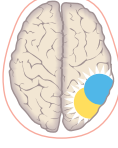

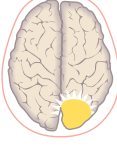

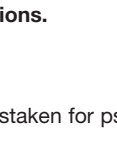

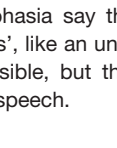

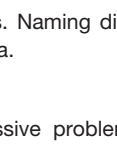

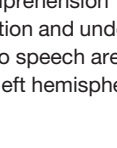

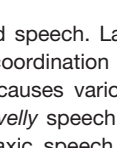

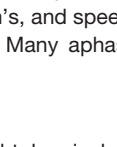

Site of lesion	Effects	R	L
Frontal	Partial seizures–focal motor seizures of contralateral limbs Conjugate deviation of head and eyes away from the lesion		
Temporal	Formed visual hallucinations Complex partial seizures Memory disturbances (e.g. <i>déjà vu</i>)		
Parietal	Partial seizures–focal sensory seizures of contralateral limbs		
Parieto-occipital	Crude visual hallucinations (e.g. shapes in one part of the field)		
Occipital	Visual disturbances (e.g. flashes)		

Figure 22.3 Effects of irritative cortical lesions.

Severe jargon aphasia is bizarre and often mistaken for psychotic behaviour.

Patients who recover from Wernicke's aphasia say that they found speech, both their own and others', like an unintelligible foreign language, i.e. incomprehensible, but they could neither stop speaking nor understand speech.

Nominal (anomic, amnesic) aphasia

This means difficulty naming familiar objects. Naming difficulty is an early feature in all types of aphasia.

Global (central) aphasia

This means the combination of the expressive problems of Broca's aphasia and the loss of comprehension of Wernicke's with loss of both language production and understanding. This is due to widespread damage to speech areas and is the commonest aphasia after a severe left hemisphere infarct. Writing and reading are also affected.

Dysarthria

Dysarthria is disordered articulation – slurred speech. Language is intact. Paralysis, slowing or incoordination of muscles of articulation or local discomfort causes various patterns of dysarthria. Examples are the *gravelly* speech of pseudobulbar palsy (p. 1080), the *jerky*, ataxic speech of cerebellar lesions, the *monotone* of Parkinson's, and speech in myasthenia that *fatigues* and dies away. Many aphasic patients are also dysarthric.

The non-dominant hemisphere

Disorders in right-handed patients with right hemisphere lesions are often difficult to recognize. There are abnormalities of perception of internal and external space. Examples are losing the way in familiar surroundings, failing to put on clothing correctly (dressing apraxia), or failure to draw simple shapes – constructional apraxia.

Memory and its disorders

Disorders of memory follow damage to the medial surfaces of both temporal lobes and their brainstem connections –

Box 22.2 Causes of an amnesic syndrome

- Dementia
- Alcohol (Wernicke–Korsakoff syndrome)
- Head injury (severe)
- Anoxic brain damage and following carbon monoxide poisoning
- Posterior cerebral artery occlusion (bilateral)
- Herpes simplex encephalitis
- Chronic sedative and solvent abuse
- Bilateral invasive tumours
- Following hypoglycaemia
- Arsenic poisoning (very rare)

the hippocampi, fornices and mammillary bodies. Bilateral lesions are necessary to cause *amnesia*. In all organic memory disorders recent events are recalled poorly, in contrast to the relative preservation of distant memories.

Memory loss (the amnesic syndrome) is part of dementia (p. 1137) but also occurs as an isolated entity (Box 22.2).

Neuroanatomy: essential elements

For clinical purposes the complexity of neuroanatomy must be reduced to its core elements:

- Cranial nerves
- Three systems of motor control:
 - corticospinal or pyramidal system
 - extrapyramidal system
 - cerebellum
- Motor unit
- Reflex arc
- Sensory pathways and pain
- Control of the bladder and sexual function.

CRANIAL NERVES (Table 22.3)

I: Olfactory nerve

This sensory nerve arises from olfactory (smell) receptors within nasal mucosa. Branches pierce the cribriform plate and synapse in the olfactory bulb. The olfactory tract passes to the olfactory cortex.

Anosmia (loss of sense of smell) is caused by head injury (shearing of olfactory neurones as they pass through the cribriform plate at the skull base) or tumours of the olfactory groove (e.g. meningioma). Olfaction is temporarily (occasionally permanently) lost or diminished after upper respiratory infections and with local disorders of the nose. Many patients with gradual onset anosmia over many years may be unaware of the deficit, e.g. in Parkinson's disease where anosmia precedes motor symptoms by many years but is often not noticed by the patient.

Detailed smell testing is difficult in routine clinical practice and rarely performed. Adequate testing requires use of commercially available kits such as scratch and sniff cards or odour filled pens with forced multiple choice identification.

II: Optic nerve and visual system (Fig. 22.4)

Light regulated by the pupillary aperture is converted into action potentials by retinal rod, cone and ganglion cells (see page 1055). The lens, under control of the ciliary muscle, produces the image (inverted) on the retina. Axons in the

Table 22.3 Cranial nerves

Number	Name	Main clinical action
I	Olfactory	Smell
II	Optic	Vision, fields, afferent light reflex
III	Oculomotor	Eyelid elevation, eye elevation, ADduction, depression in ABduction, efferent (pupil)
IV	Trochlear	Eye intorsion, depression in ADduction
V	Trigeminal	Facial (and corneal) sensation, mastication muscles
VI	Abducens	Eye ABduction
VII	Facial	Facial movement, taste fibres
VIII	Vestibular Cochlear	Balance and hearing
IX	Glossopharyngeal	Sensation – soft palate, taste fibres
X	Vagus	Cough, palatal and vocal cord movements
XI	Accessory	Head turning, shoulder shrugging
XII	Hypoglossal	Tongue movement

optic nerve (1) decussate at the optic chiasm (2), fibres from the nasal retina cross and join with uncrossed fibres originating in the temporal retina to form the optic tract (3). Each optic tract thus carries information from the contralateral visual hemifield.

From the lateral geniculate body, fibres pass in the optic radiation through the parietal and temporal lobes (4 and 5) to reach the visual cortex of the occipital lobe (6 and 7), which is somatotopically organized with macular vision located at the occipital pole (see Fig. 22.4).

Beyond the visual cortex visual information is further processed by neighbouring visual association areas to detect lines, orientation, shapes, movement, colour and depth; there is even a distinct area responsible for face recognition.

Visual acuity

This is assessed in each eye with a Snellen chart and/or Near Vision Reading Types, corrected for refractive errors with lenses or a pinhole. The patient should stand 6 metres from a well-lit chart. Acuity is recorded as distance in metres from the chart over distance at which the line should be legible, e.g. 6/6 indicates 'normal' acuity and 6/60 very poor acuity.

Visual field defects

Visual fields are assessed at the bedside by confrontation – comparing the examiner's and patient's fields, one eye at a time and quadrant by quadrant. Patience and good technique are required to get reliable results. White and red targets (traditionally hatpins) are used to assess peripheral and central fields respectively although in practice a fingertip is often substituted as a cruder screening test. More detailed quantification of fields may be obtained using Goldmann (manual) or Humphrey (automated) perimetry testing.

Field defects are described as hemianopic when half the field is affected and quadrantanopic when a quadrant is affected. Lesions posterior to the optic chiasm produce

**Figure 22.4** The visual pathway.

1. Monocular field loss – complete optic nerve lesion.
2. Bitemporal hemianopia – chiasmal lesion.
3. Homonymous hemianopia – optic tract lesion.
4. Homonymous quadrantanopia – temporal lesion.
5. Homonymous quadrantanopia – parietal lesion.
6. Homonymous hemianopia with macular sparing – occipital cortex or optic radiation.
7. Homonymous hemianopia (hemiscotoma) – occipital pole lesion.

homonymous field defects, indicating involvement of the same part of the visual field in both eyes as information from the two visual hemifields is separated beyond this point. Lesions damaging decussating nasal fibres at the optic chiasm cause bitemporal defects.

Retinal and local eye lesions

See page 1063 in Chapter 21.

Optic nerve lesions

Unilateral visual loss, commencing with a central or paracentral (off-centre) scotoma, is the hallmark of an optic nerve lesion. Because most fibres in the optic nerve subserve macular vision, lesions within the nerve disproportionately affect central vision and colour vision. A total optic nerve lesion causes unilateral blindness with loss of pupillary light reflex. Examination findings in optic neuropathy:

- Reduced acuity in affected eye
- Scotoma (usually central)
- Impaired colour vision (assess with Ishihara plates)
- An afferent pupillary defect (see below)
- Optic atrophy – pale disc (develops late)

Causes are listed in Box 22.3.

Papilloedema

Papilloedema means swelling of the optic disc. Causes are shown in Box 22.4. The earliest signs of swelling are disc pinkness, with blurring and heaping up of disc margins, nasal first. There is loss of spontaneous pulsation of retinal veins within the disc. The physiological cup becomes obliterated, the disc engorged with dilated vessels. Small haemorrhages often surround the disc.

Box 22.3 Causes of optic neuropathy

- Inflammatory (optic neuritis), e.g. demyelination, sarcoidosis, vasculitis
- Optic nerve trauma or compression, e.g. glioma, meningioma, aneurysm, bone disorders affecting orbit
- Toxic, e.g. tobacco-alcohol, ethambutol, methyl alcohol, quinine, hydroxy chloroquine, radiation
- Ischaemic optic neuropathy, e.g. giant cell arteritis
- Hereditary optic neuropathies, e.g. Leber's
- Nutritional deficiency, e.g. vitamin B₁ and B₁₂
- Infection, e.g. orbital cellulitis, syphilis, TB
- Neurodegenerative disorders, e.g. leucodystrophies
- Papilloedema and its causes (Box 22.4)

Box 22.4 Causes of optic disc swelling

- Raised intracranial pressure (papilloedema)
- Brain tumour, abscess, or haemorrhage. Idiopathic intracranial hypertension, hydrocephalus
- Optic nerve disease
- Optic neuritis, e.g. multiple sclerosis
- Ischaemic optic neuropathy, e.g. giant cell arteritis
- Toxic optic neuropathy, e.g. methanol
- Venous occlusion
- Venous sinus thrombosis
- Central retinal vein thrombosis
- Orbital mass lesions
- Retinal vascular disease
- Malignant hypertension
- Vasculitis, e.g. systemic lupus erythematosus
- Metabolic causes
- Hypercapnia, chronic hypoxia, hypocalcaemia
- Disc infiltration
- Leukaemia, sarcoidosis, optic nerve glioma

Various conditions simulate true disc swelling. Marked hypermetropic (long-sighted) refractive errors make a disc appear pink, distant and ill-defined. Myelinated nerve fibres at disc margins and hyaline bodies (drusen, p. 1064) can be mistaken for disc swelling.

Disc infiltration also causes a swollen disc with raised margins (e.g. in leukaemia).

When there is doubt about disc oedema, i.v. fluorescein angiography is diagnostic; retinal leakage is seen with papilloedema.

Papilloedema produces few if any visual symptoms other than momentary visual obscurations with changes in posture. The underlying disease is the source of the patient's symptoms. The blind spot is enlarged but this is not noticed by the patient. However, over time progressive and permanent constriction of visual fields occurs, ultimately culminating in optic atrophy.

Inflammatory optic neuropathy (optic neuritis)

Optic neuritis is one of the most common causes of subacute visual loss. Symptoms may vary from a mild fogging of central vision with colour desaturation to a dense central scotoma, but very rarely complete blindness. Pain on eye movements is almost universal. The optic disc usually appears normal despite severe visual loss (unless the inflammation is at the optic nerve head in which case the disc may appear swollen in the acute phase).

A plaque of demyelination within the optic nerve is the most common cause in Western populations. Dedicated MRI imaging of the optic nerves may show the inflammatory plaque and imaging of the brain may show additional

inflammatory lesions which confer a higher risk of developing multiple sclerosis (MS). Approximately 50% of patients go on to develop MS with prolonged follow-up (see p. 1123). Recovery of visual acuity to 6/9 or better occurs in 95% of cases over months, with recovery time improved by high-dose i.v. steroids given acutely.

Optic neuritis may be caused by infective or other inflammatory disorders, e.g. sarcoidosis or vasculitides (see Box 22.3).

Anterior ischaemic optic neuropathy

The anterior part of the optic nerve is supplied by the posterior ciliary arteries, occlusion or hypoperfusion of which leads to infarction of all or part of the optic nerve head. There is sudden or stuttering altitudinal visual loss (typically the lower half of the visual field) with disc swelling, later replaced by optic atrophy. The other eye is later affected in one-third of cases.

Individuals with small hypermetropic discs seem to be predisposed, and often there are relatively few vascular risk factors. Less commonly arteritis is the cause (see p. 536).

Optic atrophy

Optic atrophy means disc pallor, from loss of axons, glial proliferation and decreased vascularity. This may eventually develop following any type of optic neuropathy of sufficient severity to extensively damage axons within the nerve, including chronic papilloedema.

Optic chiasm

Bitemporal hemianopia or *quadrantanopia* occurs with compression of the chiasm from above or below. Common causes are:

- Pituitary tumours (p. 946)
- Meningioma
- Craniopharyngioma.

Optic tract and optic radiation

Optic tract lesions (rare) cause a homonymous hemianopia (loss of the contralateral visual field in both eyes). Optic radiation lesions cause homonymous quadrantanopic defects. Temporal lobe lesions (e.g. tumour, infarction) cause upper quadrantic defects, and parietal lobe, lower.

Occipital cortex

Homonymous hemianopic defects are produced by unilateral posterior cerebral artery infarction (see p. 1101 stroke). The macular cortex (at each occipital pole) may be spared.

Widespread bilateral occipital lobe damage by infarction ('top of the basilar' syndrome), trauma or coning causes *cortical blindness* (Anton's syndrome). The patient cannot see but characteristically lacks insight into this; he or she may even deny it. Pupillary responses remain normal (p. 1101).

The pupils

A slight difference between the size of each pupil (up to 1 mm) is common (*physiological anisocoria*) and does not vary with differing light levels. The pupil tends to become smaller and irregular in old age (senile miosis); anisocoria is more pronounced. *Convergence* becomes sluggish with ageing.

Pupillary reactions to light and accommodation may be tested (Fig. 22.5). A bright torch (not an ophthalmoscope light!) should be used to test the pupillary light reaction.

Figure 22.5 Pupillary light reflex. Afferent pathway: (1) Light activates optic nerve axons. (2) Axons (some decussating at the chiasm) pass through each lateral geniculate body, and (3) synapse at pretectal nuclei. Efferent pathway: (4) Action potentials pass to Edinger–Westphal nuclei of IIIrd nerve, then, (5) via parasympathetic neurones in IIIrd nerves to cause (6) pupil constriction.

Afferent pupillary defect. A complete optic nerve lesion causes a dilated pupil and an afferent pupillary defect (APD). For a left APD:

- The pupil is unreactive to light (i.e. the direct reflex is absent).
- The consensual reflex (constriction of the right pupil when the left is illuminated) is absent. Conversely, the left pupil constricts when light is shone in the intact right eye, i.e. the consensual reflex of the right eye remains intact.

Relative afferent pupillary defect (RAPD). This occurs with incomplete damage to one optic nerve relative to the other. An RAPD is a sensitive sign of optic nerve pathology and can provide evidence of an optic nerve lesion even after recovery of vision. For a left RAPD:

- Direct and indirect reflexes are intact in each eye but differ in relative strength.
- When the light is swung from one eye to the other, the left pupil *dilates* slightly when illuminated and *constricts* slightly when the right eye is illuminated (the consensual reflex is stronger than the direct).

Horner's syndrome (see Box 22.5)

The sympathetic nervous supply to the eye is a three neurone pathway originating in the hypothalamus and descending by way of the brainstem and cervical cord to T1 nerve root, paravertebral sympathetic chain and, on via the carotid artery wall, to the eye. Damage to any part of the pathway results in Horner's syndrome. This is significant not only because it affects vision but also because it may indicate a serious underlying pathology.

The clinical features of Horner's syndrome are:

- Unilateral miosis (constricted pupil)
- Partial ptosis

Box 22.5 Causes of Horner's syndrome

Hypothalamic, hemisphere and brainstem lesions

- Massive cerebral infarction
- Brainstem demyelination or lateral medullary infarction

Cervical cord

- Syringomyelia and cord tumours

T1 root

- Apical lung tumour or TB
- Cervical rib
- Brachial plexus trauma

Sympathetic chain and carotid artery in neck

- Following thyroid/laryngeal/carotid surgery
- Carotid artery dissection
- Neoplastic infiltration
- Cervical sympathectomy

Miscellaneous

- Congenital
- Cluster headache, usually transient
- Idiopathic

- Loss of sweating on the same side (extent depending upon the level of the lesion)
- Subtle conjunctival injection and enophthalmos may be present
- The miosis is most easily seen in low light as the pupil cannot dilate, and may not be apparent in bright light.

Myotonic pupil (Holmes–Adie pupil)

This is a dilated, often irregular, pupil, more frequent in women; it is common and usually unilateral. There is no (or very slow) reaction to bright light and also incomplete constriction to convergence. This is due to denervation in the ciliary ganglion, of unknown cause, and has no other pathological significance. A myotonic pupil is sometimes associated with diminished or absent tendon reflexes.

Argyll Robertson pupil

Now rarely seen in clinical practice. A small, irregular pupil is fixed to light but constricts on convergence. The lesion is in the brainstem surrounding the aqueduct of Sylvius. Once considered diagnostic of neurosyphilis, it is now only occasionally seen in diabetes or MS.

III, IV, VI: Oculomotor, trochlear and abducens nerves

These cranial nerves supply the extraocular muscles and disorders commonly result in abnormal eye movements and diplopia (double vision) due to breakdown of conjugate (yoked) eye movements. Diplopia may also occur with local orbital lesions or myasthenia gravis.

Examining eye movements

Pursuit (slow) eye movements and saccadic eye movements are tested separately. The examiner assesses the range of eye movements in all directions and asks the patient to report double vision. Jerky pursuit movements with saccadic intrusion (i.e. brief fast saccades interspersed with slower pursuit movements), overshoot on saccadic movements and nystagmus may indicate cerebellar or brainstem pathology.

Control of eye movements

Fast voluntary eye movements originate in the frontal lobes. Fibres descend and cross in the pons to end in the centre for lateral gaze (paramedian pontine reticular formation – PPRF), close to the Vth nerve nucleus. Each PPRF also receives input from:

- the ipsilateral occipital cortex – pathway concerned with tracking objects
- the vestibular nuclei – pathways linking eye movements with position of the head and neck (vestibulo-ocular reflex, p. 1072).

Conjugate lateral eye movements are coordinated from each PPRF via the medial longitudinal fasciculus (MLF, Fig. 22.6). Fibres from the PPRF pass both to the ipsilateral Vth nerve nucleus (lateral rectus) and, having crossed the midline, to the opposite IIIrd nerve nucleus (medial rectus and other muscles) via the MLF, thus linking the eyes for lateral gaze.

Abnormalities of conjugate lateral gaze

A destructive lesion on one side allows the eyes to be driven by the intact opposite pathway. A left frontal destructive lesion (e.g. an infarct) leads to failure of conjugate lateral gaze to the right. In an acute lesion the eyes are often deviated to the side of the lesion, past the midline and therefore look towards the left (normal) limbs; there is usually a contralateral (i.e. right) hemiparesis.

In the brainstem a unilateral destructive lesion involving the PPRF leads to failure of conjugate lateral gaze *towards* that side. There is usually a contralateral hemiparesis and lateral gaze is deviated towards the side of the paralysed limbs.

Figure 22.6 PPRF and INO. Impulses from PPRF pass via ipsilateral Vth nerve nucleus to lateral rectus muscle (ABduction) and via medial longitudinal fasciculus to opposite IIIrd nerve nucleus and thus to opposite medial rectus muscle (ADduction). A lesion of the MLF (X) causes failure of or slow ADduction in the right eye and nystagmus in the left eye with left lateral gaze. PPRF, para-median pontine reticular formation; INO, internuclear ophthalmoplegia; MLF, medial longitudinal fasciculus.

Internuclear ophthalmoplegia (INO)

Damage to one MLF causes internuclear ophthalmoplegia (INO), a common complex brainstem eye movement disorder seen frequently in MS. In a right INO there is a lesion of the right MLF (Fig. 22.6). On attempted left lateral gaze the right eye fails to ADduct. The left eye develops nystagmus in ABduction. The side of the lesion is on the side of impaired ADduction, not on the side of the (obvious, unilateral) nystagmus. When present bilaterally, INO is almost pathognomonic of MS.

One and a half syndrome

Pontine infarction involving the PPRF, Vth nerve nucleus and MLF on one side results in an ipsilateral horizontal gaze palsy and an INO so that abduction of the opposite eye (with nystagmus) is the only horizontal eye movement possible. Vertical gaze and convergence are preserved as they have distinct neural control mechanisms.

Vestibulo-ocular (Doll's eye) reflexes

Examination is of diagnostic value in coma (p. 898) and assessment of vertigo (p. 1079).

Abnormalities of vertical gaze

Failure of up-gaze may be caused by dorsal midbrain lesions, e.g. pinealoma or infarcts. When the pupillary light reflex fails in addition, this is called Parinaud's syndrome. Defective up-gaze also develops in certain degenerative disorders (e.g. progressive supranuclear palsy). Some impairment of up-gaze occurs as part of normal ageing.

Nystagmus

Nystagmus is rhythmic oscillation of eye movement, and a sign of disease of the retina, cerebellum and/or vestibular systems and their connections. Nystagmus is either *jerk* or *pendular*. Nystagmus must be sustained within binocular gaze to be of diagnostic value – a few beats at the extremes of gaze are normal.

Jerk nystagmus

Jerk nystagmus (usual in neurological disease) is a fast/slow oscillation. This is seen in vestibular, VIIIth nerve, brainstem, cerebellar lesions. Direction of nystagmus is decided by the fast component, a reflex attempt to correct the slower, primary movement.

- *Horizontal or rotary jerk nystagmus* may be either of peripheral (vestibular) or central origin (VIIIth nerve, brainstem, cerebellum and connections).
 - In peripheral lesions, nystagmus is usually acute and transient (minutes or hours) and associated with severe prostrating vertigo.
 - In central lesions nystagmus tends to be long-lasting (weeks, months or more). Vertigo caused by central lesions tends to wane after days or weeks, the nystagmus outlasting it.
- *Vertical jerk nystagmus* is caused typically by central lesions.
- *Down-beat jerk nystagmus* is a rarity caused by lesions around the foramen magnum (e.g. meningioma, cerebellar ectopia).

Pendular nystagmus

Pendular describes movements to and fro, similar in velocity and amplitude. Pendular nystagmus is usually vertical and present in all directions of gaze. The causes are generally

**Box 22.6 Some causes of a IIIrd nerve lesion**

- Aneurysm of the posterior communicating artery
- Infarction of IIIrd nerve, e.g. diabetes, atheroma
- Coning of the temporal lobe
- Midbrain infarction
- Midbrain tumour (primary or secondary)

ocular (e.g. poor visual fixation from longstanding, severe visual impairment), or congenital.

III: Oculomotor nerve

The nucleus of the IIIrd nerve lies ventral to the aqueduct in the midbrain. It supplies four external ocular muscles (superior, inferior and medial recti, and inferior oblique), levator palpebrae superioris (which lifts the eyelid) and parasympathetic constriction of the pupil. Causes of a IIIrd nerve lesion are listed in Box 22.6.

Signs of a complete IIIrd nerve palsy:

- Unilateral complete ptosis (levator weakness)
- Eye deviated down and out (unopposed lateral rectus and superior oblique)
- A fixed and dilated pupil.

Patients do not complain of diplopia as the ptosis effectively covers the eye. *Sparing of the pupil* indicates parasympathetic fibres are undamaged; these run in a discrete bundle on the surface of the nerve, thus the pupil is of normal size and reacts normally. Diabetic IIIrd nerve infarction is usually painless and pupil sparing, unlike compression by a posterior communicating artery aneurysm.

IV: Trochlear nerve

This supplies the superior oblique muscle. The patient complains of torsional diplopia (two objects at an angle) when attempting to look down (e.g. descending stairs); the head is tilted away from that side. The most common cause is head injury, often with bilateral trochlear nerve palsies occurring.

VI: Abducens nerve

This supplies the lateral rectus muscle (ABduction). Lesions cause horizontal diplopia when looking into the distance, maximal when looking to the side of the lesion. The eye cannot be fully abducted and an esotropia (inwards eye deviation) may be visible in the primary position.

The VIth nerve has a long intracranial course. It can be damaged in the brainstem (e.g. by MS or infarction). In raised intracranial pressure, it is compressed against the tip of the petrous temporal bone (may be bilateral). The nerve sheath may be infiltrated by tumours, particularly nasopharyngeal carcinoma. Microvascular ischaemia of the nerve may occur in diabetes with acute onset followed by recovery within 3 months in most cases.

Complete external ophthalmoplegia

Complete external ophthalmoplegia describes an immobile eye when IIIrd, IVth and VIth nerves are paralysed at the orbital apex (e.g. by metastasis) or within the cavernous sinus (e.g. by sinus thrombosis or meningioma).

Wernicke's encephalopathy due to thiamine deficiency (p. 1147) may cause a complex eye movement disorder or

Figure 22.7 Sensory input of Vth nerve (red) and motor output of VIth nerve (blue). GG, Gasserian ganglion; SOF, superior orbital fissure; FR, foramen rotundum; FO, foramen ovale; SF, stylomastoid foramen.

complete ophthalmoplegia, as may neuromuscular junction disorders such as myasthenia, botulism and some myopathies or metabolic disorders.

V: Trigeminal nerve

The largest cranial nerve; mainly sensory with a motor component to the muscles of mastication.

Sensory fibres (Fig. 22.7; see also Figs 22.11 and 22.12) of the three divisions – ophthalmic (V₁), maxillary (V₂) and mandibular (V₃) – pass to the trigeminal (Gasserian) ganglion at the apex of the petrous temporal bone. Ascending fibres transmitting light touch enter the Vth nucleus in the pons. Descending central fibres carrying pain and temperature form the spinal tract of V, to end in the spinal Vth nucleus that extends from the medulla into the cervical cord.

Signs of a Vth nerve lesion

A complete Vth nerve lesion causes unilateral sensory loss on the face, scalp anterior to the vertex, anterior two-thirds of the tongue and buccal mucosa; the jaw deviates to that side as the mouth opens (motor fibres). Diminution of the corneal reflex is an early and sometimes isolated sign of a Vth nerve lesion.

Causes

- **Brainstem pathology** (infarction, demyelination or tumour) may damage the nucleus, with light touch and spinothalamic pathways sometimes being differentially involved.
- **Cerebellopontine angle tumours** (acoustic neuroma or meningioma) may compress the nerve and also affect the VIIth and VIIIth nerves producing facial weakness and deafness.
- **Cavernous sinus and skull base pathology** (tumour or infection) may affect the ganglion and proximal branches.
- **Peripheral branches** may be picked off individually, e.g. the 'numb chin syndrome' seen with a breast cancer metastasis in the mandible.

Trigeminal neuralgia

Trigeminal neuralgia is discussed with facial pain (p. 1110).

Trigeminal sensory neuropathy

Causes gradually progressive unilateral facial sensory loss and tingling with normal imaging. The condition is probably heterogeneous in aetiology but may have an autoimmune basis, with inflammation of the trigeminal ganglion, occurring mainly in association with mixed and undifferentiated connective tissue disease and primary Sjögren's syndrome.

VII: Facial nerve

The VIIth nerve is largely motor, supplying muscles of facial expression. VII carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani and supplies motor fibres to the stapedius muscle. The VIIth nerve (Fig. 22.7) arises from its nucleus in the pons and leaves the skull through the stylomastoid foramen. Neurones in each VIIth nucleus supplying the upper face (principally frontalis) receive bilateral supranuclear innervation.

Unilateral facial weakness

Upper motor neurone (UMN lesions) cause weakness of the lower part of the face on the opposite side. Frontalis is spared: normal frowning of the brow is preserved; eye closure and blinking are largely unaffected. The earliest sign is slowing of one side of the face, e.g. on baring teeth. There is sometimes relative preservation of spontaneous emotional movement (e.g. smiling) compared with voluntary movement.

Lower motor neurone (LMN) lesions. A complete unilateral LMN VIIth lesion causes weakness (ipsilateral) of all facial expression muscles. The angle of the mouth falls; unilateral dribbling develops. Frowning (frontalis) and eye closure are weak. Corneal exposure and ulceration occur if the eye does not close during sleep. Taste sensation is frequently also impaired.

Causes of facial weakness

The commonest cause of a UMN lesion is hemispheric stroke with hemiparesis on the opposite side. At lower levels, lesion sites are recognized by LMN weakness with additional signs.

Pons. Here the VIIth nerve loops around the VIth (abducens) nucleus (Fig. 22.7), leading to a lateral rectus palsy (see p. 1076) with unilateral LMN facial weakness. When the neighbouring PPRF and corticospinal tract are involved, there is the combination of:

- LMN facial weakness
- Failure of conjugate lateral gaze (towards lesion)
- Contralateral hemiparesis.

Causes include pontine tumours (e.g. glioma), MS and infarction.

Cerebellopontine angle (CPA). The neighbouring Vth, VIth and VIIth nerves are compressed with VII in the CPA, e.g. by acoustic neuroma, meningioma or metastasis.

Petrous temporal bone. The nerve may be damaged within the bony facial canal, within which lies the sensory geniculate ganglion (receiving taste fibres from the anterior two-thirds of the tongue via the chorda tympani). As well as LMN facial weakness, lesions in this region cause:

- Loss of taste on the anterior two-thirds of the tongue
- Hyperacusis (loud noise distortion – paralysis of stapedius).

Causes include:

- Bell's palsy
- Trauma
- Middle ear infection
- Herpes zoster (Ramsay Hunt syndrome, p. 1077)

Skull base, parotid gland and within the face. The facial nerve can be compressed by skull base tumours and in Paget's disease of bone. Branches of VII may be damaged by parotid gland tumours as the nerve traverses the parotid, sarcoidosis (p. 845) and trauma.

Bell's palsy

This common (1 per 5000 incidence), acute facial palsy is thought to be due to viral infection (often herpes simplex) causing swelling of nerve within the tight petrous bone facial canal. There is unilateral LMN facial weakness developing over 24–48 hours, sometimes with lost or altered taste on the tongue, and hyperacusis. Pain behind the ear is common at onset. Patients often suspect a stroke and may be very distressed. Vague altered facial sensation is often reported although examination of facial sensation is normal.

Diagnosis is made on clinical grounds and tests are usually not required. The ear (and palate) should be examined for vesicles (see Ramsay Hunt syndrome below), hearing loss or evidence of local pathology such as cholesteatoma or malignant otitis externa and parotid tumours should be excluded. Involvement of other cranial nerves means facial weakness is not due to Bell's palsy. Lyme disease may account for one-quarter of cases of facial palsy in endemic areas and HIV seroconversion is the commonest cause in parts of Africa.

(Bell's *phenomenon* is the upward conjugate eye movement that occurs when the eyes are closed.)

Management and outcome

Complete, or almost complete, recovery over 3–8 weeks occurs in at least 85% of patients, even without specific treatment. Patients should be reassured that the prognosis is good and it is unlikely to recur.

Inability to blink in severe facial weakness may lead to exposure keratitis. Use of lubricating eye drops is often required and patients should be advised to carefully tape the eye closed at night. For more severe facial weakness with complete inability to close the eye, early ophthalmological assessment is required and lateral tarsorrhaphy and/or insertion of a gold weight into the upper lid may be required until recovery occurs.

Early treatment with corticosteroids (prednisolone 1 mg/kg for 7 days) improves outcome. Evidence to support use of antiviral agents is limited but aciclovir or valaciclovir is often given in combination with steroids.

Recovery sometimes takes up to a year if axons have to regrow rather than just remyelinate, in which case aberrant reinnervation of facial muscles (e.g. mouth twitching with blinking) is a frequent late complication. Cosmetic surgery may be helpful where recovery is not complete. Bell's palsy rarely recurs and recurrence should prompt a search for an alternative cause.

Ramsay hunt syndrome

This is herpes zoster (shingles) of the geniculate ganglion. There is a facial palsy (identical to Bell's) with vesicles around the external auditory meatus and/or the soft palate (sensory

de Almeida JR, Al Khabori M, Guyatt GH et al. Combined corticosteroid and antiviral treatment for Bell palsy: a systematic review and meta-analysis. *JAMA* 2009; 302:985–993.

twigs from VII). Deafness and unsteadiness may occur. Complete recovery is less likely than in Bell's. Antiviral treatment for shingles (above) should be given with steroids.

Bilateral facial weakness

Bilateral facial palsy is rare, accounting for fewer than 1% of cases of facial palsy, but is more likely than unilateral palsies to have an identifiable underlying cause. Paradoxically, bilateral weakness is often less obviously apparent than unilateral weakness as there is no facial asymmetry.

Causes include:

- Infections:
 - Lyme (bilateral in 25% – Bannwarth's syndrome)
 - Viral: HIV seroconversion, EBV
 - Mastoiditis (bilateral)
 - Diphtheria and botulism (rare)
- Sarcoidosis
- Skull base trauma and tumours
- Pontine lesions, e.g. gliomas
- Neuromuscular disorders as part of more generalized weakness
 - Guillain-Barré syndrome
 - Myasthenia
 - Myotonic dystrophy and facioscapulohumeral dystrophy
- Congenital and genetic causes (Gelsolin gene mutations).

Hemifacial spasm (HFS)

This is an irregular, painless unilateral spasm of facial muscles, usually occurring after middle age. It starts in the orbicularis oculi and usually progresses gradually over the years to involve other facial muscles on the same side. It varies from a mild to a severe, disfiguring spasm.

HFS is usually caused by compression of the root entry zone of the facial nerve, generally by vascular structures such as the vertebral or basilar arteries or their branches (a mechanism similar to that of trigeminal neuralgia see p. 1110). Other mass lesions in the cerebellopontine angle, including tumours, are the cause in approximately 1% of cases.

Occasionally HFS may occur with ipsilateral trigeminal neuralgia, one symptom usually preceding the other, a combination called *tic convulsif*. The paroxysms of pain and spasm occur independently. A compressive cause such as a vascular loop or other structural lesion is usually identified.

Management

Mild cases require no treatment. Botulinum toxin injection into affected muscles every 3–4 months is now the standard treatment. Drugs (e.g. carbamazepine) are of little value. Decompression of the VIIth nerve in the CPA is sometimes helpful. Surgical decompression of the facial nerve in the posterior fossa involves interposing a non-resorbable sponge between the nerve and any adjacent vascular loop identified at operation. The procedure results in complete resolution of symptoms in up to 90% of cases but is associated with a risk of facial weakness or deafness.

Other involuntary facial movements

Myokymia of orbicularis oculi is an irritating twitch, usually of the lower eyelid. It is a normal phenomenon, but sometimes a cause of anxiety. More extensive facial myokymia may result from intrinsic brainstem pathology.

Tics and tardive dyskinesia frequently involve facial or perioral muscles (see p. 1122).

Blepharospasm is a form of focal dystonia affecting orbicularis oculi (see p. 1122)

VIII: Vestibulo-cochlear nerve; cochlear nerve

Auditory fibres from the spiral organ of Corti within the cochlea pass to the cochlear nuclei in the pons. Fibres from these nuclei cross the midline and pass upwards via the medial lemnisci to the medial geniculate bodies and then to the temporal cortex.

Symptoms of a cochlear nerve lesion are deafness and tinnitus (p. 1050). Sensorineural and conductive deafness can be distinguished with tuning fork tests, e.g. Rinne's and Weber's (256 Hz, not 128 Hz tuning fork) (p. 1048).

Basic investigations of cochlear lesions

- Pure tone audiometry and auditory thresholds.
- Auditory evoked potentials (recording responses from repetitive clicks via scalp electrodes; lesion levels are determined from the response pattern).

Causes of deafness are listed in Table 22.4 and Table 21.1 (see p. 1048).

Vertigo and the vestibular system

The vestibular system of the inner ear detects head movements and has three primary functions:

- To stabilize gaze during head movements, e.g. looking ahead while running (the vestibulo-ocular reflex)
- To control posture and balance
- To facilitate perception of orientation and motion.

Nerve impulses generated by movement of hair cells within the three semicircular canals detect head motion in the three planes (yaw/pitch/roll). Balance is maintained by integrating information from:

Table 22.4 Some causes of vertigo and hearing loss

Conditions	Symptom(s)
Benign paroxysmal positional vertigo	V
Vestibular neuritis	V
Ménière's disease	V, D

Carcinomatous meningitis, sarcoid and tuberculous meningitis	V, D
V, vertigo; D, hearing loss.	

- The vestibular system
- The visual system
- The somatosensory system – proprioception from limbs, trunk and neck.

The *main symptoms* of vestibular lesions are vertigo and loss of balance.

Vertigo

Vertigo, is the illusion of movement of the subject or surroundings, typically rotatory, and should be distinguished from other causes of nonspecific dizziness. It can be described to patients as being similar to the sensation one feels after getting off a child's roundabout or after spinning on the spot and suddenly stopping.

Vomiting frequently accompanies acute vertigo of any cause. Vertigo is always made worse by head movements and patients prefer to remain still and maintain visual fixation. Nystagmus (p. 1075) is the principal sign.

The dizzy patient

Complaints of 'dizziness' require careful history taking and may be due to:

- Vertigo
- Presyncopal sensations due to transient cerebral hypoperfusion, e.g. orthostatic light-headedness
- Unsteadiness or disequilibrium, e.g. cerebellar or postural stability disorders
- Nonspecific 'dizziness', e.g. due to medication or anxiety and hyperventilation.

Causes of vertigo

Vertigo indicates a disturbance of the vestibular apparatus or brainstem and associated neural pathways (Table 22.4). Causes:

- Peripheral (vestibular system) causes are common. Deafness and tinnitus accompanying vertigo indicate involvement of the ear or cochlear nerve (p. 1048).
- Central causes (brainstem and connections) are rarer. Other clinical features such as diplopia, weakness, cerebellar signs or cranial nerve palsies may help localize the lesion.

Vestibular disorders

Vestibular disorders are fully discussed elsewhere (p. 1049). Attack duration and frequency and trigger factors help the clinician distinguish on history between different pathological causes. The ability to perform a Hallpike test, head impulse test and Epley particle repositioning manoeuvre are invaluable skills for all clinicians (p. 1049; see Fig. 22.8 and Fig. 21.3).

The most commonly encountered vestibular disorders presenting with vertigo are:

- **Benign positional vertigo** (BPPV) – frequent attacks lasting seconds only. Triggered by specific movements – lying down, sitting up or rolling over in bed, neck flexion or extension.
- **Vestibular neuronitis** – acute onset lasting days or weeks. Non-recurrent.
- **Migrainous vertigo** (p. 1108), really a central cause – lasting hours, occurring every few weeks or months
- **Meniere's disease** – recurrent attacks lasting minutes or hours, usually accompanied by hearing loss, tinnitus and a feeling of fullness in the ear.
- **Trauma** – vestibular disruption following head injury

Figure 22.8 The head impulse test. When tested on the normal side, a patient can maintain fixation on a distant object as the examiner rapidly turns the patient's head sideways through about 15°. If there is unilateral vestibulopathy, the patient cannot maintain fixation on the target and can be observed to make a voluntary eye movement (a saccade) back to the target after the head impulse, as shown on the right. It is essential that the head is turned as rapidly as possible otherwise smooth pursuit eye movements will compensate for the head turn.

Central causes of vertigo

Vertigo may be a manifestation of brainstem pathology including:

- Infarcts involving the vestibular nuclei in the medulla (e.g. the lateral medullary syndrome)
- Demyelination involving the brainstem
- Posterior fossa mass lesions, e.g. tumours, haemorrhage or vascular malformations
- Migraine
- CPA mass lesions and tumours compressing the vestibular nerve (technically these should be classified as 'peripheral' disorders, but are distinct from disorders of the vestibular apparatus)
- Drugs, e.g. anticonvulsant toxicity and alcohol.

Although vertigo occasionally occurs in isolation with brainstem pathology, it is more typically a single component of a more complex clinical picture, associated with other symptoms or examination findings. The brainstem nuclei and tracts are tightly packed into a small space and most pathological processes affect multiple contiguous neural pathways, resulting, e.g. in diplopia, eye movement disorders, cranial nerve palsies, cerebellar signs or hemiparesis.

Slowly growing CPA tumours such as vestibular nerve schwannomas may cause vertigo but rarely do so in the absence of unilateral deafness and tinnitus.

Vertical nystagmus usually has a central cause.

Basic investigations for vestibular problems

Bedside assessment is usually sufficient to make a diagnosis in the majority of patients:

- Examination of eye movements for nystagmus (p. 1074)
- Assessment of hearing and otoscopic examination of the ear (p. 1047)
- Head impulse (thrust) test – to assess the vestibulo-ocular reflex (VOR) and identify a unilateral vestibulopathy
- Hallpike manoeuvre – a positioning test to stimulate the posterior semicircular canal and trigger an attack in BPPV (see Fig. 21.3)

Specialist testing is occasionally required to assess vestibular function and hearing. This includes:

- Caloric testing – irrigation of the external auditory, meatus with cold and then warm water to stimulate the

FURTHER READING

horizontal semicircular canal and induce nystagmus. Test labyrinthine function in each ear separately.

- Electro-nystagmography – to quantify and characterize nystagmus under different conditions, e.g. in a rotating chair.
- Posturography – assesses body sway on a moving platform.
- Pure tone audiograms.
- High-definition MRI provides the best structural imaging of the brainstem and CPA and is useful where a central cause of vertigo is suspected.

Vestibular neuronitis

Vestibular neuronitis is a common, poorly understood problem. It is an acute attack of isolated vertigo with nystagmus, often with vomiting, believed to follow viral infections. The disturbance lasts for several days or weeks, is self-limiting and rarely recurs. Vestibular neuronitis is sometimes followed by benign positional vertigo (p. 1071). Deafness is absent. Acute treatment is with vestibular sedatives. Similar symptoms can be caused by MS or brainstem vascular lesions. Other signs are usually apparent.

Lower cranial nerves IX, X, XI, XII

The glossopharyngeal (IX), vagus (X) and accessory (XI) nerves arise in the medulla and leave the skull through the jugular foramen. The hypoglossal (XII) arises in the medulla, to leave the skull base via the hypoglossal foramen. Outside the skull, the four cranial nerves lie together, close to the carotid artery and sympathetic trunk.

Glossopharyngeal (IX)

This nerve is largely sensory, supplying sensation and taste from the posterior third of the tongue and the pharynx (afferent pathway of gag reflex). Motor fibres supply some pharyngeal muscles and parasympathetic fibres the parotid.

Vagus (X)

The vagus is a mixed nerve, largely motor, which supplies striated muscle of the pharynx (efferent gag reflex pathway), larynx (including vocal cords via recurrent laryngeal nerves) and upper oesophagus. There are sensory fibres from the larynx. Parasympathetic fibres supply the heart and abdominal viscera.

Accessory (XI)

The accessory nerve, a complex motor nerve, supplies the trapezius and sternomastoid muscles.

Hypoglossal (XII)

The hypoglossal nerve is a motor nerve to tongue muscles.

IXth and Xth nerve lesions

Principal causes of IXth, Xth, XIth and XIIth nerve lesions are listed in Box 22.7.

Isolated lesions of IXth and Xth nerves are unusual, since disease at the jugular foramen affects both nerves and sometimes XI.

A unilateral IXth nerve lesion causes diminished sensation on the same side of the pharynx, and is hard to recognize in isolation. A Xth nerve palsy produces ipsilateral failure of voluntary and reflex elevation of the soft palate (which is drawn to the opposite side) and ipsilateral vocal cords.

Bilateral lesions of IXth and Xth nerves cause palatal weakness, reduced palatal sensation, an absent gag reflex,

Box 22.7 Principal causes of IXth, Xth, XIth and XIIth nerve lesions**Within brainstem**

- Metastases
- Carotid artery dissection (XII)
- Trauma
- Lymph node biopsy in posterior triangle (XI)

dysphonia and choking with nasal regurgitation. *Bulbar palsy* is a general term describing palatal, pharyngeal and tongue weakness of LMN or muscle origin.

Recurrent laryngeal nerve lesions. Paralysis of this branch of each vagus causes hoarseness (dysphonia) and failure of the forceful, explosive part of coughing ('bovine cough'). There is no visible palatal weakness; vocal cord paralysis is seen endoscopically. Bilateral acute lesions (e.g. postoperatively) cause respiratory obstruction – an emergency.

The left recurrent laryngeal nerve (looping beneath the aorta) is damaged more commonly than the right.

Causes of recurrent laryngeal nerve lesions include:

- Mediastinal primary tumours (e.g. thymoma)
- Secondary spread from bronchial carcinoma
- Aortic aneurysm
- Trauma or surgery of neck or thorax.

XIth nerve lesions

XIth nerve lesions cause weakness of sternomastoid (rotation of the head and neck to the opposite side) and trapezius (shoulder shrugging). Nerve section (e.g. following lymph node biopsy in the neck posterior triangle) is followed by persistent neuralgic pain.

XIIth nerve lesions

LMN lesions of XII lead to unilateral tongue weakness, wasting and fasciculation. The protruded tongue deviates towards the weaker side. Bilateral supranuclear (UMN) lesions produce slow, limited tongue movements and a stiff tongue that cannot be protruded far. Fasciculation is absent.

Bulbar and pseudobulbar palsy**Bulbar palsy**

This is LMN weakness of muscles whose cranial nerve nuclei lie in the medulla (the bulb). Paralysis of bulbar muscles is caused by disease of lower cranial nerve nuclei, lesions of IXth, Xth and XIIth nerves (Box 22.7), malfunction of their neuromuscular junctions (e.g. myasthenia gravis, botulism) or disease of muscles themselves (e.g. dystrophies).

Pseudobulbar palsy

Describes bilateral supranuclear (UMN) lesions of lower cranial nerves producing weakness of the tongue and

pharyngeal muscles. This resembles, superficially, a bulbar palsy, hence pseudobulbar. Findings are a stiff, slow, spastic tongue (not wasted), dysarthria and dysphagia. Gag and palatal reflexes are preserved and the jaw jerk exaggerated. Emotional lability (inappropriate laughing or crying) often accompanies pseudobulbar palsy. Principal causes:

- Motor neurone disease – often both UMN and LMN lesions (i.e. elements of both pseudobulbar and bulbar palsy)
- Cerebrovascular disease, typically following multiple infarcts
- Neurodegenerative disorders such as progressive supranuclear palsy (p. 1120)
- Severe traumatic brain injury
- MS, mainly as a late event.

Difficulty swallowing, dysarthria and drooling also develop in later stages of Parkinson's disease.

Dropped head syndrome

As the name suggests, weakness of neck extensors cause neck flexion and inability to hold the head up. Seen mainly in the elderly it is often due to isolated neck extensor myopathy of uncertain cause, but may be a presenting feature of motor neurone disease, myasthenia or various myopathic disorders.

MOTOR CONTROL SYSTEMS

There are three systems, each of which interacts by feedback loops with the other two, with sensory input and the reticular formation:

- **The corticospinal (or pyramidal) system** enables *purposive, skilled, intricate, strong and organized* movements. Defective function is recognized by a distinct pattern of signs – loss of skilled voluntary movement, spasticity and reflex change – seen, e.g. in a hemiparesis, hemiplegia or paraparesis.
- **The extrapyramidal system** facilitates *fast, fluid* movements that the corticospinal system has generated. Defective function produces slowness (bradykinesia), stiffness (rigidity) and/or disorders of movement (rest tremor, chorea and other dyskinesias). One feature (e.g. stiffness, tremor or chorea) will often predominate.
- **The cerebellum** and its connections have a role coordinating *smooth and learned* movement, initiated by the pyramidal system, and in posture and balance control. Cerebellar disease leads to unsteady and jerky movements (*ataxia*), with characteristic limb signs of past pointing, action tremor and incoordination, gait ataxia and/or truncal ataxia.

Corticospinal (pyramidal) system

The corticospinal tracts originate in neurones of the cortex and terminate at motor nuclei of cranial nerves and spinal cord anterior horn cells. The pathways of particular clinical significance (Fig. 22.9) congregate in the internal capsule and cross in the medulla (decussation of the pyramids), passing to the contralateral cord as the lateral corticospinal tracts. This is the pyramidal system, disease of which causes upper motor neurone (UMN) lesions. 'Pyramidal' is simply a

Figure 22.9 The motor system.

Box 22.8 Features of upper motor neurone lesions

- Drift of upper limb
- Weakness with characteristic distribution
- Changes in tone: flaccid-spastic
- Exaggerated tendon reflexes
- Extensor plantar response
- Loss of skilled finger/toe movements
- Loss of abdominal reflexes
- No muscle wasting
- Normal electrical excitability of muscle

descriptive term that draws together anatomy and characteristic physical signs, and is used interchangeably with the term UMN.

A proportion of the corticospinal outflow is uncrossed (anterior corticospinal tracts). This is of no relevance in practice.

Characteristics of pyramidal lesions

(Box 22.8)

Signs of an early pyramidal lesion may be minimal. Weakness, spasticity or changes in superficial reflexes can predominate, or be present in isolation.

Pyramidal drift of an upper limb

Normally, the outstretched upper limbs are held symmetrically, when the eyes are closed. With a pyramidal lesion, when both upper limbs are held outstretched, palms

uppermost, the affected limb drifts downwards and medially. The forearm tends to pronate and the fingers flex slightly. This sign is often first to emerge, sometimes before weakness and/or reflex changes become apparent.

Weakness and loss of skilled movement

A unilateral pyramidal lesion above the decussation in the medulla causes weakness of the opposite limbs. When acute and complete, this weakness will be immediate and total, a hemiplegia, e.g. following an internal capsule infarct. With slowly progressive lesions (e.g. a hemisphere glioma) a characteristic pattern of weakness emerges – a hemiparesis.

In the upper limb, flexors remain stronger than extensors, whereas in the lower limb, extensors remain stronger than flexors. In the upper arm, weaker movements are thus shoulder abduction and elbow extension; in the forearm and hand, wrist and finger extensors and abductors are weaker than their antagonists. In the lower limb, weaker movements are hip flexion and abduction, knee flexion, ankle dorsiflexion and eversion. There is also loss of skilled movement – fine finger and toe control diminishes. Wasting (except from disuse) is not a feature. Muscles remain normally excitable electrically.

When a UMN lesion is below the decussation of the pyramids, e.g. in the cervical cord, hemiparesis is on the same side as the lesion, an unusual situation.

Changes in tone and tendon reflexes

An acute lesion of one pyramidal tract (e.g. internal capsule stroke) causes initially flaccid paralysis with loss of tendon reflexes. Increase in tone follows, usually within several days due to loss of inhibitory effects of the corticospinal pathways and an increase in spinal reflex activity. This increase in tone (spasticity) is detectable most easily in stronger muscles. Spasticity is characterized by sudden *changing resistance* to passive movement – the clasp-knife effect. Relevant tendon reflexes become exaggerated; clonus may emerge.

Changes in superficial reflexes

The normal flexor plantar response becomes extensor. In a severe acute lesion, this extensor response can be elicited from a wide area of the foot. As recovery progresses, the receptive area diminishes until the lateral posterior third of the sole remains receptive to an orange-stick stimulus (an appropriate instrument). An extensor plantar is certain when great toe dorsiflexion is accompanied by abduction of adjacent toes. Abdominal (and cremasteric) reflexes are abolished on the side affected.

Patterns of UMN disorders

There are three main patterns:

- **Hemiparesis** means weakness of the limbs on one side; it is usually caused by a lesion in the brain and occasionally in the cord.
- **Paraparesis** means weakness of both lower limbs and is usually diagnostic of a cord lesion; bilateral brain lesions occasionally cause paraparesis.
- **Tetraparesis** (syn. *quadriparesis*) means weakness of four limbs.

Hemiplegia, paraplegia and tetraplegia indicate (strictly) total paralysis, but are often used to describe severe weakness.

Hemiparesis

The level within the corticospinal system is recognized by particular features.

Motor cortex. Weakness and/or loss of skilled movement confined to one contralateral limb (an arm or a leg – monoparesis) or part of a limb (e.g. a clumsy hand) is typical of an isolated motor cortex lesion (e.g. a secondary neoplasm). A defect in cognitive function (e.g. aphasia) and focal epilepsy may occur.

Internal capsule. Corticospinal fibres are tightly packed in the internal capsule (about 1 cm²), thus a small lesion causes a large deficit. A middle cerebral artery branch infarction (p. 1100) produces a sudden, dense, contralateral hemiplegia.

Pons. A pontine lesion (e.g. an MS plaque) is rarely confined to the corticospinal tract. Adjacent structures, e.g. Vth and VIth nuclei, MLF and PPRF (p. 1075) are involved – diplopia, facial weakness, internuclear ophthalmoplegia (INO) and/or a lateral gaze palsy occur with contralateral hemiparesis.

Spinal cord. An isolated lesion of one lateral corticospinal tract (e.g. a cervical cord injury) causes an ipsilateral UMN lesion, the level indicated by changes in reflexes (e.g. absent biceps, C5/6), features of a Brown–Séquard syndrome (p. 1086) and muscle wasting at the level of the lesion (p. 1087).

Spastic paraparesis

Paraparesis indicates bilateral damage to corticospinal pathways causing weakness and spasticity (or flaccid weakness in the initial phase of spinal shock after an acute cord insult). Cord compression (p. 1135) or cord diseases are the usual causes; cerebral lesions occasionally produce paraparesis. Paraparesis is a feature of many neurological conditions; finding the cause is crucial (p. 1135).

Extrapyramidal system

The extrapyramidal system is a general term for basal ganglia motor systems, i.e. corpus striatum (caudate nucleus + globus pallidus + putamen), subthalamic nucleus, substantia nigra and parts of the thalamus. In basal ganglia/extrapyramidal disorders, two features (either or both) become apparent, in limbs and axial muscles:

- Reduction in speed (bradykinesia, meaning slow movement) or akinesia (no movement), with muscle rigidity
- Involuntary movements (e.g. tremor, chorea, hemiballismus, athetosis, dystonia).

Extrapyramidal disorders are classified broadly into *akinetic-rigid syndromes* (p. 1130) where poverty of movement predominates, and *dyskinesias* where there are involuntary movements (p. 1121).

The most common extrapyramidal disorder is Parkinson's disease.

Essential anatomy

The corpus striatum lies close to the substantia nigra, thalamic and subthalamic nuclei, lateral to the internal capsule (Figs 22.9, 22.10).

Function and dysfunction

Overall function of this system is modulation of cortical motor activity by a series of servo loops between cortex and basal ganglia (Fig. 22.10). In involuntary movement disorders there are specific changes in neurotransmitters (Table 22.5) rather than focal lesions seen on imaging or at autopsy.

Figure 22.10 Extrapyramidal system: connections and neurotransmitters. The inhibitory pathways are in blue (B, C, D, F, G) and excitatory in red (A, E, H). VA/VL, ventral anterior and ventrolateral thalamic nuclei. GPi, lateral globus pallidus. GPe, medial globus pallidus. SNr, substantia nigra pars reticulata. GLU, glutamate; ENK, enkephalin; GABA, γ -aminobutyric acid.

The model helps explain how basal ganglia disease can either reduce excitatory thalamo-cortical activity at synapse H, i.e. movement – causing bradykinesia, or increase it, causing dyskinesias.

Parkinson's disease (PD). This is characterized by slowness, stiffness and rest tremor (p. 1118). Degeneration in SNc causes loss of dopamine activity in the striatum. Dopamine is excitatory for synapse A and inhibitory for synapse B. Through the direct pathway there is reduced activity at synapse F, leading to increased inhibitory output (G) and decreased cortical activity (H).

Also in PD, in the indirect pathway, dopamine deficiency results in disinhibition of neurones synapsing at C. This leads to reduced activity at D, and to increased activity of neurones in the subthalamic nucleus. There is excess stimulation at synapse E, enhancing further inhibitory output of GPe-SNr.

The net effect via both pathways is to inhibit the ventral anterior (VA) and ventrolateral (VL) nuclei of the thalamus at synapse G. Cortical (motor) activity at H is thus reduced.

Levodopa helps slowness and tremor in PD (p. 1119) but induces unwanted dyskinesias by increasing dopamine activity at synapses A and B, it is thought by reversing sequences in both direct and indirect pathways.

Hemiballismus (p. 1121). Wild, flinging (ballistic) limb movements are caused by a lesion in the subthalamic nucleus, typically an infarct. This reduces excitatory activity at synapse E, reduces inhibition at G, with increased thalamo-cortical neuronal activity, and increases activity at H.

Table 22.5 Changes in neurotransmitters in Parkinson's and Huntington's diseases

Condition	Site	Neurotransmitter
Parkinson's	Putamen	Dopamine ↓ 90% Norepinephrine (noradrenaline) ↓ 60% 5-HT ↓ 60%
	Substantia nigra	Dopamine ↓ 90% GAD + GABA ↓↓ GAD + GABA ↓↓
	Cerebral cortex	GAD + GABA ↓↓
Huntington's	Corpus striatum	Acetylcholine ↓↓ GABA ↓↓ Dopamine: normal GAD + GABA ↓↓

GABA, γ -aminobutyric acid; GAD, glutamic acid decarboxylase, the enzyme responsible for synthesizing GABA; 5-HT, 5-hydroxytryptamine.

Proposed model of principal pathways

1. Direct pathway from striatum to medial globus pallidus (GPe) and substantia nigra pars reticulata (SNr). Inhibitory **synapse F**, GABA and substance P.
2. Indirect pathway from striatum to globus pallidus; via lateral globus pallidus (GPi; inhibitory **synapse C**, GABA, enkephalin) and subthalamic nucleus (inhibitory **synapse D**, GABA). Terminates in GPe-SNr (in excitatory **synapse E**, glutamate).
3. Direct pathways, both inhibitory and excitatory from substantia nigra pars compacta (SNc) to striatum. **Synapse A**, dopamine, D₁, excitatory; and **synapse B**, D₂, inhibitory.
4. GPe and SNr to thalamus. Inhibitory **synapse G**, GABA.
5. Thalamus to cortex. Excitatory, **synapse H**.
6. Cortex to striatum. Excitatory, glutamate.

Cerebellum

The third system of motor control modulates coordination and learned movement patterns, rather than speed. Ataxia, i.e. unsteadiness, is characteristic.

The cerebellum receives afferents from:

- proprioceptive receptors (joints and muscles)
- vestibular nuclei
- basal ganglia
- the corticospinal system
- olivary nuclei.

Efferents pass from the cerebellum to:

- each red nucleus
- vestibular nuclei
- basal ganglia
- corticospinal system.

Each lateral cerebellar lobe coordinates movement of the ipsilateral limbs. The vermis (a midline structure) is concerned with maintenance of axial (midline) posture and balance.

Cerebellar lesions (Box 22.9)

Expanding lesions obstruct the aqueduct to cause hydrocephalus, with severe pressure headaches, vomiting and papilloedema. Coning of the cerebellar tonsils (p. 1133) through the foramen magnum leads to respiratory arrest, sometimes within minutes/hours. Rarely, tonic seizures (attacks of limb stiffness) occur.

Lateral cerebellar hemisphere lesions

A lesion within one cerebellar lobe (e.g. tumour or infarction) causes disruption of the normal sequence of movements (dysynergia) on the same side.

Box 22.9 Principal causes of cerebellar syndromes

Tumours

Toxic and metabolic

- Antiepileptic drugs
- Chronic alcohol use
- Carbon monoxide poisoning
- Lead poisoning
- Solvent abuse

Inherited

- Friedreich's and other spinocerebellar ataxias
- Ataxia telangiectasia
- Essential tremor

Miscellaneous

- Multiple sclerosis
- Hydrocephalus
- Postinfective (childhood)
- Hypothyroidism
- Paraneoplastic syndromes
- High altitude cerebral oedema

Posture and gait. The outstretched arm is held still in the early stages of a cerebellar lobar lesion (cf. the drift of pyramidal lesions) but there is rebound upward overshoot when the limb is pressed downwards and released. Gait becomes broad and ataxic, faltering towards the side of the lesion.

Tremor and ataxia. Movement is imprecise in direction, force and distance (dysmetria). Rapid alternating movements (tapping, clapping or rotary hand movements) become disorganized (dysdiadochokinesis). Intention tremor (action tremor with past-pointing) is seen, but speed of fine movement is preserved, cf. extrapyramidal and pyramidal lesions.

Nystagmus. Coarse horizontal nystagmus (p. 1075) develops with a lateral cerebellar lobe lesion. The fast component is always towards the side of the lesion.

Dysarthria. Halting, jerking speech develops – scanning speech.

Other signs. Titubation – rhythmic head tremor as either forward and back (yes-yes) movements or rotary (no-no) movements – can occur, mainly when cerebellar connections are involved (e.g. in essential tremor and MS, pp. 1080 and 1124). Hypotonia (floppy limbs) and depression of reflexes (with slow, pendular reflexes) are also sometimes seen.

Midline cerebellar lesions

Cerebellar vermis lesions have dramatic effects on trunk and axial muscles. There is difficulty standing and sitting unsupported (truncal ataxia), with a rolling, broad, ataxic gait. Lesions of the flocculonodular region cause vertigo and vomiting with gait ataxia if they extend to the roof of the IVth ventricle. Box 22.9 summarizes the main causes of cerebellar disease.

Tremor

Tremor means a regular and sinusoidal oscillation of the limbs, head or trunk.

Postural tremor

Everyone has a physiological tremor (often barely perceptible) of the outstretched hands at 8–12 Hz. This is increased with anxiety, caffeine, hyperthyroidism and drugs (e.g.

Box 22.10 Features of lower motor neurone lesions

- Weakness

- Hypotonia
- Reflex loss
- Fasciculation
- Fibrillation potentials (EMG)
- Muscle contractures
- Trophic changes in skin and nails

sympathomimetics, sodium valproate, lithium) and occurs in mercury poisoning. A coarser, postural tremor is seen in benign essential tremor (usually at 5–8 Hz) and in chronic alcohol use.

Intention tremor

Tremor exacerbated by action, with past-pointing and accompanying incoordination of rapid alternating movement (dysdiadochokinesis), occurs in cerebellar lobe disease and with lesions of cerebellar connections. Titubation and nystagmus may be present.

Rest tremor

Seen typically in Parkinson's disease, this tremor is noticeably worse at rest, usually 4–7 Hz (pill-rolling, between thumb and forefinger).

Other tremors

Coarse tremor is seen following lesions of the red nucleus (e.g. infarction, multiple sclerosis) and rarely with frontal lesions.

LOWER MOTOR NEURONE (LMN) LESIONS

The LMN is the pathway from anterior horn cell (or cranial nerve nucleus) via a peripheral nerve to muscle motor endplates. The motor unit consists of one anterior horn cell, its single fast-conducting axon that leaves the cord via the anterior root, and the group of muscle fibres (100–2000) supplied via the nerve. Anterior horn cell activity is modulated by impulses from:

- corticospinal tracts
- extrapyramidal system
- cerebellum
- afferents via posterior roots.

Signs of lower motor neurone lesions

These are seen in voluntary muscles that depend upon an intact nerve supply both for contraction and metabolic integrity. Signs follow rapidly if the LMN is interrupted (Box 22.10).

Causes

Examples of LMN lesions at various levels:

- Cranial nerve nuclei (Bell's palsy) and anterior horn cell (motor neurone disease)
- Spinal root – cervical and lumbar disc protrusion, neuralgic amyotrophy (p. 1149)
- Peripheral (or cranial) nerve – trauma, entrapment (p. 1144), polyneuropathy (p. 1145).

Figure 22.11 Knee jerk: a spinal reflex arc. Sudden patellar tendon stretching generates sensory action potentials in 1α muscle spindle afferents that synapse with γ -motor fibres to spindles and α -motor fibres. Motor action potentials cause brisk extensor muscle contraction; there is also inhibition of knee flexors.

Table 22.6 Spinal levels, recording/interpretation of tendon reflexes

Level	Reflex	Symbol	Meaning
C5–6	Supinator	0	Absent
C5–6	Biceps	±	Present with reinforcement
C7	Triceps	+	Normal
L3–4	Knee	++	Brisk, normal
S1	Ankle	+++ CL	Exaggerated (abnormal) Clonus

Spinal reflex arc

Components are illustrated in Figure 22.11. The stretch reflex is the physiological basis for all tendon reflexes. In the knee jerk, a tap on the patellar tendon activates stretch receptors in the quadriceps. Impulses in first-order sensory neurones pass directly to LMNs (L3 and L4) that contract quadriceps. Loss of a tendon reflex is caused by a lesion anywhere along the spinal reflex path. The reflex lost indicates its level (Table 22.6).

Reinforcement. Distraction of the patient's attention, clenching teeth or pulling interlocked fingers enhances reflex activity. Such reinforcement manoeuvres should be done before a reflex is recorded as absent.

SENSORY PATHWAYS AND PAIN

Peripheral nerves and spinal roots

Peripheral nerves carry all modalities of sensation from either free or specialized nerve endings to dorsal roots and thence to the cord. Sensory distribution of spinal roots (dermatomes) is shown in Figure 22.12.

Spinal cord

Posterior columns

Axons in the posterior columns whose cell bodies are in the ipsilateral gracile and cuneate nuclei in the medulla

Figure 22.12 Dermatomes of spinal roots and Vth nerve.

Figure 22.13 Principal sensory pathways. Posterior columns remain uncrossed until the medulla. Spinothalamic tracts cross close to their entry into the cord.

carry sensory modalities of vibration, joint position (proprioception), light touch and two-point discrimination. Axons from second-order neurones then cross in the brainstem to form the medial lemniscus, passing to the thalamus (Fig. 22.13).

Lower motor neurone (LMN) lesions

Sensory pathways and pain

Spinothalamic tracts

Axons carrying pain and temperature sensation synapse in the dorsal horn of the cord, cross within the cord and pass in the spinothalamic tracts to the thalamus and reticular formation.

Sensory cortex

Fibres from the thalamus pass to the parietal region sensory cortex (Fig. 22.13). Connections exist between the thalamus, sensory cortex and motor cortex.

Lesions of the sensory pathways

Altered sensation (paraesthesia), tingling, clumsiness, numbness and pain are the principal symptoms of sensory lesions. The pattern and distribution point to the site of pathology (Fig. 22.14).

Peripheral nerve lesions

Symptoms are felt within the distribution of a peripheral nerve (p. 1143). Section of a sensory nerve is followed by complete sensory loss. Nerve entrapment (p. 1144) causes numbness, pain and tingling. Tapping the site of compression sometimes causes a sharp, electric-shock-like pain in the distribution of the nerve, known as Tinel's sign, e.g. in carpal tunnel syndrome (p. 1144).

Neuralgia

Neuralgia refers to pain, usually of great severity, in the distribution of a damaged nerve. Examples are:

- Trigeminal neuralgia (p. 1110)
- Postherpetic neuralgia (p. 1129)
- Complex regional pain syndrome type II (causalgia) – chronic burning pain that occasionally follows nerve section.

Spinal root lesions

Root pain

Pain of root compression is felt in the myotome supplied by the root, and there is also a tingling discomfort in the dermatome. The pain is worsened by manoeuvres that either stretch the root (e.g. straight leg raising in lumbar disc prolapse) or increase pressure in the spinal subarachnoid space (coughing and straining). Cervical and lumbar disc protrusions (p. 1148) are common causes of root lesions.

Dorsal spinal root lesions

Section of a dorsal root causes loss of all modalities of sensation within a dermatome (see Fig. 22.12). However, overlap between adjacent dermatomes makes it difficult to detect anaesthesia when a single root is destroyed.

Lightning pains. Tabes dorsalis (rare in the UK) is a form of neurosyphilis that causes low-grade inflammation

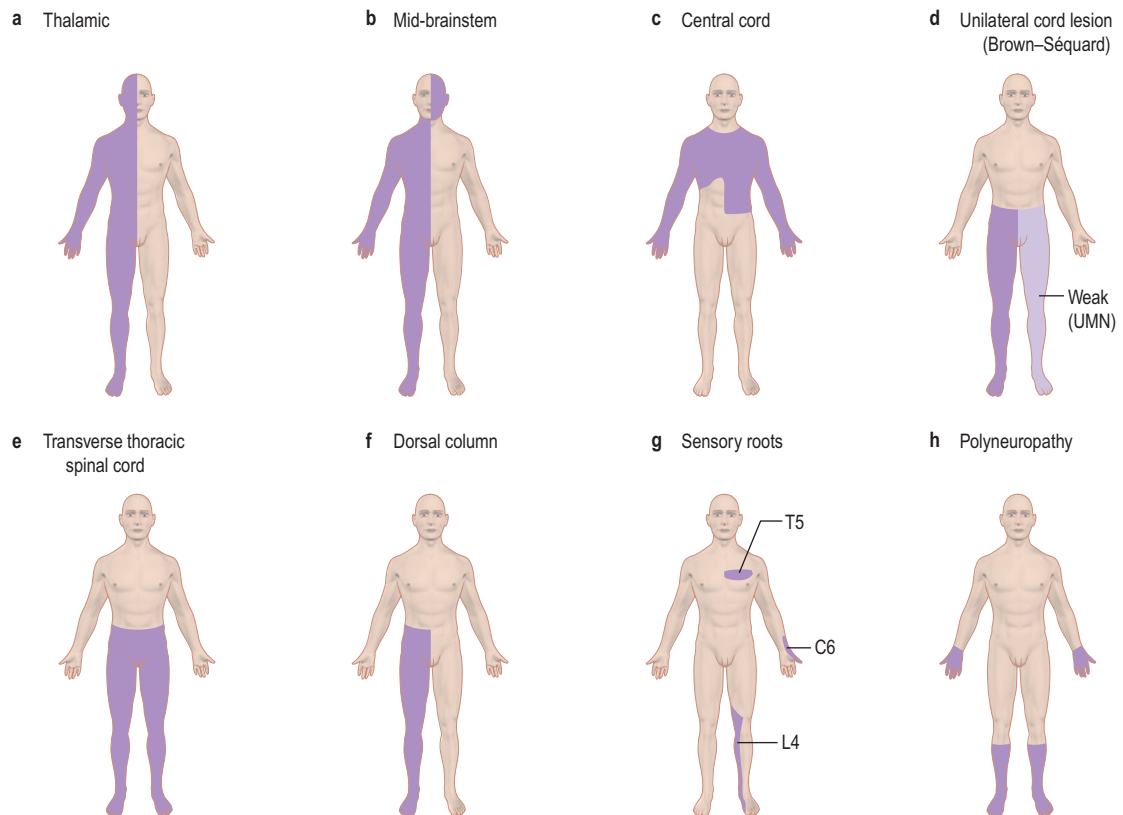

Figure 22.14 Principal patterns of loss of sensation. (a) Thalamic lesion: sensory loss throughout opposite side (rare). (b) Brainstem lesion: contralateral sensory loss below face and ipsilateral loss on face. (c) Central cord lesion, e.g. syrinx: 'suspended' areas of loss, often asymmetrical and 'dissociated', i.e. pain and temperature loss but light touch intact. (d) Hemisection of cord/unilateral cord lesion = Brown-Séquard syndrome: contralateral spinothalamic (pain and temperature) loss with ipsilateral weakness and dorsal column loss below lesion. (e) Transverse cord lesion: loss of all modalities, including motor, below lesion. (f) Dorsal column lesion, e.g. MS: loss of proprioception, vibration and light touch. (g) Individual sensory root lesions, e.g. C6, T5, L4. (h) Polyneuropathy: distal sensory loss.

of dorsal roots and spinal cord root entry zones. Irregular, sharp, stabbing pains (like lightning) involve one or two spots, typically in a calf, thigh or ankle.

Spinal cord lesions

Posterior column lesions

These cause:

- Tingling
- Electric-shock-like sensations
- Clumsiness
- Numbness
- Band-like sensations.

These symptoms, though lateralized, are often felt vaguely without a clear sensory level. Position sense, vibration sense, light touch and two-point discrimination are diminished below the lesion. Position sense loss produces a stamping gait (sensory ataxia, p. 1068).

Lhermitte's phenomenon

Electric-shock-like sensations radiate down the trunk and limbs on neck flexion. This points to a cervical cord lesion. Lhermitte's is common in acute exacerbations of MS (p. 1124), and also occurs in cervical myelopathy (p. 1149), subacute combined degeneration of the cord (p. 1147), radiation myelopathy (p. 1149) and cord compression.

Spinothalamic tract lesions

Pure spinothalamic spinal lesions cause contralateral loss of pain and temperature sensation with a clear level below the lesion. This is called *dissociated* sensory loss – pain and temperature are dissociated from light touch, which remains preserved. This is seen typically in syringomyelia where a cavity occupies the central cord (p. 1137).

The spinal level is modified by lamination of fibres within the spinothalamic tracts. Fibres from lower spinal roots lie superficially and are damaged first by compressive lesions from outside the cord. As an external compressive lesion (e.g. a midthoracic extradural meningioma; Fig. 22.15) enlarges, the spinal sensory level ascends as deeper fibres become involved. Conversely, a central cord lesion (e.g. a

syrinx, p. 1137) affects deeper fibres first. Spinothalamic tract lesions cause loss of pain and temperature perception (e.g. painless burns). Perforating ulcers and neuropathic (Charcot) joints develop.

Spinal cord compression (Fig. 22.15)

Cord compression causes progressive spastic paraparesis (or tetraparesis/quadruparesis) with sensory loss below the level of compression. Sphincter disturbance is common. Root pain is frequent but not invariable, felt characteristically at the level of compression. With thoracic cord compression (e.g. an extradural meningioma), pain radiates around the chest, exacerbated by coughing and straining, as meningeal root sheaths are stretched.

Damage to one spinothalamic tract (contralateral loss of pain and temperature) with the ipsilateral corticospinal tract is known as the *Brown-Séquard syndrome* (originally, cord hemisection). The patient complains of numbness on one side and weakness on the other. Paraparesis/spinal cord lesions are discussed on page 1135.

Pontine lesions

Since lesions (e.g. an MS plaque) lie above the decussation of the posterior columns, and both medial lemniscus and spinothalamic tracts are close together, there is loss of all forms of sensation on the side opposite the lesion. Combinations of III, IV, V, VI and VII cranial nerve nuclei are seen, and may indicate a level (Fig. 22.13).

Thalamic lesions

Thalamic pain (also called *central post-stroke pain* or *thalamic syndrome*) follows a small thalamic infarct. The patient has a stroke (hemiparesis and sensory loss). Weakness improves, but deep-seated constant pain in the paretic limbs develops. Choreo-athetotic movements occur. Secondary depression may lead to self-harm. Thalamic lesions can also cause diminished sensation alone, on the opposite side; this is less usual.

Parietal cortex lesions

Sensory loss, neglect of one side, apraxia (p. 1068) and subtle disorders of sensation occur. Pain is not a feature of destructive cortical lesions. Irritative phenomena (e.g. partial sensory seizures from a parietal cortex glioma) cause tingling sensations in a limb, or elsewhere.

Pain

Pain is an unpleasant, unique physical and psychological experience. Acute pain serves a biological purpose (e.g. withdrawal) and is typically self-limiting, ceasing as healing ensues. Some forms of chronic pain (e.g. causalgia) outlast the period required for healing, and may be permanent.

Essential physiology of pain

Pain perception is mediated by free nerve endings, terminations of finely myelinated A-delta and of non-myelinated C fibres. Chemicals released following injury produce pain either by direct stimulation or by sensitizing nerve endings. A-delta fibres give rise to perception of sharp, immediate pain, then slower-onset, more diffuse and prolonged pain is mediated by slower-conducting C fibres.

Sensory impulses enter the cord via dorsal spinal roots. Impulses ascend either in each dorsal (posterior) column or in each spinothalamic tract. Grey matter neurones in the cord

Figure 22.15 Spinal cord compression: features and anatomy.

American Society of Anesthesiologists Task Force on Chronic Pain Management and the American Society of Regional Anesthesia and Pain Medicine. Practice guidelines for chronic pain management. *Anesthesiology* 2010; 112: 810–833.

Turk DC, Wilson HD, Cahana A. Treatment of chronic non-cancer pain. *Lancet* 2011; 377:2226–2235.

are arranged in laminae labelled I–X (dorsal to ventral). A fibres terminate in laminae I and V and excite second-order neurones that project to the contralateral side via the anterior commissure and via the anterolateral column of the direct spinothalamic tract. C fibres mostly terminate in the substantia gelatinosa (laminae II and III); axons then pass through the anterior commissure to the contralateral side and rostrally, up the spino-reticulo-thalamic tract.

The spinothalamic tracts carry impulses that localize pain. Thalamic pathways to and from the cortex mediate emotional components. Sympathetic activity increases pain, e.g. hyperaemia in a painful limb.

Gate theory of pain

Gate theory, a useful way of thinking about pain, proposes that entry of afferent impulses is monitored first by the substantia gelatinosa. This gate determines whether or not sufficient activity penetrates to fire secondary neurones in the dorsal horn. This, and subsequent gates, are influenced by brain and cord regulators that alter how far a gate remains open.

Animal studies suggest that downstream regulators binding to calcium-regulated transcription factors *control* CNS endogenous opiate precursors (e.g. pro-dynorphin). These modulate pain.

Endogenous opiates

Endorphin peptides have opioid activity and probably account for placebo phenomena, effects of stress and acupuncture, and may explain in part why some patients develop chronic pain syndromes. Endorphins are CNS neurotransmitters acting at inhibitory synapses via δ , κ and μ -receptors. Dynorphin (from the precursor, pro-dynorphin) is thought to modulate nociceptive (pain) impulses entering the cord.

Management of chronic pain

Chronic pain is gravely disabling, distressing, and taxing to treat (p. 509). Multidisciplinary pain-relief clinics provide specific and supportive therapy.

Management plans for intractable pain have seven components:

Diagnostic

Rigorous attention must be paid to the diagnosis, reviewing the entire history and investigations. A specific surgical approach may become apparent (e.g. spinal stenosis, trigeminal neuralgia, glossopharyngeal neuralgia, or syringomyelia).

Psychological

Chronic pain influences quality of life. Depression (p. 1170) is commonly associated with pain when the pathology is benign; antidepressants can help. Of patients suffering pain from secondary cancer about one-third are clinically depressed.

Analgesics

Perseverance and compliance with therapy is a common problem. The WHO analgesic ladder (p. 487) is useful.

Co-analgesics

Co-analgesics have a primary use other than for pain but help either alone or when added to analgesics. Examples are:

- Tricyclic antidepressants, e.g. amitriptyline
- Duloxetine – a serotonin-norepinephrine reuptake blocker

- Anticonvulsants, e.g. carbamazepine, gabapentin and pregabalin (p. 486)
- Calcium-channel blockers, e.g. ziconotide used intrathecally in chronic refractory pain
- Muscle relaxants (spasticity)
- Capsaicin topical preparations – extracts from capsicum plants (chilli peppers) which bind to vanilloid receptors on pain neurones and deplete them of neurotransmitters such as substance P.

Stimulation

Acupuncture, ice, heat, ultrasound, massage, transcutaneous electrical nerve stimulation (TENS) and spinal cord stimulation all achieve analgesia by gating effects on large myelinated nerve fibres.

Nerve blocks

Pain pathways can be blocked either temporarily by local anaesthetic (by injection or with topical patches) or permanently with phenol, or radiofrequency lesions:

- Somatic blocks:
 - peripheral nerve and plexus injections
 - epidural and spinal analgesia
- Sympathetic blocks:
 - sympathetic ganglia injections
 - central epidural and spinal sympathetic blockade.

Neurosurgery

Highly specialized techniques have a place alongside drugs. Examples are dorsal rhizotomy, sympathectomy, cordotomy and neurostimulation.

BLADDER CONTROL AND SEXUAL DYSFUNCTION

Changes in micturition and failure of normal sexual activity due to neurological conditions are seen in sacral, spinal cord and cortical disease.

Essential functions and anatomy

The bladder has two functions: storage and voiding. Afferent pathways (T12–S4) respond to pressure within the bladder and sensation from the genitalia. As the bladder distends, continence is maintained by suppression of parasympathetic and reciprocal activation of sympathetic outflow. Both are under some voluntary control. Voiding takes place by parasympathetic activation of the detrusor, and relaxation of the internal sphincter (Table 22.7).

Cortical awareness of bladder fullness is located in the post-central gyrus, parasagittally, while initiation of

Table 22.7 Efferents to bladder and genitalia

Nerve supply	Function
Parasympathetic S2–4	Bladder wall: contraction Internal sphincter: relaxation Penis/clitoris: engorgement
Sympathetic T12–L2	Bladder wall: relaxation Internal sphincter: contraction Orgasm, ejaculation
Pudendal nerves	External sphincter (skeletal muscle)

micturition is in the pre-central gyrus. Voluntary control of micturition is located in the frontal cortex, parasagittally.

Neurological disorders of micturition

Urogenital tract disease is dealt with largely by urologists. Incontinence is common and easy to recognize; neurological causes are sometimes not obvious. These are:

Cortical:

- Post-central lesions cause loss of sense of bladder fullness
- Pre-central lesions cause difficulty initiating micturition
- Frontal lesions cause socially inappropriate micturition.

Spinal cord. Bilateral UMN lesions (pyramidal tracts) cause urinary frequency and incontinence. The bladder is small and hypertonic, i.e. sensitive to small changes in intravesical pressure. Frontal lesions can also cause a hypertonic bladder.

LMN. Sacral lesions (conus medullaris, sacral root and pelvic nerve – *bilateral*) cause a flaccid, atonic bladder that overflows (cauda equina, p. 1149), often unexpectedly.

Management. Assessment of both urological causes (e.g. calculi, prostatism, gynaecological problems) and potential neurological causes of incontinence is necessary. Intermittent self-catheterization is used by many patients, with for example spinal cord lesions.

Male erectile dysfunction

Failure of penile erection often has mixed organic and psychological causes. Depression is common. Endocrine aspects of sexual dysfunction are described on page 977. Erectile dysfunction is sometimes helped by phosphodiesterase type 5 inhibitors, e.g. sildenafil.

NEUROLOGICAL TESTS

Neuro-imaging

Skull and spinal X-rays

These show:

- Fractures of the vault or base
- Vault and skull base disease (e.g. metastases, osteomyelitis, Paget's disease, abnormal skull foramina, fibrous dysplasia)
- Enlargement or destruction of the pituitary fossa – intrasellar tumour, raised intracranial pressure
- Intracranial calcification – tuberculoma, oligodendroglioma, wall of an aneurysm, cysticercosis.

Spinal X-rays show fractures, congenital and destructive lesions (bone cysts, infection, metastases) and degenerative spondylosis.

Imaging brain and spinal cord

Brain CT and MRI are widely available worldwide. Myelography (contrast imaging of the cord and ventricles; ventriculography) is obsolete.

Brain computed tomography (CT)

A collimated X-ray beam moves synchronously across a brain slice 2–13 mm thick. Transmitted X-irradiation from a pixel, an element $<1 \text{ mm}^2$, is computer-processed to assign

a Hounsfield number to its density (air = -1000 units; water = 0 ; bone = $+1000$ units). The digital data are converted to cross-sectional images to reconstruct brain anatomy. Helical CT (spiral or volumetric CT) provides greater definition in a shorter time. It is used for two-dimensional reconstruction.

Differences in attenuation (density) between bone, brain and CSF enable recognition of normal and infarcted tissue, tumour, blood, intracerebral haemorrhage, free subarachnoid blood, subdural and extradural haematoma and oedema.

Enhancement with i.v. contrast delineates areas of altered blood supply (CT angiography).

Safety. The irradiation involved is relatively small. There are occasional reactions to contrast.

Limitations of brain CT

- Lesions under 1 cm in diameter may be missed.
- Lesions with attenuation close to bone may be missed, if near the skull.
- Lesions with attenuation similar to brain are poorly displayed (e.g. MS plaques, isodense subdural haematoma).
- CT is not good at detecting posterior fossa lesions because of surrounding bone.
- Patient cooperation: an anaesthetic is very occasionally needed.

Magnetic resonance imaging: MRI

A hydrogen nucleus is a proton whose electrical charge creates a local electrical field. Protons are aligned by sudden strong magnetic impulses and then imaged with radio-frequency waves at right angles to their alignment. The protons resonate and spin, then revert to their normal alignment. As they do so, images are made at different phases of relaxation, known as T_1 , T_2 , T_2 STIR, FLAIR, diffusion-weighted imaging (DWI) and other sequences. From these sequences, often referred to as different weightings, recorded images are compared. Gadolinium is used as i.v. contrast to show areas of increased vascularity.

Advantages of MRI

- MR distinguishes between white and grey matter in the brain and cord.
- Cord and nerve roots are imaged directly.
- Pituitary imaging.
- MRI has resolution superior to CT (around 0.5 cm).
- No radiation is involved.
- MR angiography (MRA) images blood vessels without contrast.
- MR images soft tissues.
- Tumours, infarction, haemorrhage, MS plaques, posterior fossa, foramen magnum and cord are demonstrated well by MRI.

Limitations are principally time and cost. Patients need to keep still within a narrow tube: claustrophobia is an issue; open machines are available that are less claustrophobic. Patients with pacemakers or metallic fragments in the brain cannot be imaged. MR imaging frequently shows diffuse meningeal enhancement with gadolinium for some days after lumbar puncture (p. 1091).

Doppler studies

B-mode and colour ultrasound are valuable in detection of carotid stenosis.

Bladder control and sexual dysfunction

Neurological tests

Rees PM, Fowler C, Maas C. Sexual function in men and women with neurological disorders. *Lancet* 2007; 369:512–525.

a

b

Extradural haematoma.

Digital cerebral and spinal angiography

Where advanced MRI and CT are available, these techniques are little used. Contrast is injected intra-arterially or intravenously. Angiography carries a mortality and stroke risk (<1%). Images of aorta, carotid, vertebral and brain arteries demonstrate occlusion, stenoses, atheroma, aneurysms and arteriovenous malformations (AVMs). Spinal angiography images cord AVMs.

Positron emission tomography (PET), single photon emission computed tomography (SPECT), dopamine transporter imaging (DAT) and functional MRI (fMRI)

These functional imaging techniques track uptake of radioisotopes and/or metabolites. PET is used principally in the detection of occult neoplasms, outside the CNS. SPECT is little used in cerebrovascular disease and traumatic brain injury – there are issues of reliability. DAT is used in basal ganglia disease. fMRI is largely a research tool for mapping brain function, in health and disease.

Isotope bone scanning

The radioisotope [^{99m}Tc]-pertechnetate is given intravenously. The technique is used principally in detection of vertebral, skull and bone metastases.

Electroencephalography (EEG)

EEG (Fig. 22.16) recorded from scalp electrodes (16 channels simultaneously) is of value in epilepsy and diffuse brain diseases. Videotelemetry, combining EEG with video, is invaluable in attacks difficult to diagnose.

Epilepsy

Spikes, or spike-and-wave abnormalities, are hallmarks of epilepsy, but it should be emphasized that patients with epilepsy often have a normal EEG between seizures (p. 1092).

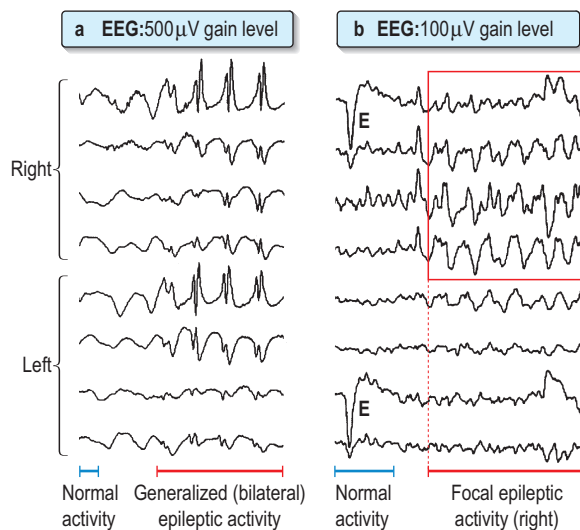

Figure 22.16 Examples of EEG traces. (a) Normal activity followed by generalized epileptic spikes in all leads. (b) Normal activity followed by focal spikes in right leads. E, eye-movement artefact.

Diffuse brain disorders

Slow-wave EEG abnormalities appear in encephalitis, prion (Creutzfeldt-Jakob) diseases and metabolic states (e.g. hypoglycaemia, hepatic coma).

Brain death

The EEG is isoelectric (flat); EEG is no longer necessary to confirm brain death (p. 898).

Electromyography and conduction studies

Electromyography

A concentric needle electrode is inserted into voluntary muscle. Amplified recordings, on an oscilloscope, are also heard through a speaker. The main EMG features:

- Normal interference pattern
- Denervation and reinnervation changes
- Myopathic, myotonic and myasthenic changes (p. 1090).

Peripheral nerve conduction (Fig. 22.17)

Four measurements are of principal value in neuropathies and nerve entrapment:

- Mean nerve (motor and sensory) conduction velocity
- Distal motor latency
- Sensory action potentials
- Muscle action potentials.

Measurements differentiate between axonal and demyelinating damage and determine whether pathology is focal or diffuse.

Cerebral-evoked potentials

Visual-evoked potentials (VEPs) record the interval visual stimuli take to reach the occipital cortex, and the amplitude

Figure 22.17 Measurement of motor conduction velocity (MCV) in ulnar nerve. The recording electrode on abductor pollicis brevis measures muscle action potential (M) from ulnar nerve stimulation at elbow (Stimulus 1) and at wrist (Stimulus 2).

MCV calculation:

M_1 = muscle action potential (MAP) from Stimulus 1

M_2 = MAP from Stimulus 2

T_1 = time from elbow to recording electrode

T_2 = time from wrist to recording electrode

$$\text{MCV} = \frac{\text{distance (metres)}}{T_1 - T_2} \times 1000 = \text{m/s}$$

Table 22.8 The normal CSF

Appearance	Crystal clear, colourless
Pressure	60–150 mm of CSF, recumbent
Cell count	<5/mm ³ No polymorphs Mononuclear cells only
Protein	0.2–0.4 g/L
Glucose	$\frac{2}{3}$ – $\frac{1}{2}$ of blood glucose
IgG	<15% of total CSF protein
Oligoclonal bands	Absent

of response. VEPs are used to confirm previous retrobulbar neuritis (p. 1073); this leaves a delayed latency despite clinical recovery.

Similar techniques for auditory and somatosensory potentials (from a limb) are also used.

Lumbar puncture and CSF examination

See Table 22.8 and Practical Box 22.3.

Indications for lumbar puncture (LP):

- Diagnosis of meningitis and encephalitis
- Diagnosis of subarachnoid haemorrhage (sometimes)
- Measurement of CSF pressure, e.g. idiopathic intracranial hypertension (p. 1110)
- Removal of CSF therapeutically, e.g. idiopathic intracranial hypertension
- Diagnosis of various conditions, e.g. MS, neurosyphilis, sarcoidosis, Behçet's, neoplastic involvement, polyneuropathies
- Intrathecal injection/drugs.

Meticulous attention should focus on microbiology in suspected CNS infection. Close liaison between clinician and microbiologist is essential. Specific techniques (e.g. polymerase chain reaction to identify bacteria) are invaluable. Repeated CSF examination is often necessary in chronic infection such as tuberculosis. Post-LP headaches, worse on standing, are a common complaint for several days (or more). Prolonged headaches can be treated by an 'autologous intrathecal blood patch' – injection of 20 mL of the patient's venous blood into the CSF.

Biopsy

Interpretation of brain, tonsillar, muscle and nerve histology requires specialist neuropathology services.

Brain and meninges

Brain biopsy (e.g. of a non-dominant frontal lobe) is sometimes used to diagnose inflammatory and degenerative brain diseases. CT and MR stereotactic biopsies of intracranial lesions are standard procedures.

Tonsillar biopsy

This is used in the diagnosis of variant Creutzfeldt-Jakob disease.

Muscle

Biopsy, with light and electron microscopy and biochemical analysis, elucidates diagnosis of inflammatory, metabolic and dystrophic disorders (p. 1152).

Practical Box 22.3

Lumbar puncture

The procedure should be explained to the patient, and consent obtained. LP should not be performed in the presence of raised intracranial pressure or when an intracranial mass lesion is a possibility.

Technique

- The patient is placed on the edge of the bed in the left lateral position with knees and chin as close together as possible.
- The third and fourth lumbar spines are marked. The fourth lumbar spine usually lies on a line joining the iliac crests.
- Using sterile precautions, 2% lidocaine is injected into the dermis by raising a bleb in either the third or fourth lumbar interspace.
- The LP needle is pushed through the skin in the midline, steadily forwards and slightly towards the head, with the head and spine bolstered horizontally with pillows.
- When the needle is felt to penetrate the dura, the stylet is withdrawn and a few drops of CSF allowed to escape.
- The CSF pressure can then be measured with a manometer connected to the needle. The patient's head must be on the same level as the sacrum. Normal CSF pressure is 60–150 mm of CSF. The level rises and falls with respiration and heart beat, and rises on coughing.
- CSF specimens are collected in three sterile bottles and a sample for CSF glucose, together with a simultaneous blood glucose sample.
- Record CSF naked-eye appearance: clear, cloudy, yellow (xanthochromic), red.
- The patient is asked to lie flat after the procedure to avoid subsequent headaches, but this manoeuvre is probably of little value.
- Analgesics may be required for post-LP headaches.

Contraindications

- Suspicion of a mass lesion in the brain or cord. Caudal herniation of the cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF
- Any cause of raised intracranial pressure
- Local infection near the LP site
- Congenital lesions in the lumbosacral region (e.g. meningocele)
- Platelet count $<40 \times 10^9/L$ and other clotting abnormalities, including anticoagulant drugs
- Unconscious patients and those with papilloedema must have a CT scan before lumbar puncture.

Notes

- Contraindications are relative; there are circumstances when LP is carried out despite them.
- Composition of normal CSF is shown in Table 22.8.

FURTHER READING

Cruse D et al. Bedside detection of awareness in the vegetative state. *Lancet* 2011; 378:2088–2094.

Peripheral nerve

Biopsy, usually of a sural nerve (ankle) or superficial branch of a radial nerve, aids diagnosis in polyneuropathies.

Psychometric assessment

Psychometric testing assesses cognitive function. Preservation of verbal IQ (a measure of past attainments) with deterioration of performance IQ (a measure of present abilities) indicates decline of cognitive function, seen for example following brain injury or in dementia. Low subtest scores (e.g. block design, various aspects of memory, visual, speech and constructional skills) indicate impaired function of specific brain regions.

Depression and lack of attention also reduce scores – a substantial problem. Opinions sometimes vary between psychologists about interpretation of tests, particularly after brain injury, limiting the value of the tests.

Table 22.9 Value of routine investigations neurology

Test	Yield	Condition
Urinalysis	Glycosuria Ketones Bence Jones protein	Polyneuropathy Coma Cord compression

Serum calcium	Hypocalcaemia	Tetany, spasms
Serum CPK	Raised	Muscle disease
Chest X-ray	Lytic bone or mass lesion	Bronchial cancer, thymoma

Routine tests

See Table 22.9.

Specialized tests in specific diseases

Various tests are employed to diagnose individual (sometimes rare) diseases. Examples are:

- Anti-cardiolipin and lupus anticoagulant antibody and detailed clotting studies in stroke (p. 538)
- Antibody to acetylcholine receptor protein and anti-MuSK antibodies in myasthenia gravis (p. 1151)
- Serum copper and caeruloplasmin in Wilson's disease (p. 1098)
- Blood lactate studies (failure to rise on exercise) in McArdle's syndrome (p. 1069)
- Anti-neuronal antibodies (paraneoplastic syndromes)
- Serum phytanic acid (elevated) in Refsum's disease
- Serum long-chain fatty acid (present) in adrenoleucodystrophy
- Genetic studies, e.g. Huntington's disease, hereditary sensorimotor neuropathies and ataxias (p. 1121 and p. 1147).

UNCONSCIOUSNESS AND COMA

Consciousness is dependent on the functioning of two separate anatomical and physiological systems:

- The ascending reticular activating system (ARAS) projecting from brainstem to thalamus. This determines arousal (the level of consciousness)
 - The cerebral cortex, which determines the content of consciousness.
- Impaired functioning of either anatomical system may cause coma.

Disturbed consciousness: definitions

- **Coma:** a state of unrousable unresponsiveness. Level of consciousness represents a continuum between being alert and deeply comatose. It may be quantified using the Glasgow Coma Scale (GCS) with a score between 3 and 15 (Table 22.10). Coma may be conveniently defined as a GCS of 8 or lower. Terms such as stupor and obtundation have been superseded by the GCS score and are no longer used.

Table 22.10 Glasgow Coma Scale

	Score

Diffuse brain dysfunction

- Drug overdose (accidental or deliberate), including alcohol
- CO poisoning
- Traumatic brain injury
- Hypoglycaemia, hyperglycaemia
- Severe uraemia (p. 620)
- Hepatic encephalopathy (p. 336)
- Respiratory failure with CO₂ retention (p. 814)
- Hypercalcaemia, hypocalcaemia
- Hypoadrenalism, hypopituitarism and hypothyroidism
- Hyponatraemia, hypernatraemia
- Metabolic acidosis
- Hypothermia, hyperpyrexia
- Seizures – post-ictal state and non-convulsive status
- Metabolic rarities, e.g. porphyria
- Extensive cortical damage
- Hypoxic-ischaemic brain injury, e.g. cardiac arrest
- Encephalitis, meningitis, cerebral malaria
- Subarachnoid haemorrhage

Direct effect within brainstem

- Brainstem haemorrhage, infarction or demyelination
- Brainstem neoplasm, e.g. glioma
- Wernicke–Korsakoff syndrome

Pressure effect on brainstem

- Tumour, massive hemisphere infarction with oedema, haematoma, abscess
- Cerebellar mass

- **Delirium:** The term used to describe a confusional state in which reduced attention is a cardinal feature, usually with altered behaviour, cognition, orientation and a fluctuating level of consciousness (from agitation to hypoarousal) (see p. 1187).

Mechanisms and causes of coma (Box 22.11)

Altered consciousness is produced by four mechanisms affecting the ARAS in the brainstem or thalamus, and/or widespread impairment of cortical function (Fig. 22.18).

- **Brainstem lesion.** A discrete brainstem or thalamic lesion, e.g. stroke may damage the ARAS.
- **Brainstem compression.** A supratentorial mass lesion within the brain compresses the brainstem, inhibiting the ARAS, e.g. 'coning' from a brain tumour or

Figure 22.18 Anatomy of vegetative state, locked-in syndrome and brainstem death. (Adapted from Bates D. *Coma and brainstem death*. Medicine 2004; 32, with permission of Elsevier.)

Figure 22.19 MRI showing extensive cortical damage following meningitis resulting in a permanent vegetative state.

haemorrhage. Mass lesions within the posterior fossa are particularly prone to cause brainstem compression and hydrocephalus.

- **Diffuse brain dysfunction.** Generalized severe metabolic or toxic disorders (e.g. alcohol, sedatives, uraemia, hypercapnia) depress cortical and ARAS function.
- **Massive cortical damage.** Unlike brainstem lesions, extensive damage of the cerebral cortex and cortical connections is required to cause coma, e.g. meningitis or hypoxic-ischaemic damage after cardiac arrest (see Fig. 22.19).

A single focal hemisphere (or cerebellar) lesion does not produce coma unless it compresses the brainstem. Cerebral oedema frequently surrounds masses, increasing their pressure effects.

The commonest causes of coma are:

- Metabolic disorders – 35%
- Drugs and toxins – 25%
- Mass lesions – 20%
- Other – including trauma, stroke and CNS infections.

The unconscious patient

Immediate assessment and management

- Check the airway, breathing and circulation.
- Stix for blood glucose; if hypoglycaemic give glucose (25 mL 50%).

Figure 22.20 Assessing level of consciousness.

- Treat seizures with buccal midazolam and if not terminated, intravenous phenytoin.
- If there is fever and meningism, give intravenous antibiotics.
- Intravenous naloxone or flumazenil (overdose) and thiamine (Wernicke's encephalopathy) in people who use excess alcohol.

Obtain as much history as possible

Limited history is one of the problems faced in assessing the unconscious patient. What were the circumstances? Ask paramedics, police, and witnesses. Contact the patient's relatives, friends and GP and obtain past hospital notes. Look for drug details/bottles and identification data.

General and neurological examination

General examination (Fig. 22.20)

- Measure the patient's temperature (with a low reading rectal thermometer if hypothermic). Check for meningism.
- Sniff the patient's breath for ketones, alcohol and hepatic fetor.
- Survey the skin for signs of trauma or spinal injury, rash (meningococcal sepsis), jaundice or stigmata of chronic liver disease, cyanosis, injection marks.
- Respiratory pattern; e.g. Cheyne–Stokes (alternating hyperpnoea and periods of apnoea indicating bilateral cerebral or upper brainstem dysfunction) or acidotic (Kussmaul) respiration (deep, sighing hyperventilation seen in diabetic ketoacidosis and uraemia).

Neurological examination

Neurological examination aims to determine:

- Depth of coma (GCS)
- Brainstem function
- Lateralization of pathology.

Glasgow Coma Scale

Assessment of the GCS score is repeated regularly to determine whether the patient's level of consciousness is progressively declining. Use painful stimulus (e.g. nail bed pressure) to each limb and central area (sternal rub or pressure over supraorbital nerve) and record *best* response. Shout commands.

Figure 22.21 Examination of the pupils.

Figure 22.22 Medial temporal lobe (uncal) herniation causing compression.

Fundi

Look for papilloedema and subhyaloid retinal haemorrhage (seen in SAH).

Brainstem function

Pupils

Record their size and reaction to light (Fig. 22.21):

- **Dilatation of one pupil** that then becomes fixed to light indicates compression of the IIIrd nerve. This is a potential neurosurgical emergency (Fig. 22.22).
- **Bilateral mid-point reactive pupils** (i.e. normal pupils) are characteristic of metabolic comas and follow coma due to sedative drugs except opiates.
- **Bilateral light-fixed, dilated pupils** are one cardinal sign of brain death. They can occur in deep coma of any cause, but particularly in barbiturate intoxication and hypothermia.
- **Bilateral pinpoint, light-fixed pupils** occur with pontine lesions (e.g. haemorrhage) and with opiates.
- Mydriatic drugs and previous pupillary surgery can cause diagnostic difficulty.

Eye movements and position

- Dysconjugate eyes (divergent ocular axes) indicate a brainstem lesion, e.g. *skew deviation* (one eye up, one eye down; Fig. 22.23).
- Conjugate gaze deviation – towards the lesion in the frontal lobe and the normal limbs (unopposed activity of the intact frontal eye fields drives eyes to the opposite side); away from the lesion in the brainstem and towards

Figure 22.23 Dysconjugate eye position. This usually indicates brainstem lesion (the eyes may be mildly dysconjugate in metabolic coma).

Figure 22.24 Conjugate gaze deviation. (a) Frontal lesion. (b) Brainstem lesion.

Figure 22.25 Doll's eye movements. (a) Normal. (b) Abnormal.

the weak limbs (the PPRF in the pons controls lateral gaze to the ipsilateral side – page 1075) (Fig. 22.24).

- **Vestibulo-ocular reflex.** Passive head turning produces conjugate ocular deviation away from the direction of rotation (doll's head reflex). This reflex disappears in deep coma, in brainstem lesions and in brain death (Fig. 22.25).

- In light coma, slow, side-to-side eye movements are seen ('windscreen wiper' eyes Fig. 22.26). Also seen with extensive cortical damage in deep coma.

Other brainstem reflexes

- Corneal reflex
- Gag/cough reflex (via ET tube if intubated)
- Respiratory drive (p. 794).

Lateralizing signs

Coma makes it difficult to recognize lateralizing signs. These are helpful:

- **Asymmetry of response to visual threat** in a stuporose patient: suggests hemianopia
- **Asymmetry of face.** Drooping or dribbling on one side, blowing in and out of mouth when the paralysed cheek does not move
- **Asymmetry of tone.** Unilateral flaccidity or spasticity may be the only sign of hemiparesis
- **Asymmetry of decerebrate and decorticate posturing**
- **Asymmetrical response** to painful stimuli
- **Asymmetry of tendon reflexes and plantar responses.** Both plantars are often extensor in deep coma.

Figure 22.26 'Windscreen wiper' eyes ('ping pong' eyes). Slow side-to-side movements demonstrate diffuse cortical dysfunction. This is common in light coma and implies normal brainstem function. In deep coma it indicates extensive cortical damage.

Coma 'look-alikes'

- Psychogenic coma.
- 'Locked-in' syndrome – complete paralysis except vertical eye movements/blinking in ventral pontine infarction. Patients have a functioning cerebral cortex and are fully aware but unable to communicate except through eye movements (Table 22.11).
- Severe paralysis, e.g. myaesthetic crisis or severe Guillain-Barré syndrome.

Diagnosis and investigations in coma

Often, the cause is evident (e.g. head injury, metabolic disorder, overdose). Where lateralizing signs or brainstem pathology are found on examination, a mass lesion or infarction/haemorrhage is likely (note hypoglycaemia may also cause focal signs). If no cause is evident after clinical assessment, further investigations are essential.

Blood and urine

- **Drugs screen** – blood alcohol and salicylates, urine toxicology including screening for benzodiazepines, narcotics, amphetamines
- **Biochemistry** (urea, electrolytes, glucose, calcium, liver biochemistry)
- **Metabolic and endocrine studies** (TSH, cortisol)
- **Arterial blood gases** – for acidosis or high CO₂ levels
- **Other**, e.g. cerebral malaria (request *thick* blood film) and porphyria (p. 1043).

Brain imaging

CT brain imaging is the most readily available and safest modality in the unconscious patient (MRI is useful where CT is normal but presents greater monitoring challenges in the unconscious patient). CT is quick and effective in demonstrating all types of brain haemorrhage and most mass lesions; infarcts may be missed in the early stages and where only the brainstem is affected.

Table 22.11 Features distinguishing between coma and related states

Feature	Vegetative	Minimally conscious	Locked-in	Coma	Brain death
Awareness	Absent	Present	Present	Absent	Absent
Sleep-wake cycles	Present	Present	Present	Absent	Absent
Noxious stimuli	Response	Response	Response (eyes only)	Response ±	Response: nil
Glasgow Coma Scale	E4, M1–4, V1–2	E4, M1–5, V1–4	E4, M1, V1	E1–2, M1–4, V1–2	E1, M1–3, V1
Motor function	No purposeful movement	Consistent or inconsistent sounds/movements	Vertical eye movements/blinking	No purposeful movement	None/only reflex spinal movement
Respiration	Preserved	Preserved	Preserved	Variable	Absent
EEG	Slow waves, usually	Data insufficient	Normal, usually	Slow waves, usually	Typically absent
Cerebral metabolism (PET)	Severely reduced	Data insufficient	Mildly reduced	Reduced	Severely reduced/absent
Prognosis	Varies: usually continued VS or death	Varies	Varies: full recovery unlikely	Recovery, VS, or death	Already dead

EEG, electroencephalography; PET, positron emission tomography; VS, vegetative state.

EEG and PET are not required to confirm brain death.

Reproduced from Royal College of Physicians 2003. *The vegetative state: guidance on diagnosis and management*. Report of a Working Party. London: RCP, with permission.

CSF examination

Lumbar puncture should be performed in coma only after careful risk assessment. It is contraindicated when an intracranial mass lesion is a possibility: CT is essential to exclude this. CSF examination is likely to alter therapy only if undiagnosed meningoencephalitis or other infection is present or in subarachnoid haemorrhage where CT may give a false negative result, particularly after 24 h.

Electroencephalography

EEG is of some value in the diagnosis of metabolic coma, encephalitis and non-convulsive status epilepticus.

General management

Comatose patients need careful nursing, meticulous attention to the airway, and frequent monitoring of vital functions.

Longer-term essentials are:

- Skin care – turning (to avoid pressure sores and pressure palsies)
- Oral hygiene – mouthwashes, suction
- Eye care – prevention of corneal damage (lid taping, irrigation)
- Fluids – nasogastric or i.v.
- Feeding – via a fine-bore nasogastric tube or via peg
- Sphincters – catheterization when essential (use penile urinary sheath if possible in men); rectal evacuation.

Prognosis in coma and the vegetative state

Prognosis depends on the cause of coma and the extent of brain damage sustained. Metabolic and toxic causes of coma have the best prognosis when the underlying problem can be corrected. Following hypoxic-ischaemic brain injury, e.g. after cardiac arrest, only 11% make a good recovery and following stroke the prognosis is worse still with only 7% recovering. Of those patients who do not recover consciousness, a substantial proportion will remain in a vegetative or minimally responsive state.

- **The vegetative state (VS)** is usually a consequence of extensive cortical damage. Brainstem function is intact so breathing is normal without the need for mechanical ventilation and the patient appears awake with eye opening and sleep-wake cycles. However there is no sign of awareness or response to environmental stimuli except reflex movements. Patients may remain in this state for years. It is considered permanent (PVS) if there is no recovery after 12 months where trauma is the cause and after 6 months for all other causes. Prolonged support of patients after this time presents a number of ethical issues – families may apply to the courts for withdrawal of feeding in PVS.
- **Minimally conscious state (MCS)** describes patients with some limited awareness, e.g. apparent, vague pain perception. A patient may emerge from VS into MCS. Distinguishing VS from MCS requires careful specialist assessment over a long period. Functional brain imaging has recently been used for this purpose.
- **Brainstem death** is discussed on page 897.

Distinction between these states is essential before addressing issues of prognosis and cessation of supportive care.

STROKE AND CEREBROVASCULAR DISEASE

Stroke is the third most common cause of death (11% of all deaths in the UK) and the leading cause of adult disability worldwide. Although data are difficult to obtain, approximately two-thirds of the global burden of strokes is in middle- and low-income countries. Stroke rates are higher in Asian and black African populations than in Caucasians. Stroke risk increases with age but one-quarter of all strokes occur before the age of 65. The death rate following stroke is 20–25%.

Definitions

- **Stroke.** To the public, *stroke* means weakness, usually permanent on one side, often with loss of speech. Stroke is *defined* as a syndrome of rapid onset of cerebral deficit (usually focal) lasting >24 h or leading to death, with no cause apparent other than a vascular one. Hemiplegia following middle cerebral arterial thromboembolism is the typical example.
- **Transient ischaemic attack (TIA)** means a brief episode of neurological dysfunction due to temporary focal cerebral or retinal ischaemia without infarction, e.g. a weak limb, aphasia or loss of vision, usually lasting seconds or minutes with complete recovery. TIAs may herald a stroke. The arbitrary time of <24 hours is no longer used.

Avoid the vague term 'cerebrovascular accident'.

Pathophysiology

The underlying pathology responsible for stroke is either infarction or haemorrhage. Stroke mechanism and pathophysiology depends on the population studied but is broadly as follows (Fig. 22.27):

- Ischaemic stroke/infarction (80%)
 - Thrombotic
 - Large artery stenosis
 - Small vessel disease
 - Cardio-embolic
 - Hypoperfusion
- Haemorrhagic stroke (17%) (see p. 1104)
 - Intracerebral haemorrhage (12%) (see p. 1104)
 - Subarachnoid haemorrhage (5%) (see p. 1105)
- Other (3%), e.g. arterial dissection, venous sinus thrombosis, vasculitis (see p. 1108).

Ischaemic stroke

Arterial disease and atherosclerosis is the main pathological process causing stroke. Arterial branch points such as the origin of the great vessels arising from the aorta, the proximal internal carotid artery and its distal intracranial branches are particularly affected (Fig. 22.28). Non-Caucasian populations tend to have more intracranial narrowing and white populations more extracranial disease (which is strongly correlated with co-morbid coronary artery and peripheral vascular disease).

Thrombosis at the site of ruptured mural plaque leads to artery to artery embolism or vessel occlusion.

Large artery stenosis usually causes stroke by acting as an embolic source rather than by occlusion of the vessel (which may not in itself cause stroke if it occurs gradually and collateral circulation is adequate).

Figure 22.28 Principal sites of stenoses in extracerebral arteries (shown in bold, 1 to 4).

Small vessel disease. Small penetrating arterial branches supply the deep brain parenchyma and are affected by a different pathological process, an occlusive vasculopathy – lipohyalinosis – that is a consequence of hypertension. This leads to small infarcts called ‘lacunes’ and/or gradual accumulation of diffuse ischaemic change in deep white matter.

Cardio-embolic stroke. The heart is a common source of embolic material. Atrial fibrillation (and other arrhythmias) causing thrombosis in a dilated left atrium is the commonest cause. Cardiac valve disease, including congenital valve disorders, infective vegetations, rheumatic and degenerative calcific changes may cause embolization. Mural thrombosis may occur in a damaged or akinetic segment of the ventricle. A patent foramen ovale (PFO), which is a common variant, may occasionally allow passage of fragments of thrombus (e.g. from a lower limb DVT) from the right atrium to the left when Valsalva causes shunting of blood across the PFO. Pulmonary arteriovenous fistulas may also act as a conduit for paradoxical embolization. Rarer causes include fat emboli after long bone fracture, atrial myxomas and iatrogenic causes such as cardiac bypass and air embolism.

Simultaneous infarcts in different vascular territories are very suggestive of a proximal source of emboli in the heart or aorta.

Hypoperfusion. Severe hypotension, e.g. in cardiac arrest, may lead to borderzone infarction in the watershed areas between vascular territories, particularly if there is severe stenosis of proximal carotid vessels. The parieto-occipital area between the middle and posterior cerebral artery territories is particularly vulnerable.

Carotid and vertebral artery dissection

Dissection accounts for around 1 in 5 strokes below age 40 and is sometimes a sequel of trivial neck trauma or hyperextension, e.g. after whiplash, osteopathic manipulation, hairwashing in a salon, or exercise. It is now thought that subtle collagen disorders, e.g. partial forms of Marfan’s syndrome, may be a predisposing factor.

Most dissections are in large extracranial neck vessels. Blood penetrates the subintimal vessel wall forming a false lumen, but it is thrombosis within the true lumen due to tissue thromboplastin release that leads to embolization from the site of dissection and stroke, sometimes days after the initial event.

Pain in the neck or face is often the clue leading to diagnosis. Horner’s syndrome or lower cranial nerve palsies may occur with carotid dissection, as these structures are intimately associated with the carotid artery in the neck.

Venous stroke

Only 1% of strokes are venous. Thrombosis within intracranial venous sinuses, such as the superior sagittal sinus, or in cortical veins may occur in pregnancy, hypercoagulable states and thrombotic disorders or with dehydration or malignancy. Cortical infarction, seizures and raised intracranial pressure result.

For haemorrhagic stroke, see [page 1104](#).

Transient ischaemic attacks

TIA’s are usually the result of microemboli, but different mechanisms produce similar clinical events. For example, TIA’s may be caused by a fall in cerebral perfusion (e.g. a cardiac dysrhythmia, postural hypotension or decreased flow through atheromatous arteries). Infarction is usually averted by autoregulation. Rarely, tumours and subdural haematomas cause episodes indistinguishable from thromboembolic TIA’s. Principal sources of emboli to the brain are cardiac thrombus and atheromatous plaques/thrombus within the aortic arch, carotid and vertebral systems. Cardiac thrombus often results from atrial fibrillation or myocardial infarction. Cardiac valve disease may be a source of emboli, e.g. calcific material

Table 22.12 Factors reducing stroke risk

Risk factor	Action	Reduction in stroke risk		
		Infarction	Haemorrhage	Relative risk reduction in secondary prevention
Hypertension	Treat and monitor	++	++	28%
Smoking	Stop	++	+	33%
Lifestyle	More active	+	0	
Alcohol	Moderate intake	+	0 0	
High cholesterol	Statins, diet	+	0	24%
Atrial fibrillation	Anticoagulate	+	<i>Increases risk slightly</i>	67%
Obesity	Weight reduction	Probable	Probable	
Diabetes	Good control	Probable	0	
Severe carotid stenosis	Surgery	++	0	44%
Sleep apnoea	Treat	+	0	

++: Major correlation with reduced stroke risk, +: moderate correlation, SAH: subarachnoid haemorrhage.

or vegetations in infective endocarditis. Polycythaemia is also a cause.

Risk factors for stroke

The principal risk factors and effects of altering these are shown in Table 22.12.

Hypertension is overall the most modifiable stroke risk factor; stroke is decreasing in the 40–60 age group partly because hypertension is now more effectively identified and treated. There is a linear relationship between blood pressure and stroke risk. Other risk factors are similar to vascular risk factors for cardiovascular disease, including smoking, dyslipidaemia, diabetes, obesity, inactivity and genetic/ethnic factors.

Other risk factors and rarer causes of stroke

- Thrombocythaemia, polycythaemia and hyperviscosity states. Thrombophilia (e.g. protein C deficiency, factor V Leiden) is weakly associated with arterial stroke but predisposes to cerebral venous thrombosis.
- Anti-cardiolipin and lupus anticoagulant antibodies (antiphospholipid syndrome, p. 538) predispose to arterial thrombotic strokes in young patients.
- Low-dose oestrogen-containing oral contraceptives do not increase stroke risk significantly in healthy women but probably do so with other risk factors, e.g. uncontrolled hypertension or smoking.
- Migraine is a rare cause of cerebral infarction.
- Vasculitis (systemic lupus erythematosus (SLE), polyarteritis, giant cell arteritis, granulomatous CNS angiitis) is a rare cause of stroke.
- Amyloidosis can present as recurrent cerebral haemorrhage (p. 1042).
- Hyperhomocysteinaemia predisposes to thrombotic strokes. Folic acid therapy does not reduce the incidence.
- Neurosyphilis, mitochondrial disease, Fabry's disease (p. 1042).
- Sympathomimetic drugs such as cocaine, and possibly over-the-counter cold remedies containing vasoconstrictors, neuroleptics in older patients.
- CADASIL (cerebral dominant arteriopathy with subcortical infarcts and leucoencephalopathy) is a rare inherited cause of stroke/vascular dementia.

Figure 22.29 Arteries supplying brain and cord.

Vascular anatomy

Knowledge of normal arterial anatomy and likely sites of atheromatous plaques and stenoses helps understanding of the main stroke syndromes.

The circle of Willis is supplied by the two internal carotid arteries (the anterior cerebral circulation) and by the vertebro-basilar posterior cerebral circulation. The distribution of the anterior, middle and posterior cerebral arteries that supply the cerebrum is shown in Figures 22.28–22.30.

Clinical syndromes

Transient ischaemic attacks (TIAs)

Features

TIAs cause sudden loss of function, and usually last minutes or hours (by classical definition <24 h, but this is not used now). The site is often suggested by the type of attack. Clinical features of the principal forms of TIA are given in Box 22.12. Hemiparesis and aphasia are the commonest.

Amaurosis fugax

This is a sudden transient loss of vision in one eye. When due to the passage of emboli through the retinal arteries, arterial obstruction is sometimes visible through an

a Medial view of right hemisphere**b Lateral view of left hemisphere****Figure 22.30 The three major cerebral arteries.**

An underlying condition may be evident:

- Atheroma
- Hypertension
- Postural hypotension
- Bradycardia or low cardiac output
- Diabetes mellitus
- Rarely, arteritis, polycythaemia, neurosyphilis, HIV
- Antiphospholipid syndrome (p. 538).

Differential diagnosis

TIAs can be distinguished, usually on clinical grounds, from other transient episodes (p. 1116). Occasionally, events identical to TIAs are produced by mass lesions. Focal epilepsy is usually recognized by its positive features (e.g. limb jerking and loss of consciousness) and progression over minutes. In a TIA, involuntary limb movements do occur occasionally; deficit is usually instantaneous. A focal prodrome in migraine sometimes causes diagnostic difficulty. Headache, common but not invariable in migraine, is rare in TIA. Typical migrainous visual disturbances are not seen in TIA.

Prognosis

Prospective studies show that 5 years after a single thromboembolic TIA:

- 30% have had a stroke, a third of these in the first year
- 15% have suffered a myocardial infarct.

TIAs in the anterior cerebral circulation carry a more serious prognosis than those in the posterior circulation (see Table 22.12).

The ABCD² score can help to stratify stroke risk in the first 2 days:

■ Age >60 years	1 point
■ BP >140 mmHg systolic and/or diastolic >90 mmHg	1 point
■ Clinical features	
– unilateral weakness	2
– isolated speech disturbance	1
– other	0
■ Duration of symptoms (minutes)	
– >60	2
– 10–59	1
– <10	0
■ Diabetes	
– present	1
– absent	0

A score of <4 is associated with a minimal risk whereas >6 is high risk for a stroke within 7 days of a TIA.

If patients are considered to have had a high risk TIA, i.e. ABCD² score >4, or have had two recent TIAs, especially within the same vascular territory, then the patient should ideally be admitted for investigation and commencement of secondary prevention. ALL patients should be referred to a TIA Clinic and ideally seen within 24 h. Investigation and treatment should be regarded as *urgent* and *completed* within 2 weeks.

Investigations should include Doppler of internal carotid arteries, cardiac echo, ECG and 24 h tape CT/MR brain including angiography. Treat with medical therapy (p. 1095) and surgical treatment if appropriate (p. 1104).

Cerebral infarction

Major thromboembolic cerebral infarction usually causes an obvious stroke. The clinical picture is thus very variable,

Box 22.12 Features of transient ischaemic attacks

Anterior circulation

Carotid system

- Amaurosis fugax
- Aphasia
- Hemiparesis
- Hemisensory loss
- Hemianopic visual loss

Posterior circulation

Vertebrobasilar system

- Diplopia, vertigo, vomiting
- Choking and dysarthria
- Ataxia
- Hemisensory loss
- Hemianopic visual loss
- Bilateral visual loss
- Tetraparesis
- Loss of consciousness (rare)
- Transient global amnesia (possibly)

ophthalmoscope during an attack. A TIA causing an episode of amaurosis fugax is often the first clinical evidence of internal carotid artery stenosis – and forerunner of a hemiparesis.

Clinical findings in TIA

Diagnosis of TIA is often based solely upon its description. It is unusual to witness an attack as they are so brief. Consciousness is usually preserved in TIA. There may be clinical evidence of a source of embolus, e.g.:

- Carotid arterial bruit (stenosis)
- Atrial fibrillation or other dysrhythmia
- Valvular heart disease/endocarditis
- Recent myocardial infarction.

depending on the infarct site and extent. While the general site can be deduced from physical patterns (e.g. cortex, internal capsule, brainstem), clinical estimations of precise vascular territories are often inaccurate, when compared to imaging.

Following vessel occlusion brain ischaemia occurs, followed by infarction. The infarcted region is surrounded by a swollen area which does not function but is structurally intact. This is the *ischaemic penumbra*, which is detected on MRI and can regain function with neurological recovery.

Within the ischaemic area, hypoxia leads to neuronal damage. There is a fall in ATP with release of glutamate, which opens calcium channels with release of free radicals. These alterations lead to inflammatory damage, necrosis and apoptotic cell death.

Clinical features

Stroke most typically seen is caused by infarction in the internal capsule following thromboembolism in a middle cerebral artery branch (Fig. 22.31). A similar picture is caused by internal carotid occlusion (see Fig. 22.28). Limb weakness on the opposite side to the infarct develops over seconds, minutes or hours (occasionally longer). There is a contralateral hemiplegia or hemiparesis with facial weakness. Aphasia is usual when the dominant hemisphere is affected. Weak limbs are at first flaccid and areflexic. Headache is unusual. Consciousness is usually preserved. Exceptionally, an epileptic seizure occurs at the onset. After a variable interval, usually several days, reflexes return, becoming exaggerated. An extensor plantar response appears. Weakness is maximal at first; recovery occurs gradually over days, weeks or many months.

Figure 22.31 CT: Massive middle cerebral artery infarct.

Brainstem infarction

This causes complex signs depending on the relationship of the infarct to cranial nerve nuclei, long tracts and brainstem connections (Table 22.13).

- **The lateral medullary syndrome** (posterior inferior cerebellar artery (PICA) thrombosis and Wallenberg's syndrome) is a common example of brainstem infarction presenting as acute vertigo with cerebellar and other signs (Table 22.14 and Fig. 22.32). It follows thromboembolism in the PICA or its branches, vertebral artery thromboembolism or dissection. Features depend on the precise structures damaged.
- **Coma** follows damage to the brainstem reticular activating system.
- **The locked-in syndrome** is caused by upper brainstem infarction (p. 1095).
- **Pseudobulbar palsy** (p. 1080) can follow lower brainstem infarction.

Other patterns of infarction

Lacunar infarction

Lacunae are small (<1.5 cm³) infarcts seen on MRI or at autopsy. Hypertension is commonly present. Minor strokes (e.g. pure motor stroke, pure sensory stroke, sudden unilateral ataxia and sudden dysarthria with a clumsy hand)

Table 22.13 Features of brainstem infarction

Clinical feature	Structure involved
Hemiparesis or tetraparesis	Corticospinal tracts
Sensory loss	Medial lemniscus and spinothalamic tracts
Diplopia	Oculomotor system
Facial numbness	Vth nerve nuclei
Facial weakness	VIIIth nerve nucleus
Nystagmus, vertigo	Vestibular connections
Dysphagia, dysarthria	IXth and Xth nerve nuclei
Dysarthria, ataxia, hiccups, vomiting	Brainstem and cerebellar connections
Horner's syndrome	Sympathetic fibres
Coma, altered consciousness	Reticular formation

Table 22.14 Clinical deficits associated with problems in vascular supply

Vascular supply	Neurological deficits
Left middle cerebral artery	Right-sided weakness involving face and arm > leg with dysphasia
Right middle cerebral artery	Left-sided weakness involving face and arm > leg, visual and/or sensory neglect, denial of disability
Lateral medulla (posterior inferior cerebellar artery and/or parent vertebral artery)	Ipsilateral Horner's syndrome, Xth nerve palsy, facial sensory loss, limb ataxia with contralateral spinothalamic sensory loss. Vertiginous and unable to eat due to failing laryngeal closure and ineffective coughing. Cervical radiculopathies if involvement of radicular branches of the vertebral artery
Posterior cerebral artery	Homonymous hemianopia with varied deficits due to parietal and/or temporal lobe
Internal capsule	Motor, sensory or sensorimotor loss, face = arm = leg. Possible profound dysarthria from involvement of corticobulbar fibres but not dysphasia or other cortical deficits
Bilateral paramedian thalamus	Coma or disturbed vigilance, ophthalmoplegia (internal and/or external), ataxia and memory impairment. Some require ventilation
Carotid artery dissection	Ipsilateral Horner's syndrome from compression of sympathetic plexus around the carotid artery, can also affect lower cranial nerves (Xth and XIIth most clinically obvious). If ipsilateral cerebral infarction follows, clinical picture can mimic brain stem event

Figure 22.32 Medulla (cross-section): structures at risk after brainstem infarction.

are syndromes caused typically by single lacunar infarcts. Lacunar infarction is often symptomless.

Hypertensive encephalopathy (p. 778)

This is due to cerebral oedema, causing severe headaches, nausea and vomiting. Agitation, confusion, fits and coma occur if the hypertension is not treated. Papilloedema develops, either due to ischaemic optic neuropathy or following the brain swelling due to multiple acute infarcts. MRI shows oedematous white matter in the parieto-occipital regions.

Multi-infarct dementia (vascular dementia)

Multiple lacunes or larger infarcts cause generalized intellectual loss seen with advanced cerebrovascular disease. In the late stages, there is dementia, pseudobulbar palsy and a shuffling gait – the *marche à petits pas* (small steps), sometimes called atherosclerotic Parkinsonism. *Binswanger's disease* is a term for widespread low attenuation in cerebral white matter, usually with dementia, TIAs and stroke episodes in hypertensive patients (the changes being seen on imaging/autopsy).

Visual cortex infarction

Posterior cerebral artery infarction or infarction of the middle cerebral artery macular branch causes combinations of hemianopic visual loss and cortical blindness (Anton's syndrome, Fig. 22.30 and p. 1073).

Weber's syndrome

Ipsilateral IIIrd nerve palsy with contralateral hemiplegia is due to a unilateral infarct in the midbrain. Paralysis of upward gaze is usually present.

Watershed (borderzone) infarction

Cortical infarcts, often multiple, follow prolonged periods of low perfusion (e.g. hypotension after massive myocardial infarction or cardiac bypass surgery). Infarcts occur in the borderzones, between areas supplied by the anterior, middle and posterior cerebral arteries. Cortical visual loss, memory loss and intellectual impairment are typical. In some cases, a vegetative state or minimal conscious state follows (p. 1096).

Acute stroke: immediate care and thrombolysis

(See also Box 22.14)

Paramedics and members of the public are encouraged to make the diagnosis of stroke on a simple history and examination – **FAST**:

- **Face** – sudden weakness of the face
- **Arm** – sudden weakness of one or both arms

Box 22.13 Stroke: further investigation and management

Further investigations

- Routine bloods (for ESR, polycythaemia, infection, vasculitis, thrombophilia, syphilitic serology, clotting studies, autoantibodies, lipids)
- Chest X-ray
- ECG
- Carotid Doppler studies
- MR angiography, if appropriate

Further management

- Drugs for hypertension, heart disease, diabetes, other medical conditions
- Antiplatelet agents, e.g. aspirin and elopidogrel
- Question of endarterectomy
- Question of anticoagulation – Table 22.15
- Speech therapy, dysphagia care, physiotherapy, occupational therapy
- Specific issues, e.g. epilepsy, pain, incontinence
- Preparations for future care

- **Speech** – difficulty speaking, slurred speech
- **Time** – the sooner treatment can be started, the better.

Dedicated units with multidisciplinary, organized teams deliver higher standards of care than a general hospital ward, reducing stroke mortality and long-term disability. Evidence-based guidelines have contributed to clear protocols. Admission to hospital should proceed without delay, for imaging, care and investigation.

Following a stroke, immediate, continued and meticulous attention to the airway and to swallowing is essential. Management of unconscious or stuporose patients is outlined on page 1096.

In cerebral infarction, the issue is thrombolysis. **Practical Box 22.4** outlines the current proposals for stroke thrombolysis. Alteplase is commonly used although tenecteplase is also effective. The benefit of thrombolysis is shown on CT perfusion scans (Fig. 22.33) and decreases with time, even within the time window of 4.5 h. **Every minute counts.** If thrombolysis is not given, aspirin 300 mg daily should be given as soon as a diagnosis of ischaemic stroke or thromboembolic TIA is confirmed, reducing to 75 mg after several days. Following thrombolysis aspirin should not be started until 24–48 h later.

Investigations

The purpose of investigations in stroke is:

- to confirm the clinical diagnosis and distinguish between haemorrhage and thromboembolic infarction;
- to look for underlying causes and to direct therapy;
- to exclude other causes, e.g. tumour.

Sources of embolus should be sought (e.g. carotid bruit, atrial fibrillation, valve lesion, evidence of endocarditis, previous emboli or TIA) and hypertension/postural hypotension assessed. Brachial BP should be measured on each side; >20 mmHg difference is suggestive of subclavian artery stenosis.

Routine investigations in thromboembolic stroke and TIA are listed in Box 22.13.

Imaging in acute stroke

CT and MRI:

- **Non-contrast CT** will demonstrate haemorrhage immediately but cerebral infarction is often not detected or only subtle changes are seen initially (Fig. 22.34a).

Practical Box 22.4

Thrombolysis in acute ischaemic stroke

Eligibility

- Age ≥ 18 years
- Clinical diagnosis of acute ischaemic stroke
- Assessed by experienced team
- Measurable neurological deficit
- Blood tests: results available
- CT or MRI consistent with acute ischaemic stroke
- Timing of onset well established
- Thrombolysis should commence as soon as possible and up to 4.5 hours after acute stroke

Exclusion criteria

Historical

- Stroke or head trauma within the prior 3 months
- Any prior history of intracranial haemorrhage
- Major surgery within 14 days
- Gastrointestinal or genitourinary bleeding within the previous 21 days
- Myocardial infarction in the prior 3 months
- Arterial puncture at a non-compressible site within 7 days
- Lumbar puncture within 7 days

Clinical

- Rapidly improving stroke syndrome
- Minor and isolated neurological signs
- Seizure at the onset of stroke if the residual impairments are due to postictal phenomena
- Symptoms suggestive of subarachnoid haemorrhage, even if the CT is normal
- Acute MI or post-MI pericarditis
- Persistent systolic BP >185 , diastolic BP >110 mmHg, or requiring aggressive therapy to control BP
- Pregnancy or lactation
- Active bleeding or acute trauma (fracture)

Laboratory

- Platelets $<100\,000/\text{mm}^3$
- Serum glucose <2.8 mmol/L or >21.2 mmol/L
- INR >1.7 if on warfarin
- Elevated partial thromboplastin time if on heparin

Dose of i.v. alteplase (tissue plasminogen activator)

- Total dose 0.9 mg/kg (max. 90 mg)
- 10% of total dose by initial i.v. bolus over 1 minute
- Remainder infused i.v. over 60 minutes

Adapted from Adams HP Jr, del Zoppo G, Alberts MJ et al. *Stroke* 2007; 38(5):1655–1711.

Figure 22.33 CT perfusion scans: (a) pre-thrombolysis; (b) post-thrombolysis showing reperfusion of the ischaemic site. (Courtesy of Professor Adrian Dixon, Cambridge Radiology Department, UK.)

- **MRI** shows changes early in infarction (Fig. 22.35a) and a later MRI shows the full extent of the damaged area or penumbra (Fig. 22.35b).
- **Diffusion-weighted MRI (DWI)** can detect cerebral infarction immediately (see Fig. 22.34b) but is as accurate as CT for the detection of haemorrhage.

Figure 22.34 Middle cerebral artery infarction. (a) CT performed initially shows only very subtle low density changes in right MCA territory. (b) Diffusion-weighted MRI done at the same time shows full extent of the area of ischaemia. (Courtesy of Dr Paul Jarman.)

Figure 22.35 MRI of cerebral infarction and subsequent MRA performed in the same patient. (a) Early changes. (b) Changes after 5 days. (c) MR angiography showing internal carotid artery occlusion. (Courtesy of Dr Paul Jarman.)

CT is still more widely available than MRI and should be performed if MRI is unavailable so that there is no delay in giving thrombolysis for cerebral infarction.

More detailed studies involving perfusion-weighted images and diffusion-weighted MRI will differentiate the infarct core and the penumbral area which is potentially recoverable.

Treatment of acute stroke

This is shown in Box 22.14. Thrombolysis has been shown to improve outcome and should be used immediately if

Box 22.14 Stroke: immediate management

1. Admit to multidisciplinary stroke unit
2. General medical measures
 - Airway: confirm patency and monitor
 - Continue care of the unconscious or stuporose patient
 - Oxygen by mask
 - Monitor BP
 - Look for source of emboli
 - Assess swallowing
3. Is thrombolysis appropriate?
 - If so ([Practical Box 22.4](#)) immediate brain imaging is essential.
4. Brain imaging
 - CT should always be available. This will indicate haemorrhage, other pathology and sometimes infarction
 - MR is better overall, if immediately available
5. Cerebral infarction
 - If CT excludes haemorrhage, give immediate thrombolytic therapy. Aspirin, 300 mg/day, is given if thrombolytic therapy is contraindicated
6. Cerebral haemorrhage
 - If CT shows haemorrhage, give no drugs that could interfere with clotting. Neurosurgery may occasionally be needed

Adapted from Brown M. *Medicine* 2000; 28(7):64.

Figure 22.36 CT scan of massive infarction in the middle carotid artery territory. There is hemisphere swelling with brain shift. (Courtesy of Dr Paul Jarman.)

there are no contraindications. In a massive middle cerebral artery infarct, hemispheric swelling occurs with oedema ([Fig. 22.36](#)). Decompressive hemicraniectomy reduces the intracranial pressure and the mortality but extensive neurological deficits remain.

Later investigations

MR angiography (MRA) or CT angiography is valuable in anterior circulation TIAs to confirm surgically accessible arterial stenoses, mainly internal carotid stenosis ([Fig. 22.35c](#)). If ultrasound suggests carotid stenosis, normotensive patients with TIA or stroke in the anterior circulation should have vascular imaging.

Carotid Doppler and duplex scanning. These screen for carotid (and vertebral) stenosis and occlusion: in skilled hands they demonstrate accurately the degree of internal carotid stenosis.

Long-term management

Medical therapy

Risk factors ([Table 22.12](#)) should be identified and addressed.

Table 22.15 Anticoagulants and stroke prevention

Indication	Comment
Valvular heart disease	Heparin/warfarin of benefit in chronic rheumatic heart disease, particularly mitral stenosis
Recent MI	
Intracardiac thrombus	Heparin/warfarin if there is evidence of intracardiac thrombus
Atrial fibrillation	Anticoagulants long term reduce stroke incidence in atrial fibrillation
Acute internal carotid artery thrombus Acute basilar artery thrombus Internal carotid artery dissection Extracranial vertebral artery dissection	Anticoagulants reserved for imaging-confirmed cases of arterial thrombosis or dissection. They have not been shown to be beneficial in stroke prevention after thromboembolism from carotid or vertebrobasilar sources
Prothrombic states, e.g. protein C deficiency	Anticoagulation, in consultation with haematologist
Recurrent TIAs or stroke on full antiplatelet therapy	If no remediable cause, a trial of anticoagulants may be justified
Cerebral venous thrombosis including sinus thrombosis	Benefits of anticoagulation outweigh risks of haemorrhage

Antihypertensive therapy

Recognition and good control of high blood pressure is the major factor in primary and secondary stroke prevention. Transient hypertension, often seen following stroke, usually does not require treatment provided diastolic pressure does not rise >100 mmHg. Sustained severe hypertension needs treatment (p. 781); BP should be lowered slowly to avoid any sudden fall in perfusion.

Antiplatelet therapy (see also p. 425)

Long-term soluble aspirin (75 mg daily) reduces substantially the incidence of further infarction following thromboembolic TIA or stroke. Aspirin inhibits cyclo-oxygenase, which converts arachidonic acid to prostaglandins and thromboxanes; predominant therapeutic effects are reduction of platelet aggregation. Clopidogrel and dipyridamole are also used (p. 425). Combined aspirin 75 mg daily and clopidogrel 75 mg daily provide optimal prophylaxis against further thromboembolic stroke or TIA. Dipyridamole 200 mg twice daily is used if clopidogrel is contraindicated.

Anticoagulants

Heparin and warfarin should be given when there is atrial fibrillation, other paroxysmal dysrhythmias or when there are cardiac valve lesions (uninfected) or cardiomyopathies. Brain haemorrhage must be excluded by CT/MRI. Patients must be aware of the small risk of cerebral (and other) haemorrhage. Anticoagulants are potentially dangerous in the two weeks following infarction because of the risk of provoking cerebral haemorrhage; there are wide differences in clinical practice. Antithrombins are now being used. [Table 22.15](#) outlines the issues in secondary stroke prevention.

Other measures

Polycythaemia and any clotting abnormalities should be treated (p. 402). Statin therapy should be given for all.

Surgical approaches**Internal carotid endarterectomy**

Surgery is usually recommended in TIA or stroke patients with internal carotid artery stenosis >70% (see ABCD², above). Successful surgery reduces the risk of further TIA/stroke by around 75%. Endarterectomy has a mortality around 3%, and a similar risk of stroke. Percutaneous transluminal angioplasty (stenting) is an alternative. The value of surgery for asymptomatic carotid stenosis is debatable.

Stroke in the elderly

While in the elderly the yield of investigation in stroke diminishes, age is no barrier to recovery; elderly patients benefit the most from good rehabilitation. Consider social isolation, pre-existing cognitive impairment, nutrition, skin and sphincter care, and reassess swallowing. Carotid endarterectomy over 75 years carries little more risk than in younger cases. Fibrinolysis is not contraindicated.

Rehabilitation: multidisciplinary approach

Physiotherapy has particular value in the first few weeks after stroke to relieve spasticity, prevent contractures and teach patients to use walking aids. The benefits of physiotherapy for longer-term outcome are still inadequately researched. Baclofen and/or botulinum toxin are sometimes helpful in the management of severe spasticity.

Speech and language therapists have a vital understanding of aphasic patients' problems and frustration. Return of speech is hastened by conversation generally. If swallowing is unsafe because of the risk of aspiration, either nasogastric feeding or percutaneous gastrostomy will be needed. Video-fluoroscopy while attempting to swallow is helpful.

Physiotherapy, occupational and speech therapy have a vital role in assessing and facilitating the future care pathway. Stroke is frequently devastating and, particularly during working life, alters radically the patient's remaining years. Many become unemployable, lose independence and are financially embarrassed. Loss of self-esteem makes depression common.

At home, aids and alterations may be needed: stair and bath rails, portable lavatories, hoists, sliding boards, wheelchairs, tripods, stair lifts, electric blinds and modified sleeping arrangements, kitchen, steps, flooring and doorways. Liaison between hospital-based and community care teams, and primary care physician is essential.

Prognosis

About 25% of patients die within 2 years of a stroke, nearly 10% within the 1st month. This early mortality is higher following intracranial haemorrhage than thromboembolic infarction. Poor outcome is likely when there is coma, a defect in conjugate gaze and hemiplegia. Many complications, particularly in the elderly, are preventable, e.g. aspiration. Co-ordinated care reduces deaths.

Recurrent strokes are, however, common (10% in the 1st year) and many patients die subsequently from myocardial infarction. Of initial stroke survivors, some 30–40% remain alive at 3 years.

Gradual improvement usually follows stroke, although late residual deficits are typically substantial. One-third of survivors return to independent mobility and one-third have disability requiring institutional care.

The outlook for recovery of language varies: in general, if language is intelligible at all at 3 weeks, prognosis for fluent speech is good, but many are left with word-finding difficulties.

Intracranial haemorrhage

This comprises:

- intracerebral and cerebellar haemorrhage
- subarachnoid haemorrhage
- subdural and extradural haemorrhage/haematoma.

Intracerebral haemorrhage**Aetiology**

Intracerebral haemorrhage causes approximately 15% of strokes. Rupture of microaneurysms (Charcot–Bouchard aneurysms, 0.8–1.0 mm diameter) and degeneration of small deep penetrating arteries are the principal pathology. Such haemorrhage is usually massive, often fatal, and occurs in chronic hypertension and at well-defined sites – basal ganglia, pons, cerebellum and subcortical white matter.

In normotensive patients, particularly over 60 years, *lobar* intracerebral haemorrhage occurs in the frontal, temporal, parietal or occipital cortex. Cerebral amyloid angiopathy (rare) is the cause in some of these haemorrhages, and the tendency to rebleed is associated with particular apolipoprotein E genotypes.

Recognition

At the bedside, there is no entirely reliable way of distinguishing between haemorrhage and thromboembolic infarction. Both produce stroke. Intracerebral haemorrhage tends to be dramatic with severe headache. It is more likely to lead to coma than thromboembolism.

Brain haemorrhage is seen on CT imaging immediately (*cf.* infarction, p. 1091) as intraparenchymal, intraventricular or subarachnoid blood. Routine MRI may not identify an acute small haemorrhage correctly in the first few hours but MRI diffusion-weighted (MRI-DW) is as good as CT.

Management: haemorrhagic stroke

The principles are those for cerebral infarction. The immediate prognosis is less good. Antiplatelet drugs and, of course, anticoagulants are contraindicated. Control of hypertension is vital. Urgent neurosurgical clot evacuation is occasionally necessary when there is deepening coma and coning (particularly in cerebellar haemorrhage).

Cerebellar haemorrhage (Fig. 22.37)

There is headache, often followed by stupor/coma and signs of cerebellar/brainstem origin (e.g. nystagmus, ocular palsies). Gaze deviates towards the haemorrhage. Skew deviation (p. 1094) may develop. Cerebellar haemorrhage sometimes causes acute hydrocephalus, a potential surgical emergency.

Figure 22.37 CT: Cerebellar haemorrhage.

Subarachnoid haemorrhage (SAH)

SAH means spontaneous arterial bleeding into the subarachnoid space, and is usually clearly recognizable clinically from its dramatic onset. SAH accounts for some 5% of strokes and has an annual incidence of 6 per 100 000.

Causes

The causes of SAH are shown in Table 22.16; it is unusual to find any contributing disease.

Saccular (berry) aneurysms (Fig. 22.38)

Saccular aneurysms develop within the circle of Willis and adjacent arteries. Common sites are at arterial junctions:

- Between posterior communicating and internal carotid artery – posterior communicating artery aneurysm
- Between anterior communicating and anterior cerebral artery – anterior communicating and anterior cerebral artery aneurysm
- At the trifurcation or a bifurcation of the middle cerebral artery – middle cerebral artery aneurysm.

Other aneurysm sites are on the basilar, posterior inferior cerebellar, intracavernous internal carotid and ophthalmic arteries. Saccular aneurysms are an incidental finding in 1% of autopsies and can be multiple.

Aneurysms cause symptoms either by spontaneous rupture, when there is usually no preceding history, or by direct pressure on surrounding structures; for example, an enlarging unruptured posterior communicating artery aneurysm is the commonest cause of a painful 3rd nerve palsy (p. 1081).

Table 22.16 Underlying causes of subarachnoid haemorrhage

Cause of aneurysm	(%)
Saccular (berry) aneurysms	70%
Arteriovenous malformation (AVM)	10%
No arterial lesion found	15%
Rare associations	(<5%)
Bleeding disorders	
Mycotic aneurysms – endocarditis	
Acute bacterial meningitis	
Tumours, e.g. metastatic melanoma, oligodendroglioma	
Arteritis (e.g. SLE)	
Spinal AVM → spinal SAH	
Coarctation of the aorta	
Marfan's, Ehlers–Danlos syndrome	
Polycystic kidneys	

Figure 22.38 Digital subtraction angiogram: posterior communicating artery aneurysm.

Arteriovenous malformation (AVM)

AVMs are vascular developmental malformations, often with a fistula between arterial and venous systems causing high flow through the AVM and high pressure arterialization of draining veins. An AVM may also cause epilepsy, often focal. The risk of a first haemorrhage (20% fatal and 30% resulting in permanent disability) is approximately 2–3% per year. Once an AVM has caused a haemorrhage, the risk of rebleeds is increased– to approximately 10% per year. AVMs may be ablated with endovascular treatment (catheter injection of glue into the nidus usually), surgery or stereotactic radiotherapy. A multidisciplinary team approach with neurologist, interventional neuro-radiologist and neurosurgeon is required in deciding on treatment options.

Cavernous haemangiomas (cavernomas) are common (0.1–0.5% prevalence) and consist of a tangle of low pressure dilated vessels without a major feeding artery; they are frequently symptomless (Fig. 22.39) and seen incidentally on imaging. Multiple cavernomas often have a genetic basis, with linkage to two loci on chromosome 7q. Cavernomas may cause seizures. Small haemorrhages may occur but are usually low pressure bleeds and rarely cause severe deficits. Surgical resection is rarely needed except where the cavernoma is gradually enlarging or causing significant neurological symptoms.

Clinical features of subarachnoid haemorrhage

There is a sudden very severe headache, often occipital (mean time to peak headache 3 min). Headache is usually followed by vomiting and often by coma and death. Survivors of SAH may remain comatose or drowsy for hours, days, or longer. SAH is a *possible* diagnosis in any sudden headache.

Following major SAH there is neck stiffness and a positive Kernig's sign. Papilloedema is sometimes present, with retinal and/or subhyaloid haemorrhage (tracking beneath the retinal hyaloid membrane). Minor bleeds cause few signs, but almost invariably headache (approximately 17% of patients have small 'sentinel bleeds' in the weeks before presenting with SAH).

Investigations

CT imaging is the immediate investigation (Fig. 22.40). Subarachnoid and/or intraventricular blood is usually seen (sensitivity of CT to detect subarachnoid blood is 95% within 24 h of onset but much lower over subsequent days). Lumbar puncture is not necessary if SAH is confirmed by CT, but should be performed if doubt remains. CSF becomes yellow (xanthochromic) within 12 h of SAH and remains detectable for 2 weeks. Visual inspection of supernatant CSF is usually

Figure 22.39 MR T2: Symptomatic frontal cavernoma (arrow).

Figure 22.40 Subarachnoid haemorrhage CT showing blood around the brainstem (arrow).

FURTHER READING

White PM, Lewis SC, Gholkar A et al. Hydrogel-coated coils versus bare platinum coils for the endovascular treatment of intracranial aneurysms (HELPS): a randomised controlled trial. *Lancet* 2011; 377: 1655–1662.

sufficiently reliable for diagnosis. Spectrophotometry to estimate bilirubin in the CSF released from lysed cells is used to define SAH with certainty. CT angiography or catheter angiography to identify the aneurysm or other source of bleeding is performed in patients potentially fit for surgery. In some, no aneurysm or source of bleeding is found, despite a definite SAH.

Differential diagnosis

SAH must be differentiated from migraine. This is sometimes difficult – a short time to maximal headache intensity and the presence of neck stiffness usually indicate SAH. *Thunderclap headache* is used (confusingly) to describe either SAH or a sudden (benign) headache for which no cause is ever found. The syndrome of reversible cerebral vasoconstriction (Call-Fleming syndrome) presents with thunderclap headache. Acute bacterial meningitis occasionally causes a very abrupt headache, when a meningeal microabscess ruptures; SAH also occasionally occurs at the onset of acute bacterial meningitis. Cervical arterial dissection can present with a sudden headache.

Complications

Blood in the subarachnoid space can lead to obstructive hydrocephalus, seen on CT. Hydrocephalus can be asymptomatic but may cause deteriorating consciousness following SAH. Shunting may be necessary. Arterial spasm (visible on angiography and a cause of coma or hemiparesis) is a serious complication of SAH and a poor prognostic feature.

Management

Immediate treatment of SAH is bed rest and supportive measures. Hypertension should be controlled. Nimodipine, a calcium-channel blocker given for 3 weeks, reduces mortality.

All SAH cases should be discussed urgently with a neurosurgical centre. Nearly half of SAH cases are either dead or moribund before reaching hospital. Of the remainder, a further 10–20% rebleed and die within weeks. Failure to diagnose SAH, e.g. mistaking SAH for migraine, contributes to this mortality.

Where angiography demonstrates an aneurysm (the cause of the vast majority of SAH), endovascular treatment by placing platinum coils via a catheter in the aneurysm sac to promote thrombosis and ablation of the aneurysm, is now the first line treatment. Endovascular coiling has a lower complication rate than surgery but direct surgical clipping of the aneurysm neck is still required in some selected cases.

Figure 22.41. Bilateral subdural haematomas. (a) CT scan. (Courtesy of Dr Paul Jarman). (b) MR T1.

For asymptomatic (unruptured) aneurysms over 8 mm in diameter the risk of treatment is less than the risk of haemorrhage if not treated. Patients who remain comatose or who have persistent severe deficits after SAH have a poor outlook.

Subdural and extradural bleeding

These conditions can cause death following head injuries unless treated promptly.

Subdural haematoma (SDH)

SDH means accumulation of blood in the subdural space following rupture of a vein. This usually follows a head injury, sometimes trivial. The interval between injury and symptoms can be days, or extend to weeks or months. Chronic, apparently spontaneous SDH is common in the elderly, and also occurs with anticoagulants.

Headache, drowsiness and confusion are common; symptoms are indolent and can fluctuate. Focal deficits, e.g. hemiparesis or sensory loss, develop. Epilepsy occasionally occurs. Stupor, coma and coning may follow.

Extradural haemorrhage (EDH)

EDH typically follows a linear skull vault fracture tearing a branch of the middle meningeal artery. Extradural blood accumulates rapidly over minutes or hours. A characteristic picture is of a head injury with a brief duration of unconsciousness, followed by improvement (the lucid interval). The patient then becomes stuporose, with an ipsilateral dilated pupil and contralateral hemiparesis, with rapid transtentorial coning. Bilateral fixed dilated pupils, tetraplegia and respiratory arrest follow. An acute progressive SDH presents similarly.

Management

Possible extradural or subdural bleeding needs immediate imaging. CT (Fig. 22.41a) is the most widely used investigation because of its immediate availability. MRI is more sensitive for the detection of small haematomas. T₁-weighted MRI (Fig. 22.41b) shows bright images due to the presence of methaemoglobin.

EDHs require urgent neurosurgery: if it is performed early, the outlook is excellent. When far from a neurosurgeon, e.g. in wartime or at sea, drainage through skull burr-holes has been lifesaving when an EDH has been diagnosed clinically.

Subdural bleeding usually needs less immediate attention but close neurosurgical liaison is necessary. Even large

collections can resolve spontaneously without drainage. Serial imaging is needed to assess progress.

Cortical venous thrombosis and dural venous sinus thrombosis

Intracranial venous thromboses are usually (>50%) associated with a pro-thrombotic risk factor, e.g. oral contraceptives, pregnancy, genetic or acquired pro-thrombotic states and dehydration. Head injury is also a cause. Infection, e.g. from a paranasal sinus, may be present. Venous thromboses can also arise spontaneously.

Cortical venous thrombosis

The venous infarct leads to headache, focal signs (e.g. hemiparesis) and/or epilepsy, often with fever.

Dural venous sinus thromboses

Cavernous sinus thrombosis causes ocular pain, fever, proptosis and chemosis. External and internal ophthalmoplegia with papilloedema develops.

Sagittal and lateral sinus thrombosis cause raised intracranial pressure with headache, fever, papilloedema and often epilepsy.

Management

MRI, MRA and MR venography (MRV) show occluded sinuses and/or veins. Treatment is with heparin initially, though its value is questioned, followed by warfarin for 6 months. Anti-convulsants are given if necessary.

HEADACHE, MIGRAINE AND FACIAL PAIN

Headache is an almost universal experience and one of the most common symptoms in medical practice. It varies from an infrequent and trivial nuisance to a pointer to serious disease. Headache symptoms are unpleasant, disabling, common worldwide and have a substantial economic impact because of time lost from work.

Mechanisms

Pain receptors are located at the base of the brain in arteries and veins and throughout meninges, extracranial vessels, scalp, neck and facial muscles, paranasal sinuses, eyes and teeth. Curiously, brain substance is almost devoid of pain receptors. Head pain is mediated by the Vth and IXth cranial nerves and upper cervical sensory roots.

A general approach to assessing headache symptoms

In assessing patients with headache the aim should be to make a confident diagnosis based on the history. Examination is helpful in excluding underlying medical disorders as a cause of headache but will not distinguish between different types of primary headache.

There is an internationally agreed classification for headaches that defines all headache patterns. Headache is divided into primary headache disorders such as migraine, and secondary headaches due to underlying pathology such as raised intracranial pressure or meningitis (Box 22.15). It is also useful to distinguish between episodic (recurrent) headache, single first headache episodes and patients with chronic headache.

In an outpatient clinic setting most headaches will be benign. Fewer than 1% of outpatients with non-acute headache have a serious underlying cause but in the Emergency Department there will be a much higher prevalence of serious

Box 22.15 Some causes of secondary headache

- Raised intracranial pressure, e.g. idiopathic intracranial hypertension
- Infections, e.g. meningitis, sinusitis
- Giant cell arteritis
- Intracranial haemorrhage, esp. SAH or SDH
- Low CSF volume (low pressure) headache
- Post-traumatic headache
- Cervicogenic headache
- Acute glaucoma

underlying pathology presenting with headache. New onset severe headache in those without a previous headache history, especially in older patients (>50), requires exclusion of underlying pathology causing secondary headache.

There are some widely believed 'headache myths'. Headaches are not caused by hypertension except rarely with malignant hypertension (p. 778). Eyestrain from refractive error does not cause headache and sinusitis is rarely the explanation for recurrent or chronic headache.

Taking a headache history

Ask about:

- Headache location (e.g. hemicranial), severity and character (e.g. throbbing vs non-throbbing)
- Associated symptoms, e.g. nausea, photophobia, phonophobia and motion sensitivity
- Presence of autonomic symptoms, e.g. tearing or ptosis
- Relieving or exacerbating features, e.g. effect of posture
- Headache pattern. Is headache episodic and part of a pattern of previous similar headaches? Age at onset and headache frequency
- Duration of headache episodes (helpful in distinguishing between different primary headache types)
- Triggers
- Pattern of analgesic use
- Family history of headache
- 'Red flag' symptoms – fever (meningitis, sinusitis)
- Sudden onset in less than 1 minute (SAH)
- Features of raised intracranial pressure
- Jaw claudication (giant cell arteritis).

Examination

Examination should include fundoscopy to look for papilloedema. In older patients, temporal arteries should be palpated for loss of pulsatility and tenderness that may be features of giant cell arteritis (GCA). Fever and neck stiffness suggest meningitis. Examination is generally normal in patients with primary headache disorders.

Investigations

Investigations, including brain imaging, do not contribute to the diagnosis of primary headache disorders. Neuroimaging is indicated only where history or examination suggests an underlying secondary cause. Older patients with new onset headache and those with 'red flag' symptoms should have brain CT. In patients over 50 with new headache ESR should be checked to exclude GCA.

Primary headache disorders

Migraine

Migraine is the commonest cause of episodic headache (15–20% of women and 5–10% of men); in 90%, onset is

Headache, migraine and facial pain

van Gijn J, Kerr RS, Rinkel GJ. Subarachnoid haemorrhage. *Lancet* 2007; 369:306–318.

before 40 years of age. Episodes of headache are associated with sensory sensitivity such as to light, sound or movement, and sometimes with nausea and vomiting. There is a spectrum of severity between individuals and from one attack to another. Migraine is usually high impact, with inability to function normally during episodes. Headache frequency in migraine varies from an occasional inconvenience to frequent headaches severely impacting quality of life, and may transform into chronic daily headache.

Mechanisms

Genetic factors play a part in causing the neuronal hyperexcitability that is probably the biological basis of migraine. Migraine is polygenic but a rare form of familial migraine is associated with mutations in the α -1 subunit of the P/Q-type voltage-gated calcium channel or neuronal sodium channel (SCN1A), and a dominant loss of function mutation in a potassium channel gene (TRESK) has recently been identified in some patients with migraine with aura.

The pathophysiology of migraine is now thought to have a primarily neurogenic rather than vascular basis. Spreading cortical depression – a wave of neuronal depolarization followed by depressed activity spreading slowly anteriorly across the cerebral cortex from the occipital region – is thought to be the basis of the migraine aura. Activation of trigeminal pain neurones is the basis of the headache. The innervation of the large intracranial vessels and dura by the first division of the trigeminal nerve is known as the trigeminovascular system. Release of calcitonin gene-related peptide (CGRP), substance P and other vasoactive peptides including 5-HT by activated trigeminovascular neurones causes painful meningeal inflammation and vasodilation. Peripheral and central sensitization of trigeminal neurones and brainstem pain pathways makes otherwise innocuous sensory stimuli (such as CSF pulsation and head movement) painful and light and sound perceived as uncomfortable.

Clinical features

Migraine without aura

Migraine typically starts around puberty with increasing prevalence into the 4th decade. There is a spectrum of severity and associated features, but attacks have recognizable core features (Box 22.16). Most migraine attacks are usually of sufficient severity to prevent sufferers continuing with normal activities and sleep usually helps, with a washed out feeling following the attack. The scalp may be tender to touch during episodes (allodynia) and the preference is to be still in a dark, quiet environment.

Box 22.16 Migraine: simplified diagnostic criteria

Headache lasting 4 hours to 3 days (untreated)

At least two of:

- Unilateral pain (may become holocranial later in attack)
- Throbbing type pain
- Moderate to severe in intensity
- Motion sensitivity (headache made worse with head movement or physical activity)

At least one of:

- Nausea/vomiting
- Photophobia/phonophobia
- Normal examination and no other cause of headache

Some patients recognize changes in routine as trigger factors:

- Sleep (too little or too much)
- Stress (including let down after a period of stress)
- Hormonal factors for women – changes in oestrogen levels, e.g. menstrual migraine (usually just before menses) and worsening with the OC pill and menopause
- Eating – skipping meals and alcohol. Contrary to popular belief, individual foods are rarely a trigger
- Other – sensory stimuli such as bright lights or loud sounds. Physical exertion. Changes in weather patterns, e.g. stormy weather. Minor head injuries may trigger a worsening of migraine frequency and severity.

Migraine with aura

Approximately 25% of migraine sufferers experience focal neurological symptoms immediately preceding the headache phase in some or all attacks – termed migraine aura. Most never experience aura and presence of aura is therefore not required for a diagnosis of migraine. Aura usually evolves over 5–20 minutes with symptoms changing as the wave of spreading neuronal depression moves across the surface of the cortex. It rarely lasts longer than 60 minutes and is followed immediately by the headache phase.

Visual aura is the commonest type, with positive visual symptoms such as shimmering, teichopsia (zig-zag lines also called fortification spectra) and fragmentation of the image (like looking through a pane of broken glass) often accompanied by patches of loss of vision which may move across the visual field (scotomas) and even evolve into hemianopia or tunnel vision. Positive sensory symptoms (mainly tingling), dysphasia and rarely loss of motor function may also occur and may occur successively within the same episode of aura following the visual symptoms.

Migraine aura usually presents no diagnostic difficulty, but problems with diagnosis may sometimes arise in men over the age of 50 who develop migraine aura for the first time without subsequent headache (sometimes referred to as acephalic migrainous aura). This is frequently misdiagnosed as a transient ischaemic attack (see p. 1098). Distinguishing the two conditions is often difficult and relies on the characteristic evolution of symptoms over minutes and presence of positive symptoms in aura in contrast to TIA where symptom onset is acute and negative symptoms (visual loss as opposed to visual distortion and teichopsia) the norm. There may also be a history of previous typical migraine aura in early adult life to help distinguish the conditions.

Migraine-related dizziness

Vertigo is now recognized as being a migrainous symptom in some individuals with attacks lasting for hours in the context of migraine attacks. There is an overlap with what is sometimes described as basilar migraine, a poorly defined migraine subtype associated with brainstem aura type symptoms before or during attacks, including perioral paraesthesiae, diplopia, unsteadiness and rarely reduced level of consciousness.

Hemiplegic migraine

This rare autosomal dominant disorder causes a hemiparesis and/or coma and headache, with recovery within 24 hours. Some patients have permanent cerebellar signs as it is allelic with episodic ataxia. It is distinct from commoner forms of migraine.

Management

General measures include:

- Explanation
- Avoidance of trigger factors and lifestyle modification where possible.

Acute treatment of attacks

Analgesics such as high-dose dispersible aspirin (900 mg), paracetamol 1g or a non-steroidal anti-inflammatory (e.g. naproxen 250–500 mg), are often effective, with an antiemetic such as metoclopramide if necessary. Acute treatment should be taken as soon as possible after onset of headache. Patients should be aware that repeated use of analgesics leads to further headaches (see medication overuse; headache p. 1110).

Triptans (5-HT_{1B/1D} agonists) are specific for migraine and may be effective where simple analgesics are insufficient. Sumatriptan was the first marketed; almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan and zolmitriptan are now available, with various routes of administration. Subcutaneous sumatriptan injection may be effective where vomiting prevents absorption of oral medication (*note*: nasal triptan sprays rely on gastrointestinal rather than nasal absorption). Triptans should be avoided when there is vascular disease, and like analgesics, not overused. CGRP antagonists, e.g. telcagepant, are proving to be very effective for acute treatment of migraine.

Migraine suppression medication

Where migraine episodes are frequent, e.g. >1–2 per month, and impacting on quality of life, migraine suppression medication should be offered. The key principles are that a period of 3–6 months treatment is usually sufficient to reduce headache frequency and severity by approximately 50%, with the effect of ‘resetting’ migraine frequency beyond the treatment period. However, these medications will not be effective where ongoing analgesic overuse is an issue. Treatment options include:

- Anticonvulsants. Valproate (800 mg) used off licence or topiramate (100–200 mg daily) are generally the most effective options
- Beta-blockers, e.g. propranolol slow release 80–160 mg daily
- Tricyclics, e.g. amitriptyline 10 mg increasing weekly in 10 mg steps to 50–60 mg
- Botulinum toxin was recently recommended as a treatment for chronic migraine (see p. 1110). The technique involves 31 injections over the scalp and neck repeated every 3 months
- Pizotifen is rarely used. Flunarizine (a calcium antagonist) and methysergide are used in refractory patients.

Tension-type headache (TTH)

The exact pathogenesis of this headache type remains unclear. There is overlap with migraine and many headaches traditionally subsumed under this category probably in fact represent mild migraine. Since there are no diagnostic tests to separate TTH from mild migraine it is difficult to know if the conditions are biologically distinct. In contrast to migraine, pain is usually mild to moderate severity, bilateral and relatively featureless, with tight band sensations, pressure behind the eyes, and bursting sensations being described.

Depression is also a frequent co-morbid feature. TTH is often attributed to cervical spondylosis, refractive errors or high blood pressure: evidence for such associations is poor.

Simple analgesics are often effective but overuse should be avoided. Physical treatments such as massage, ice packs, and relaxation are often recommended. Frequent or chronic TTH may respond to migraine suppression medications as above, with tricyclics often being used first-line.

Trigeminal autonomic cephalgias

The trigeminal autonomic cephalgias are a group of primary headache disorders characterized by unilateral trigeminal distribution pain (usually in the ophthalmic division of the nerve) and prominent ipsilateral autonomic features.

Cluster headache

Cluster headache is distinct from migraine and much rarer (1 per 1000). It affects adults, mostly males aged between 20 and 40. Patients describe recurrent bouts (clusters) of excruciating unilateral retro-orbital pain with parasympathetic autonomic activation in the same eye causing redness or tearing of the eye, nasal congestion or even a transient Horner’s syndrome. The pain is reputed to be the worst known to man and patients often contemplate, and sometimes commit, suicide, such is the severity of the pain. Unlike migraine attacks patients prefer to move about or rock rather than remain still.

Attacks are shorter than migraine, usually 30–90 minutes, and may occur several times per day, especially during sleep. Clusters last one to two months with attacks most nights before stopping completely and typically recurring a year or more later, often at the same time of year. Although the cause is not known, hypothalamic activation is seen on functional imaging studies during an attack.

Management. Analgesics are unhelpful. Subcutaneous sumatriptan is the drug of choice for acute treatment as no other drug works quickly enough. High flow oxygen is also used. Most prophylactic migraine drugs are unhelpful. Verapamil, lithium and/or a short course of steroids help terminate a bout of cluster headaches.

Paroxysmal hemicrania and SUNCT

Paroxysmal hemicrania is a rare condition with similarities to cluster headache, differing mainly in that attacks are briefer (10–30 min) and more frequent (>5 per day, at any time of day) and do not occur in clusters. Women are more often affected than men. There is a rapid and complete response to indometacin.

SUNCT (short-lasting unilateral neuralgiform headache with conjunctival injection and tearing) is very rare. Attacks are short, 5 seconds to 2 minutes, and very frequently occurring in bouts. Distinguishing from trigeminal neuralgia can be difficult.

Other primary headache disorders

- **Primary stabbing headache** (*‘ice pick headache’*). Momentary jabs or stabs of localized pain occurring either in the same spot or moving about the head. Symptoms wax and wane and are more common in patients with other primary headache disorders, particularly migraine. Treatment is usually not needed but it responds well to indometacin.
- **Primary cough headache** is a sudden sharp head pain on coughing. No underlying cause is found but intracranial pathology should be excluded. The problem often resolves spontaneously. Indometacin is the

treatment of choice; lumbar puncture with removal of CSF can help.

- **Primary sex headache** is characterized by explosive headache at or before orgasm. It often resolves spontaneously after several attacks. Investigation to exclude subarachnoid haemorrhage is required after the first episode.
- **Other varieties** of primary headache include hemicrania continua, primary exertional headache, hypnic headache (headache triggered by sleep), and primary thunderclap headache.

Chronic daily headache

Defined as headache on ≥ 15 days per month for at least 3 months. Up to 4% of the population are affected by daily or near daily headache. Although there are many possible causes, including secondary headache disorders, in practice primary headache disorders, particularly migraine, are responsible for the majority. Where migraine is the cause, the term chronic migraine is now preferred.

Overuse of analgesic medication or triptans (termed medication overuse headache) is often a major factor leading to and maintaining chronicity, particularly in those with migrainous biology. Use of ≥ 10 doses per month of any analgesic or triptan, particularly codeine or opiate-containing drugs such as co-codamol, or numerous over-the-counter analgesics, may eventually lead to transformation of episodic headache into chronic daily headache.

Explanation that medication overuse is part of the problem is essential to help patients withdraw from or substantially reduce analgesic intake. This is a difficult process for many patients, especially as there may be a period of transient rebound worsening of headache after withdrawal. Concurrent introduction of migraine suppression medication (see above) may help withdrawal but will not be effective if patients cannot withdraw from frequent analgesic use. Occasionally hospital admission for analgesic withdrawal with parenteral administration of dihydroergotamine is required.

Secondary headache disorders

Raised intracranial pressure headache

Any headache present on waking and made worse by coughing, straining or sneezing may be due to raised intracranial pressure (ICP) caused by a mass lesion. Vomiting often accompanies pressure headaches. Visual obscurations (momentary bilateral visual loss with bending or coughing) are characteristic and seen in the presence of papilloedema. Occasionally, where ICP rises quickly, papilloedema may not be present.

Neuroimaging is mandatory where raised ICP is suspected. Where no mass lesion, venous sinus thrombosis or hydrocephalus is detected on imaging in the presence of papilloedema, idiopathic intracranial hypertension (IIH) may be the cause and lumbar puncture is performed to measure CSF opening pressure.

Idiopathic intracranial hypertension (IIH)

IIH probably results from reduced CSF resorption. IIH typically develops in younger overweight female patients, many of whom have polycystic ovaries. Headaches and transient visual obscurations due to the florid papilloedema are the presenting features. A VIth nerve palsy may develop – a false localizing sign (p. 1076). CSF pressure is very elevated, with

normal constituents. Brain imaging is normal although ventricles may be small and appear 'slit-like'.

Various drugs, e.g. tetracyclines, and vitamin A supplements have been implicated. Other causes of papilloedema should be excluded. Sagittal sinus thrombosis can cause a similar picture and should always be looked for on MR venography.

It is usually self-limiting. However, optic nerve damage can result from longstanding severe papilloedema with progressive loss of peripheral visual fields. Regular monitoring of visual fields with perimetry is essential. Repeated lumbar puncture, acetazolamide, and thiazide diuretics are used to reduce CSF production. Weight reduction is helpful. Ventricleperitoneal shunt insertion is sometimes necessary or optic nerve sheath fenestration to protect vision.

Low CSF volume (low pressure) headache

Although seen most often following lumbar puncture, CSF leaks may occur spontaneously leading to postural headache, worse on standing or sitting and relieved completely by lying flat. The patient may give a history of vigorous Valsalva, straining or coughing just prior to onset. Leptomeningeal enhancement may be seen on MRI but is not reliably present. Lumbar puncture is generally avoided for obvious reasons, but may reveal low opening pressure. The site of the leak is usually within the spine, thus treatment consists of injection of autologous blood into the spinal epidural space to seal the leak (a 'blood patch'), or occasionally surgical repair of the dural tear. Intravenous caffeine infusion and bed rest are sometimes effective.

Post-traumatic headache

Pre-existing migraine may worsen following head injury. *De novo* headache sometimes follows a minor head injury but post-traumatic headache is an ill defined entity. Improvement over a few weeks is the norm but where litigation is ongoing symptoms can persist for long periods. Subdural haematoma and low pressure headache need to be considered as a possible cause.

Facial pain

The face has many pain-sensitive structures: teeth, gums, sinuses, temporomandibular joints, jaw and eyes. Dental causes are common and should always be considered. Facial pain is also caused by specific neurological conditions.

Trigeminal neuralgia

Trigeminal neuralgia typically starts in the 6th and 7th decades; hypertension is the main risk factor. Compression of the trigeminal nerve at or near the pons by an ectatic vascular loop is the usual cause. High resolution MRI studies may demonstrate the vascular loop in contact with the nerve in a high proportion of cases. Younger patients are more likely to have multiple sclerosis or cerebellopontine angle tumours (acoustic schwannomas, meningiomas, epidermoids) as the cause.

Clinical features

Paroxysms of knife-like or electric shock-like pain, lasting seconds, occur in the distribution of the Vth nerve. Pain tends to commence in the mandibular division (V_3) but may spread over time to involve the maxillary (V_2) and occasionally the ophthalmic divisions (V_1). Bilateral TN is rare (3%) and usually

due to intrinsic brainstem pathology such as demyelination. Episodes occur many times a day with a refractory period after each. They may be brought on by stimulation of one or more trigger zones in the face. Washing, shaving, a cold wind or chewing are examples of trivial stimuli that provoke pain. The face may be screwed up in agony. Spontaneous remissions last months or years before (almost invariable) recurrence. There are no signs of Vth nerve dysfunction on examination.

Treatment

Carbamazepine (600–1200 mg daily) reduces severity of attacks in the majority. Oxcarbazepine, lamotrigine and gabapentin are also used. If drugs fail or are not tolerated, a number of surgical options are available which in general are more effective than medical treatments. Percutaneous radiofrequency selective ablation of the trigeminal ganglion is performed as a day-case procedure; recurrence may occur after an average of two years. Microvascular decompression of the nerve in the posterior fossa has a high long-term success rate (approx. 90%).

Atypical facial pain

Facial pain differs from trigeminal neuralgia in quality and distribution and trigger points are absent. The condition is probably heterogeneous in aetiology but is believed by some (on little evidence) to be a somatic manifestation of depression. Tricyclic antidepressants and drugs used in neuropathic pain are sometimes helpful.

Other causes of facial pain

Facial pain occurs in the trigeminal autonomic cephalgias (see above), occasionally in migraine and in carotid dissection.

Giant cell arteritis (temporal arteritis)

A granulomatous large vessel arteritis seen almost exclusively in people over 50 (p. 1108).

Clinical features

- **Headache** is almost invariable in giant cell arteritis (GCA). Pain develops over inflamed superficial temporal and/or occipital arteries. Touching the skin over an inflamed vessel (e.g. combing hair) causes pain. Arterial pulsation is soon lost; the artery becomes hard, tortuous and thickened. The scalp over inflamed vessels may become red. Rarely, gangrenous patches appear.
- **Facial pain.** Pain in the face, jaw and mouth is caused by inflammation of facial, maxillary and lingual branches of the external carotid artery in GCA. Pain is characteristically worse on eating (jaw claudication). Mouth opening and protruding the tongue become difficult. A painful, ischaemic tongue occurs rarely.
- **Visual problems.** Visual loss from arterial inflammation and occlusion occurs in 25% of untreated cases. Posterior ciliary artery occlusion causes anterior ischaemic optic neuropathy in three-quarters of these. Other mechanisms are central retinal artery occlusion, cilioretinal artery occlusion and posterior ischaemic optic neuropathy. There is sudden monocular visual loss (partial or complete), usually painless. Amaurosis fugax (p. 1098) may precede permanent blindness.

When the posterior ciliary vessels are affected, ischaemic optic neuropathy causes the disc to become swollen and pale; retinal branch vessels usually remain normal. When the

central retinal artery is occluded, there is sudden permanent unilateral blindness, disc pallor and visible retinal ischaemia. Bilateral blindness may develop, with the second eye being affected 1–2 weeks after the first.

Diagnosis and management

The condition should always be suspected in older patients with new facial pain or headache. The usual screening test is checking the ESR, which is greatly elevated (>50); liver enzymes are usually also elevated. The diagnosis should be established immediately by superficial temporal artery biopsy because of the risk of blindness. Immediate high doses of steroids (prednisolone, initially 1 mg/kg) should be started in a patient with typical features, even before biopsy. Since the risk of visual loss persists, long-term treatment is recommended, for a year at least.

EPILEPSY AND LOSS OF CONSCIOUSNESS

Epilepsy

An epileptic seizure can be defined as: a sudden synchronous discharge of cerebral neurones causing symptoms or signs that are apparent either to the patient or an observer. For example a limited discharge affecting only part of the cortex may cause a subjective aura apparent only to the patient, or a generalized seizure may cause a convulsion witnessed by an observer that the patient may be unaware of. This definition excludes disorders such as migrainous aura that are more gradual in onset and usually more prolonged, and EEG discharges that do not have a clinical correlate. Epilepsy is an ongoing liability to recurrent epileptic seizures.

Epidemiology

Epilepsy is common. Its population prevalence is 0.7–0.8% (higher in developing countries). Approximately 440 000 people in the UK have epilepsy. The incidence of epilepsy is age-dependent, being highest at the extremes of life, most cases starting before the age of 20 or after the age of 60. The cumulative incidence (lifetime risk) of epilepsy is over 3% and the lifetime risk of having a single seizure is 5%. The fact that the prevalence is much lower than the cumulative incidence in part reflects the fact that epilepsy often goes into remission.

Different types of epileptic seizure

Seizures are divided by clinical pattern into two main groups (Box 22.17, Fig. 22.42) – *partial* seizures and *generalized* seizures.

- **A partial (focal) seizure** is caused by electrical discharge restricted to a limited part of the cortex of one cerebral hemisphere. Partial seizures are further sub-divided according to whether or not there is loss of awareness:
 - simple partial seizures – without loss of awareness, e.g. one limb jerking (a Jacksonian seizure).
 - complex partial seizures – with loss of awareness, e.g. a temporal lobe seizure.
- **In generalized seizures**, there is simultaneous involvement of both hemispheres, always associated with loss of consciousness or awareness.

Partial seizures with electrical activity confined to one part of the brain may spread after a few seconds, due to failure

Epilepsy and loss of consciousness

Box 22.17 Classification of seizures

1. **Generalized seizures**
 - A. Absence seizures with 3 Hz spike-and-wave discharge (*petit mal*)
 - B. Generalized tonic-clonic seizures (*grand mal*)
 - C. Myoclonic seizures
 - D. Tonic and atonic seizures
2. **Partial seizures**

Focal seizures – localization-related epilepsy

 - A. Simple partial seizures (without impaired awareness, e.g. Jacksonian seizures)
 - B. Complex partial seizures (with impaired awareness, e.g. temporal lobe seizures)
 - C. Partial seizures with secondary generalization
3. **Unclassifiable seizures**

Seizures that do not fit a category above

Abridged from International League against Epilepsy.

Figure 22.42 Seizure types.

of inhibitory mechanisms, to involve the whole of both hemispheres causing a *secondary generalized seizure*. The patient may remember the initial partial seizure before losing consciousness, in which case this is called an *aura*; but sometimes the spread of electrical activity is so rapid that the patient does not experience any warning before a secondary generalized seizure.

Generalized seizure types

Typical absence seizures (*petit mal*)

This generalized epilepsy almost invariably begins in childhood. Each attack is accompanied by 3 Hz spike-and-wave EEG activity (Fig. 22.16, p. 1090). There is loss of awareness and a vacant expression for <10 seconds before returning abruptly to normal and continuing as though nothing had happened. Apart from slight fluttering of the eyelids there are no motor manifestations. Patients often do not realize they have had an attack but may have many per day. Typical absence attacks are never due to acquired lesions such as tumours – they are a manifestation of primary generalized

epilepsy. Children with absence seizures may go on to develop generalized convulsive seizures. Absence seizures are often confused with the complex partial seizures of temporal lobe epilepsy.

Generalized tonic-clonic seizures (GTCS, *grand mal* seizures)

Prodrome. There is often no warning or there may be an aura prior to a secondary generalized seizure.

Tonic-clonic phase. An initial tonic stiffening is followed by the clonic phase with synchronous jerking of the limbs, reducing in frequency over about 2 minutes until the convulsion stops. The patient may utter an initial cry and falls, sometimes suffering serious injury. The eyes remain open and the tongue is often bitten. There may be incontinence of urine or faeces.

Post-ictal phase. A period of flaccid unresponsiveness is followed by gradual return of awareness with confusion and drowsiness lasting 15 minutes to an hour or longer. Head-ache is common after a GTCS.

Myoclonic, tonic and atonic seizures

Myoclonic seizures or 'jerks' take the form of momentary brief contractions of a muscle or muscle groups, e.g. causing a sudden involuntary twitch of a finger or hand. They are common in primary generalized epilepsies. **Tonic** seizures consist of stiffening of the body, not followed by jerking.

Atonic seizure. A sudden collapse with loss of muscle tone and consciousness.

Partial seizure types

Simple partial seizures

One example is a *focal motor seizure (Jacksonian)*. These simple partial seizures originate within the motor cortex. Jerking typically begins on one side of the mouth or in one hand, sometimes spreading to involve the entire side. This visible spread of activity is called the *march* of a seizure. Local temporary paralysis of the limbs affected sometimes follows – Todd's paralysis. With some frontal seizures, conjugate gaze (p. 1075) deviates away from the epileptic focus and the head turns; this is known as an *adversive seizure*.

Complex partial seizures (temporal lobe seizures)

These usually arise from the temporal lobe (60%) or the frontal lobe. The preceding aura (in effect a simple partial seizure) often includes a rising epigastric sensation and nausea with a wide variety of possible psychic phenomena (often hard for the patient to describe) or hallucinations including:

- *Déjà vu* or *jamais vu*
- Olfactory hallucinations
- Formed visual hallucinations or misperceptions, e.g. micropsia or macropsia (objects appear small or large, respectively)
- Fear (may be mistaken for panic attacks).

There follows a period of complete or partial loss of awareness of surroundings, lasting for 1–2 minutes on average (as opposed to 10 seconds in absence seizures) which the patient generally does not remember subsequently. This stage is accompanied by speech arrest and often by *automatisms* – semi-purposeful stereotyped motions such as lip smacking or dystonic limb posturing, or more complex motor behaviours such as walking in a circle or undressing. The attacks may be followed by a short period of post-ictal confusion or may develop into a secondary generalized convulsive seizure.

Box 22.18 Causes of epilepsy

- Primary generalized epilepsy, e.g. JME
- Developmental, e.g. hamartomas, neuronal migration abnormalities
- Hippocampal sclerosis
- Brain trauma and surgery
- Intracranial mass lesions, e.g. tumour, neurocysticercosis
- Vascular, e.g. cerebral infarction, AVM
- Encephalitis and inflammatory conditions, e.g. herpes simplex, MS
- Metabolic abnormalities, e.g. hyponatraemia, hypocalcaemia
- Neurodegenerative disorders, e.g. Alzheimer's
- Drugs, e.g. ciclosporin, lidocaine, quinolones, tricyclic antidepressants, antipsychotics, lithium, stimulant drugs, e.g. cocaine
- Alcohol withdrawal

Box 22.19 Juvenile myoclonic epilepsy (JME)

- 10% of all epilepsy patients
- Starts in teenage years
- Clinical features:
 - Myoclonic jerks
 - Generalised Tonic Clonic Seizures (GTCS)
 - Absence in one-third
 - Triggers: sleep deprivation, alcohol, strobe lighting
- Abnormal EEG
- Good response to treatment
- Requires life-long treatment

Epilepsy syndromes and causes of epilepsy

(Box 22.18)

The range of causes of epilepsy is different at different ages and in different countries.

- **Children and teenagers** – genetic, perinatal and congenital disorders predominate
- **Younger adults** – trauma, drugs and alcohol are common
- **Older ages (over 60 years)** – cerebrovascular disease and mass lesions such as neoplasms

Primary generalized epilepsies (PGE)

Presenting in childhood and early adult life, these account for up to 20% of all patients with epilepsy. The cause is thought to be polygenic with complex inheritance. The brain is structurally normal but abnormalities of ion channels influencing neuronal firing, abnormalities of neurotransmitter release and synaptic connections are probably the underlying molecular pathological substrates. They include:

- **Childhood absence epilepsy:** absence seizures. Spontaneous remission by age 18 is usual.
- **Juvenile myoclonic epilepsy (JME, see Box 22.19):** this accounts for 10% of all epilepsy patients. Typically myoclonic jerks start in teenage years (usually ignored by the patient – ask about jerks when taking an epilepsy history – see Box 22.19), followed by generalized tonic-clonic seizures that bring the patient to medical attention. One-third of patients also have absences. Seizures and jerks often occur in the morning after waking. Lack of sleep, alcohol and strobe or flickering lights are seizure triggers in JME. JME usually responds well to treatment, is usually associated with EEG abnormalities and requires life-long treatment.
- **Monogenic disorders.** Research has identified a number of single gene epilepsy disorders, e.g. autosomal dominant nocturnal frontal lobe epilepsy (caused by mutations in the nicotinic acetylcholine receptor gene). These are rarities.

Symptomatic and localization-related epilepsy (LRE)

Almost any process disrupting the cortical grey matter can cause epilepsy. This is usually localization-related epilepsy with partial seizures arising from the affected area of cortex, with or without secondary generalized seizures (these may obscure the focal onset). In general, the response to treatment is less good than with PGE.

Hippocampal sclerosis

This is a major cause of epilepsy. Hippocampal sclerosis (damage with scarring and atrophy of the hippocampus and surrounding cortex) is the main pathological substrate causing temporal lobe epilepsy and the leading cause of localization-related epilepsy. Childhood febrile convulsions are the main risk factor. Hippocampal sclerosis is usually visible on MRI. It is one of the commoner causes of refractory epilepsy, in which case it may be amenable to surgical resection of the damaged temporal lobe.

Genetic and developmental disorders

Over 200 genetic disorders include epilepsy among their features, e.g. tuberous sclerosis. These account for fewer than 2% of epilepsy cases. Neuronal migration defects during brain development, dysplastic areas of cerebral cortex and hamartomas contribute to seizures both in infancy and adult life.

Trauma, hypoxia and neurosurgery

Traumatic brain injury may cause epilepsy, sometimes years after the event. The risk is not increased after mild injury (loss of consciousness or post-traumatic amnesia <30 min). Depressed skull fracture, penetrating injury and intracranial hemorrhage increase risk significantly.

Perinatal brain injury and cerebral palsy. Periventricular leukomalacia and brain haemorrhage associated with prematurity and fetal hypoxia may cause early onset epilepsy. One-third of children with cerebral palsy have epilepsy.

Brain surgery is followed by seizures in up to 17% of cases. Prophylactic anticonvulsant use after surgery is not recommended.

Brain tumours and other mass lesions

Mass lesions involving the cortex cause epilepsy. Seizures are one of the commonest presenting features of brain tumours. 6% of cases of adult onset epilepsy are caused by brain tumours.

Vascular disorders

Stroke and small vessel cerebrovascular disease – is the commonest cause of epilepsy after the age of 60.

Cortical venous thrombosis or venous sinus thrombosis

Arteriovenous malformations commonly cause epilepsy

Cavernous haemangiomas (cavernomas) usually present with epilepsy (see Fig. 22.39).

Neurodegenerative disorders

Neurodegenerative disorders involving the cerebral cortex such as Alzheimer's disease are associated with an increased risk of epilepsy.

Encephalitis and inflammatory conditions

Seizures are often the presenting feature of encephalitis, cerebral abscess, and tuberculomas. They also occur in chronic meningitis (e.g. TB) and may rarely be the first sign of acute bacterial meningitis. Neurocysticercosis is a major cause of seizures in countries where the pork tapeworm is endemic, e.g. India and South America.

Alcohol and drugs

Chronic alcohol use is a common cause of seizures. These occur either while drinking heavily or during periods of withdrawal. Alcohol-induced hypoglycaemia and head injury also cause seizures.

Several drugs including antipsychotic drugs, tricyclic antidepressants, SSRIs, lithium, class Ib anti-arrhythmics such as lidocaine, ciclosporin and mefloquine sometimes provoke fits, either in overdose or at therapeutic doses in individuals with a low seizure threshold. Stimulant drugs such as cocaine also cause seizures.

Withdrawal of antiepileptic drugs (especially barbiturates) and benzodiazepines may provoke seizures.

Metabolic abnormalities

Seizures can be caused by:

- Hypocalcaemia, hypoglycaemia, hyponatraemia
- Acute hypoxia
- Uraemia, hepatic encephalopathy
- Porphyria.

The first fit

Diagnosis

The diagnosis of a seizure is essentially a clinical one based on taking a history from the patient and any witnesses (Boxes 22.20, 22.21).

Investigations have a limited role in distinguishing between a seizure and other causes of a blackout or attack (p. 1116).

The majority of patients referred to a first fit clinic have not had a seizure. The commonest error is to misdiagnose a syncopal blackout for a seizure.

Box 22.20 Diagnosis of a seizure: taking a history after an episode of loss of consciousness

Witness account is crucial

What happened:

- Before: aura vs presyncopal prodrome
- During: convulsion, automatisms vs brief syncopal blackout and pallor
- After: post-ictal confusion and headache vs rapid recovery in syncope

Circumstances

- Seizure triggers? Sleep deprivation, alcohol binge or drugs
- Syncope triggers? Pain, heat, prolonged standing, etc.

Epilepsy risk factors?

- Childhood febrile convulsions
- Significant head injury
- Meningitis or encephalitis
- Family history of epilepsy

Previous unrecognized seizures?

- Myoclonic jerks
- Absences
- Auras (simple partial seizures)

Alcohol excess?

Medication lowering seizure threshold?

Hold a driving licence?

Box 22.21 Useful points when diagnosing epilepsy

Diagnosis is a clinical one. Tests such as EEG have little role in distinguishing between epilepsy and other attack types:

- Poor clinical discriminators between types of blackout
 - Urinary incontinence – may occur in both seizure and syncope
 - Presence of injury
- Good discriminators between types of blackout
 - Prolonged recovery period (seizure)
 - Bitten tongue – side usually (seizure)
 - Colour change – pallor (syncope), cyanosis (seizure)
- Stereotyped attacks are usually due to epilepsy
- If in doubt, do not diagnose epilepsy – best to wait and see rather than label and treat as epilepsy
- There is no role for a 'trial of anticonvulsant treatment' in uncertain cases

Box 22.22 Checklist after a first seizure

- Tests:
 - Bloods and ECG
 - EEG
 - MRI brain (most patients)
- Avoid or remove precipitants: drugs, alcohol, sleep deprivation
- Advice on safety, e.g. avoid swimming, baths, working at heights
- Stop driving and ask patient to inform DVLA (in the UK)
- Discuss recurrence risk and treatment

Which investigations are needed?

Blood tests including serum calcium, and an ECG (rhythm, conduction abnormalities, QT interval) are necessary in most patients following an episode of loss of consciousness (Box 22.22).

Electroencephalography

EEG is most useful to categorize epilepsy and understand its cause, rather than as a means of confirming a doubtful diagnosis of epilepsy. EEG has a high false negative rate in epilepsy (over 20% even with awake and sleep recordings) and a low false positive rate (1% of people without epilepsy have epileptiform changes on EEG).

- **EEG abnormalities in epilepsy:** focal cortical spikes (e.g. over a temporal lobe) or generalized spike-and-wave activity (in PGE). Epileptic activity is continuous in status epilepticus.
- **Sleep recordings or 24 h ambulatory EEG** increase sensitivity when routine EEG is normal.
- **Inpatient EEG videotelemetry** helpful for diagnosis in attacks of uncertain cause.

Brain imaging

MRI is indicated in most patients after a first seizure, particularly with partial onset seizures and in older patients where the chance of a focal brain lesion is greatest. In patients below the age of 30 with a definite electro-clinical diagnosis of primary generalized epilepsy brain imaging is not essential.

Recurrence risk after a first fit

Some 70–80% of people will have a second seizure, the risk being highest in the first 6 months after the initial seizure. The vast majority of those who have a second seizure will have further seizures if not started on treatment. The risk of seizure recurrence is significantly increased by features of PGE on

EEG, partial seizures and the presence of structural brain lesions.

Treatment

Emergency measures

Most seizures last only minutes and end spontaneously. A prolonged seizure (>5 min) or repeated seizures may be terminated with rectal diazepam, i.v. lorazepam or buccal midazolam. Give oxygen and monitor airway in post-ictal phase.

Status epilepticus

This medical emergency (Practical Box 22.5) means continuous seizures for 30 minutes or longer (or two or more seizures without recovery of consciousness between them over a similar period). Status epilepticus has a mortality of 10–15%. The longer the duration of status, the greater the risk of permanent cerebral damage. Rhabdomyolysis may lead to acute kidney injury in convulsive status epilepticus.

Over 50% of cases occur without a previous history of epilepsy. Some 25% with apparent refractory status have *pseudostatus* (non-epileptic attack disorder).

Not all status is convulsive. In *absence status*, for example, status is non-convulsive – the patient is in a continuous, distant, stuporose state. *Focal status* also occurs. *Epilepsia partialis continua* is continuous seizure activity in one part of the body, such as a finger or a limb, without loss of consciousness. This is often due to a cortical neoplasm or, in the elderly, a cortical infarct.

Antiepileptic drugs (AEDs) (Table 22.17)

AEDs are indicated when there is a firm clinical diagnosis of epilepsy and a substantial risk of recurrent seizures. Some general principles apply:

- Introduce AEDs at low dose and slowly titrate upwards until the seizures are controlled or side effects become unacceptable.
- Aim for monotherapy – 70% of patients will have good seizure control with a single AED.
- If seizures not controlled with first AED, gradually introduce second agent and then slowly withdraw the first AED. If still not seizure free then combination therapy is required.
- Epilepsy is one of the few disorders where non-generic ('brand name') prescribing is justified to ensure consistent drug levels.
- Routine monitoring of AED levels is not needed and should be reserved for assessing compliance and

toxicity. Measuring sodium valproate levels is rarely useful as levels fluctuate widely.

- There are interactions between AEDs (and with other medications), e.g. between sodium valproate and lamotrigine. New generation AEDs have fewer interactions.
- Phenytoin is no longer considered a first-line AED; it is now principally used in emergency control of seizures (see status epilepticus). Levetiracetam is increasingly used in most types of epilepsy.

Practical Box 22.5

Status epilepticus – management

Early status (up to 30 min):

- Administer oxygen, monitor ECG, BP, routine bloods (include sugar, calcium, drug screen, anticonvulsant levels urgently)
- Give lorazepam i.v. 4 mg bolus. Repeat once if necessary. Buccal midazolam is an alternative

Established status (30–90 min):

- Phenytoin: give 15 mg/kg i.v. diluted to 10 mg/mL in saline into a large vein at 50 mg/min (ECG monitoring required)

or

- Fosphenytoin: this is a pro-drug of phenytoin and can be given faster than phenytoin. Doses are expressed in phenytoin equivalents (PE): fosphenytoin 1.5 mg = 1 mg phenytoin. Give 15 mg/kg (PE) fosphenytoin (15 mg × 1.5 = 21.5 mg) diluted to 10 mg/mL in saline at 50–100 mg (PE)/min

If ongoing seizures:

- Phenobarbital 10 mg/kg i.v. diluted 1 in 10 in water for injection at <100 mg/min.
- Valproate i.v. (25 mg/kg) is an alternative

Refractory status (over 90 min) – general anaesthesia

- Only in intensive care setting, intubation and ventilation usually required
- Propofol bolus 2 mg/kg, repeat, followed by continuous infusion of 5–10 mg/kg per hour
- Thiopentone and midazolam infusions may also be used
- Continuous EEG monitoring used to assess efficacy of treatment – aim for EEG burst suppression pattern
- Reinstate previous AED medication via NG tube
- Establish diagnosis: CT or MRI may reveal an underlying cause
- Remember: 25% of apparent status turns out to be pseudostatus

Table 22.17 Antiepileptic drugs and common seizure types

	Generalized tonic-clonic seizures (grand mal)	Focal seizures with or without secondary generalization	Myoclonic seizures
First-line	Sodium valproate Levetiracetam Lamotrigine Carbamazepine Oxcarbazepine Topiramate	Carbamazepine Lamotrigine Levetiracetam Sodium valproate Oxcarbazepine Topiramate	Sodium valproate Levetiracetam Topiramate
Second-line and/or add-ons	Phenobarbital Clobazam Clonazepam Phenytoin	Clobazam Gabapentin Pregabalin Zonisamide Lacosamide Tiagabine	Clonazepam Clobazam Lamotrigine Piracetam
May worsen attacks			Carbamazepine Oxcarbazepine

Unwanted effects of drugs. Intoxication with most AEDs causes unsteadiness, nystagmus and drowsiness. Side-effects are commoner with multiple AEDs. Skin rashes are seen particularly with lamotrigine, carbamazepine and phenytoin. A wide variety of idiosyncratic drug reactions may occur, e.g. blood dyscrasias with carbamazepine.

Epilepsy in women

Birth defects. The overall risk of birth defects in babies of mothers who take one AED is around 7%, as compared with 3% in women without epilepsy. Counselling before conception is essential. The risk to the fetus of uncontrolled seizures is greater than the risks of continuing AED treatment. If drugs cannot be safely stopped, monotherapy is preferable at the minimum effective dose. Sodium valproate is associated with a higher rate of serious malformations (e.g. neural tube defects) and should be stopped or substituted if possible. Folic acid (5 mg/day) supplements should be taken before conception and throughout the first trimester. Vitamin K 20 mg orally should also be taken during the month before delivery to prevent neonatal haemorrhage. Antenatal screening is necessary.

Contraception. AEDs inducing hepatic enzymes (e.g. carbamazepine, phenytoin and phenobarbital) reduce efficacy of oral contraceptives. A combined contraceptive pill containing a higher dose of oestrogen or the progesterone only pill provides greater contraceptive security. An IUCD or barrier methods of contraception are often used in preference to oral contraceptives.

Breast-feeding. Mothers taking AEDs need not in general be discouraged from breast-feeding, though manufacturers are often hesitant in assuring that there is no risk to the baby.

Epilepsy and driving

Patients should be asked to stop driving after a seizure and to inform the regulatory authorities if they hold a driving licence. After a seizure, a temporary driving ban until seizure free is usual but regulations vary from country to country. Many driving regulatory bodies also suggest refraining from driving while withdrawing from AEDs.

Lifestyle and safety

People with epilepsy (the term 'epileptic' is no longer used) should be encouraged to lead lives as unrestricted as reasonably possible, though with simple, safety measures such as avoiding swimming and dangerous sports such as rock-climbing. Advice at home includes leaving bathroom and lavatory doors unlocked and taking showers rather than baths. Epilepsy triggers such as sleep deprivation, excess alcohol and drugs should be avoided, and strobe lighting where there is EEG evidence of a photo-paroxysmal response.

Drug withdrawal

Withdrawal of AEDs should be considered after a seizure-free period of at least 2–3 years. There is a 50% seizure recurrence rate after withdrawal so careful discussion and explanation are essential.

Refractory epilepsy

- Seizures may persist despite treatment, especially with temporal lobe partial epilepsy.
- Re-evaluate the diagnosis.
- Consider concordance (compliance).
- Combine AEDs and use maximum tolerated dose.
- Refer to a specialist unit for consideration of epilepsy surgery.

Box 22.23 Causes of blackouts and 'funny turns'

- Epilepsy
- Syncope
 - Neurocardiogenic syncope (vasovagal)
 - Cardiac syncope (Stokes–Adams attacks)
 - Micturition syncope
 - Cough syncope
 - Postural hypotension
 - Carotid sinus syncope
- Non-epileptic attacks (pseudoseizures)
- Panic attacks and hyperventilation
- Hypoglycaemia
- Drop attacks
- Hydrocephalic attacks
- Basilar migraine
- Severe vertigo
- Cataplexy, narcolepsy, sleep paralysis

- Other non-pharmacological treatments such as vagal nerve stimulation and the ketogenic low carbohydrate diet may sometimes be useful.

Epilepsy surgery

Temporal lobectomy will result in seizure freedom in 50–70% of selected patients with uncontrolled seizures caused by hippocampal sclerosis (defined by imaging and confirmed by EEG).

Other causes of blackouts (Box 22.23)

The distinction between a fit (seizure), a faint (syncope) or another type of attack is primarily a clinical one, dependent on the history and an eyewitness account. Mistaking a syncopeal loss of consciousness for a seizure is the most frequent error made in differential diagnosis.

Syncope or faints

The simple faint that over half the population experiences at some time (particularly in childhood, in youth or in pregnancy) is due to sudden reflex bradycardia with vasodilatation of both peripheral and splanchnic vasculature (*neurocardiogenic or vasovagal syncope*).

- Precipitants: a common response to prolonged standing, fear, venesection or pain. Syncope almost never occurs in the recumbent posture.
- Prodrome. Usually brief. Dizziness and light-headed feeling often with nausea, sweating, feeling of heat and visual grey-out.
- The blackout (p. 1068): Usually lie still but jerking and twitching movements can occur and are sometimes mistaken for a convulsion. Appearance is pale. Incontinence of urine or faeces can occur and is not a good discriminator between seizure and syncope.
- Recovery is rapid, usually seconds but may be followed by a feeling of general fatigue (as opposed to post-ictal drowsiness and confusion following a seizure).

Other types of syncope

Cardiac syncope (Stokes–Adams attacks) are potentially serious and often treatable. Typically, there is little or no warning. Cardiac arrhythmias, e.g. due to heart block, or left ventricular outflow tract obstruction may be the cause. Syncope during exercise is often cardiac in origin.

Micturition syncope occurs during *micturition* in men, particularly at night.

Cough syncope occurs when venous return to the heart is obstructed by bouts of severe coughing. Also occasionally seen with laughter.

Postural hypotension (p. 676) can cause syncope and occurs in the elderly, in autonomic neuropathy, with some drugs, e.g. antihypertensives.

Carotid sinus syncope (p. 676) due to a vagal response caused by pressure over the carotid sinus baroreceptors in the neck, e.g. due to a tight collar.

Convulsive syncope. collapsing in a propped up position following a syncope results in a delayed restoration of cerebral blood flow and may result in a secondary anoxic seizure following syncope.

Syncope: investigation

A 12-lead ECG should always be performed after a syncope to identify heart block, pre-excitation or long QT syndrome. Cardiac ECG holter monitoring and echocardiography are required where cardiac syncope is suspected. An implantable loop recorder is occasionally needed for infrequent events with a possible cardiac origin. Tilt table testing (p. 684) is sometimes diagnostic, but has low sensitivity.

Other conditions

Non-epileptic attack disorder (pseudoseizures) regularly cause difficulty in diagnosis. Attacks may look like grand mal fits. Usually there are bizarre thrashing, non-synchronous limb movements, but there can be extreme difficulty in separating these attacks from seizures. EEG videotelemetry is valuable. Apparent status epilepticus can occur. The serum prolactin level is of some value: this rises during a grand mal seizure but not during a pseudoseizure (or a partial seizure).

Panic attacks (see p. 1178) trigger sudden sympathetic activation and often hyperventilation leading to respiratory alkalosis. They cause some or all of the following symptoms: dizziness, chest pains or tightness, a feeling of choking or shortness of breath, tingling in face and extremities, palpitations, trembling and a feeling of dissociation or of impending doom. Consciousness is usually preserved and attacks easily recognized.

Hypoglycaemia (p. 1015) causes confusion followed by loss of consciousness, sometimes with a convulsion, dysphasia or hemiparesis. There is often warning, with hunger, malaise, shaking and sweating. Prompt recovery occurs with i.v. (or oral) glucose. Prolonged hypoglycaemia causes widespread cerebral damage. Hypoglycaemic attacks unrelated to diabetes are rare (p. 1030). Feeling faint after fasting does not indicate anything serious.

Vertigo. When acute, vertigo can be sufficiently severe as to cause prostration: a few seconds' unresponsiveness sometimes follows.

Migraine. Severe basilar migraine and familial hemiplegic migraine may occasionally lead to loss of consciousness.

Drop attacks are instant, unexpected episodes of lower limb weakness with falling, largely in women over 60 years. Awareness is preserved. They are due to sudden change in lower limb tone, presumably of brainstem origin. Sudden attacks of leg weakness also occur in hydrocephalus.

Transient ischaemic attacks are almost never a cause of loss of consciousness.

Sleep disorders

Sleep architecture and insomnia are discussed on page 1167. Myoclonic jerks when falling asleep are a normal phenomenon (p. 1121). Seizures may occur predominantly or solely during sleep.

Narcolepsy and cataplexy

Narcolepsy is caused by abnormalities of the brain neurotransmitter hypocretin (orexin) which is a regulator of sleep.

CSF levels are usually low, thought in most cases to be due to autoimmune damage to the hypothalamic cells secreting the neurotransmitter. Narcolepsy is strongly associated with HLA-DR2 and HLA-DQB1*0602 antigens. The prevalence is estimated at 30–50/100 000.

There are four main clinical features but not all patients have the full tetrad:

- **Excessive daytime sleepiness (EDS).** This is the usual presenting symptom and the main cause of disability. Patients have frequent irresistible sleep attacks during the day, often in inappropriate circumstances, e.g. during meals or conversations or while driving. EDS may be quantified with the Epworth Sleepiness Scale. Nighttime sleep may be disrupted and paradoxically insomnia may occur.
- **Cataplexy** is sudden loss of muscle tone leading to head droop or even falling with intact awareness. Attacks are often set off by sudden surprise or emotion, e.g. laughter.
- **Hypnagogic/hypnopompic hallucinations.** Dream-like hallucinations occurring while falling asleep or waking from sleep. Often frightening.
- **Sleep paralysis.** A brief paralysis on waking or while falling asleep due to intrusion of REM atonia into wakefulness. This occasionally occurs in people without narcolepsy.

Diagnosis and treatment

Multiple Sleep Latency Testing demonstrating rapid transition from wakefulness to sleep and short time to onset of REM sleep confirms the diagnosis. HLA testing may also be useful.

Good sleep hygiene advice is necessary. Modafinil dexamfetamine and methylphenidate are used to treat EDS, often with only partial response. Tricyclic antidepressants, particularly clomipramine, or SSRIs can improve cataplexy. Sodium oxybate is also used.

Parasomnias

Disruptive motor or verbal behaviours occurring during sleep. They are divided into REM and non-REM parasomnias depending on which stage of sleep they arise in. They include sleepwalking, night terrors, confusional arousals and REM sleep behaviour disorder (which may be an early feature of Parkinson's disease).

Obstructive sleep apnoea (see p. 818)

MOVEMENT DISORDERS

Disorders of movement divide broadly into two categories:

- Hypokinesias – characterized by slowed movements with increased tone (Parkinsonism)
- Hyperkinesias – excessive involuntary movements.

Both types may co-exist, for example in Parkinson's disease where there are both slowed movements and tremor. Many of these disorders (not all) relate to dysfunction of the basal ganglia.

Parkinsonian disorders

Idiopathic Parkinson's disease

In 1817, James Parkinson, a physician in Hoxton, London, published *The Shaking Palsy*, describing this common worldwide condition that has a prevalence of 150/100 000.

FURTHER READING

Dauvilliers Y, Arnulf I, Mignot E. Narcolepsy with cataplexy. *Lancet* 2007; 369: 499–511.

Zeman A, Reading P. The science of sleep. *Clin Med* 2005; 5:97–101.

Parkinson's disease is clinically and pathologically distinct from other parkinsonian syndromes.

The causes of idiopathic Parkinson's disease (PD) is still not fully understood. The relatively uniform worldwide prevalence suggests that a single environmental agent is not responsible. There may be multiple interacting risk factors including genetic susceptibility:

Age and gender. Prevalence increases sharply with age, particularly over 70 years with prevalence of 1 in 200 over age 80. Ageing changes are likely to be an important factor in causation. Prevalence is higher in men (1.5:1 M:F)

Environmental factors. Epidemiological studies consistently show a small increased risk with rural living and drinking well water. Pesticide exposure has been implicated and pesticide-induced rodent models of PD exist, which increases biological plausibility of a link. The chemical compound MPTP, a potent mitochondrial toxin, causes severe Parkinsonism, leading to suggestions that oxidative stress may be a factor leading to neuronal cell death in idiopathic PD. Studies consistently show that non-smokers have a higher risk of PD than smokers (even after controlling for shorter life expectancy in smokers), an observation that is difficult to explain.

Genetic factors. Idiopathic PD is not usually familial, but twin studies show there is a significant genetic component in early onset PD (onset before 40). Several genetic loci for Mendelian inherited monogenic forms of PD have now been identified (Table 22.18), designated PARK 1–11. Most of these are rare but together they account for a large proportion of early onset and familial PD, and a small proportion (perhaps 1–2%), of sporadic late onset cases. The main significance of the PARK genes is that they provide insights into the pathophysiological mechanisms underlying PD that may be relevant to sporadic cases. Research is ongoing to determine whether polymorphisms in these and other genes may, in combination, constitute a susceptibility to PD which can be triggered by environmental factors or the ageing process.

Pathology

The pathological hallmarks of PD are the presence of neuronal inclusions called Lewy bodies and loss of the dopaminergic neurones from the pars compacta of the substantia nigra in the midbrain that project to the striatum of the basal ganglia (Fig. 22.10). Lewy bodies contain tangles of α -synuclein and ubiquitin and become gradually more widespread as the condition progresses, spreading from the lower brainstem, to the midbrain and then into the cortex. Degeneration also occurs in other basal ganglia nuclei. The extent of nigrostriatal dopaminergic cell loss correlates with the degree of akinesia.

Symptoms and signs

PD almost always presents with the typical motor symptoms of tremor and slowness of movement but it is likely that the pathological process starts many years before these symptoms develop. By the time of first presentation, on

average 70% of dopaminergic nigrostriatal cells have already been lost.

Prodromal premotor symptoms

Patients develop a variety of nonspecific non-motor symptoms during the approximately seven years, sometimes longer, before the motor symptoms become manifest. These include:

- Anosmia (present in 90%) – the olfactory bulb is one of the first structures to be affected
- Depression/anxiety (50%)
- Aches and pains
- REM sleep behaviour disorder
- Autonomic features – urinary urgency, hypotension
- Constipation
- Restless legs syndrome.

Motor symptoms

These develop slowly and insidiously and are often initially attributed to 'old age' by patients. The core motor features of PD are:

- Akinesia
- Tremor
- Rigidity
- Postural and gait disturbance.

Slowness causes difficulty rising from a chair or getting into or out of bed. Writing becomes small (micrographia) and spidery, tending to tail off. Relatives often notice other features – slowness and an impassive face. Idiopathic PD is almost always initially more prominent on one side. The diagnosis is usually evident from the overall appearance.

Akinesia

Poverty/slowness of movement (also called bradykinesia) is the cardinal clinical feature of Parkinsonism and the main cause of disability. What distinguishes it from slowness of movement from other causes is a progressive *fatiguing* and *decrement* in amplitude of repetitive movements.

There is difficulty initiating movement. The upper limb is usually affected first and is almost always unilateral for the first years. Rapid dexterous movements are impaired causing difficulty writing (micrographia), and doing up buttons and zips for example. Facial immobility gives a mask-like semblance of depression. Frequency of spontaneous blinking diminishes, producing a *serpentine stare*.

Akinesia is tested for clinically by asking the patient to perform rapid alternating movements such as opening and closing the hand repetitively or pronating and supinating the arm, looking for progressive slowing and decrement in amplitude of movement.

Tremor

The presenting symptom in 70% of patients. Almost always starts in the fingers and hand and like akinesia, is unilateral initially, spreading later to the leg on the same side and then

Table 22.18 Selected Parkinson's disease genes

LOCUS	Protein	Inheritance	Comments
PARK1	α -synuclein	AD	Rare but a major protein in Lewy bodies
PARK2	Parkin	AR	Responsible for most cases of juvenile PD and 20% of early onset PD cases
PARK6	Pink-1	AR	Rare. Protein involved in mitochondrial function
PARK8	LRRK2 (a kinase of unknown function)	AD	Phenotype almost identical to sporadic PD. Found in 1% of apparently sporadic PD patients. High frequency in Jewish and north African Arab patients

the opposite arm. The tremor is present at rest and reduces or stops completely when the hand is in motion. The frequency is 3–6 Hz and it is often described as *pill-rolling* because the patient appears to be rolling something between thumb and forefinger. As with most tremors it is made worse by emotion or stress.

Rigidity

A sign rather than a symptom usually. Stiffness on passive limb movement is described as 'lead pipe' as it is present throughout the range of movement and unlike spasticity, is not dependent on speed of movement. When stiffness occurs with tremor (not always visible), a ratchet-like jerkiness is felt, described as cogwheel rigidity.

Postural and gait changes

A stooped posture is characteristic. Gait gradually becomes shuffling with small stride length, slow turns, freezing and reduced arm swing. Postural stability eventually deteriorates, leading to falls, but this is a late stage feature which should arouse suspicion of an alternative diagnosis if present during the first 5 years.

Speech and swallowing

Speech becomes quiet, indistinct and flat. Drooling may be an embarrassing problem and swallowing difficulty is a late feature that may eventually lead to aspiration pneumonia as a terminal event.

Cognitive and psychiatric changes

Cognitive impairment is now recognized to be common in late stage PD (80%) and may develop into dementia. Visual hallucinations on treatment, and psychosis are not uncommon, and may herald evolving cognitive decline. Cholinesterase inhibitors (p. 1141) may be helpful.

Depression is common, probably due to involvement of serotonergic and adrenergic systems, and an important cause of reduced quality of life in PD. Anxiety is also co-morbid with PD.

The clinical evolution of PD

PD worsens slowly over the years as more neuronal cells become affected by the pathological process. Initial symptoms may be trivial, especially if affecting the non-dominant hand, but worsening akinesia and tremor eventually cause significant disability if untreated. Symptoms which are initially unilateral eventually spread to the opposite side, and axial symptoms such as walking difficulty and postural instability develop.

Most patients respond well to treatment and there is generally a period of several years in which symptoms are well controlled with relatively little disability. Response to dopaminergic drugs is never lost but treatment-related fluctuations may develop (see below) which can be limiting, especially for patients with early age at onset. Eventually, usually by mid-70s, late stage, treatment-unresponsive, features such as cognitive impairment, swallowing difficulty, loss of postural stability and falls start to emerge.

The rate of progression is very variable, with a benign form running over several decades. Usually the course is over 10–20 years, with death resulting from bronchopneumonia and immobility.

Diagnosis

There is no laboratory test; diagnosis is made by recognizing physical signs and distinguishing idiopathic PD from other Parkinsonian syndromes. Patients with suspected PD should be referred to a specialist without initiation of treatment.

MRI imaging is normal and not necessary in typical cases. Dopamine transporter (DaT) imaging makes use of a radio-labelled ligand binding to dopaminergic terminals to assess the extent of nigrostriatal cell loss. It may occasionally be needed to distinguish PD from other causes of tremor, or drug-induced Parkinsonism, but it cannot discriminate between PD and other akinetic-rigid syndromes.

Treatment

Education about the condition is necessary and physical activity is beneficial and should be encouraged. Dopamine replacement with levodopa or a dopamine agonist (DA) improves motor symptoms and is the basis of pharmacological therapy. Treatment of non-motor symptoms such as depression, constipation, pain and sleep disorders is also necessary and significantly improves quality of life.

Dopamine replacement may not always be needed in early stage PD and is only started when symptoms start to cause disability. The mechanism of action of drugs in PD is shown in Figure 22.43.

Levodopa

Levodopa remains the most effective form of treatment and all patients with PD will eventually need it. It is combined with a dopa decarboxylase inhibitor – benserazide (co-beneldopa) or carbidopa (co-careldopa) – to reduce the peripheral adverse effects (e.g. nausea and hypotension); 50 mg of L-dopa (e.g. co-careldopa 62.5 mg) three times daily, increasing after 1 week to 100 mg three times daily is a typical starting dose. The response is often dramatic.

Dopamine agonists

Dopamine agonists (DA) may be used in combination with levodopa or as initial monotherapy in younger patients (below age 65–70) with mild to moderate impairment. Although less

Figure 22.43 Drugs in Parkinson's disease. Levodopa crosses the blood-brain barrier, enters the nigrostriatal neurone and is converted to dopamine. (a) Carbidopa and benserazide reduce peripheral conversion of levodopa to dopamine, thus reducing side-effects of circulating dopamine. (b) Dietary amino acids from high-protein meals can inhibit active transport across blood-brain barrier by competing with levodopa. (c) Levodopa is converted (AAAD) to dopamine. (d) Amantadine enhances dopamine release. (e) Dopamine agonists react with dopamine receptors. (f) Monoamine oxidase B inhibitors block dopamine breakdown. (g) COMT inhibitors prolong dopamine activity by blocking breakdown. AAAD, aromatic amino acid decarboxylase; COMT, catechol-O-methyl transferase.

efficacious in symptom control than levodopa and generally less well tolerated, DAs are associated with fewer motor complications over a 5 year period. Non-ergot DAs (Pramipexole and ropinirole or rotigotine via transdermal patch) are used in preference to ergot-derived drugs, which may be associated with fibrotic reactions including cardiac valvular fibrosis. Domperidone is used as an antiemetic when initiating DA therapy (other antiemetics should not be used as they may worsen symptoms by blocking central dopamine receptors).

Other drugs used in PD

- **Selegiline** 5–10 mg once daily (a monoamine oxidase B inhibitor) reduces catabolism of dopamine in brain. Mild symptomatic effect. **Rasagiline** is another MAOB inhibitor.
- **Amantadine** has a modest anti-Parkinsonian effect but is mainly used to improve dyskinesias in advanced disease.
- **Anticholinergics** (e.g. **trihexyphenidyl**) may help tremor but are now rarely used in PD except in younger patients. High propensity to cause confusion in older patients.
- **Apomorphine** is a potent, short-acting, DA administered subcutaneously by an autoinjector pen as intermittent 'rescue' injection for off periods or by continuous infusion pump. Used in advanced PD.

Long-term response to treatment

As the disease progresses, medical therapy for PD becomes more difficult as higher doses of dopamine replacement therapy are required and response becomes more unpredictable with the development of motor fluctuations and dyskinesias, but response to dopaminergic drugs is never lost.

Approximately 10% of patients per year develop motor complications in the form of 'wearing off' (the duration of effect of individual doses of LD becomes progressively shorter), dyskinesias (involuntary choreiform movements) and eventually, on/off phenomenon (sudden, unpredictable transitions from mobile to immobile). Eventually, patients may alternate between the on state with dopamine-induced dyskinesias and periods of complete immobility (off).

Management of motor complications of treatment represents one of the greatest challenges in the management of PD. Management strategies include:

- Dose fractionation of levodopa – increasing dose frequency
- Addition of COMT (catechol-O-methyl transferase) inhibitor **entacapone** (200 mg with each levodopa dose) to prolong duration of action. Also available as a combined preparation with levodopa and carbidopa
- Slow release levodopa – mostly used for overnight symptoms as absorption is erratic and difficult to predict, so limiting effectiveness in control of daytime symptoms
- Avoiding protein-rich meals (which impair levodopa absorption) and taking doses at least 40 minutes prior to meals
- Apomorphine continuous subcutaneous infusion (see above)
- Deep brain stimulation and L-dopa intestinal gel (see below).

Deep brain stimulation (DBS)

Stereotactic insertion of electrodes into the brain has proved to be a major therapeutic advance in selected patients

(usually under age 70) with disabling dyskinesias and motor fluctuations not adequately controlled with medical therapy. Targets include:

- Subthalamic nucleus – response similar to levodopa with reduction in dyskinesia
- Globus pallidus – improves dyskinesia but levodopa still required for motor symptoms
- Thalamus – for tremor only.

L-dopa intestinal gel infusion

Continuous infusion of this gel into the small intestine via a jejunostomy using a patient-operated pump is effective for selected patients with severe motor complications. At present, it is used only where apomorphine or DBS are contraindicated, partly because of high costs.

Tissue transplantation

Transplantation of embryonic mesencephalic dopaminergic cells directly into the putamen has produced mixed results but is potentially promising with research ongoing to refine the technique. Stem cells and gene therapy approaches are in development.

Physiotherapy, OT and physical aids

Physiotherapy, occupational therapy and speech therapy all have a role to play in managing PD and reducing disability, speech and swallowing problems and falls. Walking aids are often a hindrance early on, but later a frame or a tripod may help. A variety of external cueing techniques may help with freezing.

Other akinetic-rigid syndromes

Drug-induced Parkinsonism

Dopamine blocking or depleting drugs, particularly neuroleptics (with the exception of clozapine), induce Parkinsonism or worsen symptoms in affected patients, and may precipitate symptoms in elderly patients in the presymptomatic phase.

Atypical Parkinsonism

A number of neurodegenerative disorders affect the basal ganglia causing prominent Parkinsonism as part of the clinical picture and may be mistaken for idiopathic PD in the early stages. These include:

- **Progressive supranuclear palsy** (Steele–Richardson–Olszewski syndrome). Causes Parkinsonism, postural instability with early falls, vertical supranuclear gaze palsy, pseudobulbar palsy and dementia. Tau deposition seen pathologically.
- **Multiple system atrophy**. Autonomic symptoms and ataxia occur in addition to Parkinsonism. Pathologically α -synuclein positive glial cytoplasmic inclusions occur.
- **Corticobasal degeneration**. Alien limb phenomena, myoclonus and dementia.

These disorders are relentlessly progressive, although they sometimes respond to levodopa, and usually cause death within a decade. 'Red flag' symptoms suggesting one of these disorders include:

- Symmetrical presentation and absence of tremor
- Levodopa unresponsiveness (or poor response)
- Early falls (within first year)
- Additional neurological features.

Dementia with Lewy bodies

See page 1140.

Wilson's disease

This rare and treatable disorder of copper metabolism is inherited as an autosomal recessive. Copper deposition occurs in the basal ganglia, the cornea and liver (p. 341), where it can cause cirrhosis. All young patients (below age 50) with an akinetic-rigid syndrome or any hyperkinetic movement disorder, or with liver cirrhosis should be screened for Wilson's disease (check serum copper and caeruloplasmin). Intellectual impairment develops. Neurological damage is reversible with early treatment. Diagnosis, and treatment with the chelating agent penicillamine is discussed on page 341.

Hyperkinetic movement disorders

There are five hyperkinetic movement disorders. These can sometimes be difficult to separate from one another and may occur in combination.

- Tremor – rhythmic sinusoidal oscillation of a body part
- Chorea – excessive, irregular movements flitting from one body part to another ('dance-like')
- Myoclonus – brief electric shock-like jerks
- Tics – stereotyped movements or vocalizations (may be temporarily suppressed)
- Dystonia – sustained muscle spasms causing twisting movements and abnormal postures.

Essential tremor

This common condition, often inherited as an autosomal dominant trait, causes a bilateral, fast, low amplitude tremor, mainly in the upper limbs. The head and voice are occasionally involved. Tremor is postural, such as when holding a glass or cutlery. Essential tremor occurs at any age but usually starts in early life. Tremor is slowly progressive but rarely produces severe disability. There may be a cerebellar-type action tremor component. Anxiety exacerbates the tremor.

Treatment is often unnecessary, and unsatisfactory. Many patients are reassured to find they do not have PD, with which essential tremor is often confused. Small amounts of alcohol, beta-blockers (propranolol), primidone or gabapentin may help. Sympathomimetics (e.g. salbutamol) make all tremors worse. Stereotactic thalamotomy and thalamic DBS are used in severe cases.

Chorea

There are a wide variety of possible causes of chorea. These include:

- Systemic disease – thyrotoxicosis, SLE, antiphospholipid syndrome, primary polycythaemia
- Genetic disorders – Huntington's disease and genetic phenocopies, neuroacanthocytosis, benign hereditary chorea
- Structural and vascular disorders affecting the basal ganglia
- Drugs (e.g. levodopa and OC pill)
- Post-infectious (Sydenham's chorea), following months after streptococcal infection or as part of acute rheumatic fever
- Pregnancy.

Treatment is of the underlying cause, but dopamine blocking drugs such as phenothiazines (e.g. sulpiride) and

dopamine depleting drugs (tetrabenazine) reduce chorea (as the prototypical excessive movement condition the treatment is the *opposite* of PD).

Huntington's disease (HD)

A cause of chorea, usually presenting in middle life, initially with subtle 'fidgetiness' followed by development of progressive psychiatric and cognitive symptoms.

Prevalence worldwide is about 5/100 000. HD is due to a CAG trinucleotide repeat expansion which forms the basis of the diagnostic test (p. 42). This results in translation of an expanded polyglutamine repeat sequence in *huntingtin*, the protein gene product, the function of which is unclear. The expansion is thought to be a toxic 'gain of function' mutation. Most adult onset patients have 36–55 repeats and there is an inverse relationship between repeat length and age at onset, with juvenile onset patients having over 60 repeats. Expansion of the unstable CAG repeat during meiosis, particularly spermatogenesis, is the molecular basis for the phenomenon of anticipation (a tendency for successive generations to have earlier onset and more severe disease) particularly when inherited from the father.

HD is inherited in an autosomal dominant manner with complete penetrance (all gene carriers will develop the disease eventually). Previous family history is often not known. There is no disease modifying treatment at present, although chorea can improve with treatment, but progressive neurodegeneration leads to dementia and ultimately death after 10–20 years. Patients with small or intermediate range expansions may present in old age with isolated chorea.

Absence of treatment results in a low take-up rate for presymptomatic testing in at-risk individuals. Test centres have protocols for counselling families and addressing ethical issues.

Hemiballismus

Hemiballismus (see Fig. 22.10) describes violent swinging movements of one side caused usually by infarction or haemorrhage in the contralateral subthalamic nucleus.

Acute chorea-hemiballismus also occurs after diabetic non-ketotic hyperglycaemia, with signal change seen in the basal ganglia on CT or MRI, thought to be due to osmotic shifts causing myelinolysis.

Myoclonus

Cortical myoclonus is usually distal (hands and fingers especially) and stimulus sensitive (spontaneous but also triggered by touch or loud noises) and caused by a wide variety of pathologies affecting the cerebral cortex; spinal and brainstem myoclonus are caused by localized lesions affecting these structures.

Primary myoclonus

Physiological myoclonus. Nocturnal myoclonus consisting of sudden jerks (often with a feeling of falling) on dropping off to sleep or waking – is common and not pathological. The startle response is also a form of brainstem myoclonus.

Myoclonic dystonia (DYT11). Myoclonic 'lightning jerks' often with dystonia, inherited as a rare autosomal dominant disorder due to mutations in the ϵ -sarcoglycan gene. The condition is thought to be allelic with benign essential myoclonus (caused by disruption of the same gene).

Myoclonus in epilepsy

Myoclonic jerks occurs in several forms of epilepsy (p. 1112). An antiepileptic drug, e.g. valproate, may be helpful.

FURTHER READING

Lorenz D, Deuschl G. Update on the pathogenesis and treatment of essential tremor. *Curr Opin Neurol* 2007; 20:447–452.

Progressive myoclonic epilepsy-ataxia syndromes

These rare conditions include genetic and metabolic disorders where myoclonus accompanies progressive epilepsy, cognitive decline and/or ataxia. *Lafora body disease*, *neuro-nal ceroid lipofuscinosis* and *Unverricht-Lundborg disease* are examples.

Secondary myoclonus

Myoclonus may be seen in a wide variety of metabolic disorders including hepatic and renal failure (asterixis), as part of several dementias and neurodegenerative disorders (e.g. Alzheimer's disease) and encephalitis.

Post-anoxic myoclonus sometimes follows severe cerebral anoxia.

Tics

Tics are common (15% lifetime prevalence), brief stereotyped movements usually affecting the face or neck but which may affect any body part including vocal tics. Unlike other movement disorders they may be transiently suppressed, leading to a build-up of anxiety and overflow after release.

Simple transient tics (e.g. blinking, sniffing or facial grimacing) are common in childhood, but may persist. Adult onset tics are rare and usually due to a secondary cause. The borderland between normal and pathological is vague.

Tourette's syndrome

The commonest cause of tics, characterized by multiple motor tics and at least one vocal tic, starting in childhood and persisting longer than a year. Boys are affected more often than girls in a 3:1 ratio. Behavioural problems including attention deficit hyperactivity disorder (ADHD) and obsessive-compulsive disorder (OCD) are common and may sometimes be the major cause of disability. There is sometimes explosive barking and grunting of obscenities (coprolalia) and gestures (copropraxia) or echolalia (copying what other people say). Many affected individuals never come to medical attention. The cause is not known but it may be a complex problem with histaminergic neurotransmission.

Dystonias (Box 22.24)

Dystonia is most usefully classified by aetiology, into:

- **Primary dystonias** – where dystonia is the only, or main, clinical manifestation (usually genetic)
- **Secondary dystonia** – due to brain injury, cerebral palsy or drugs for example

Box 22.24 A classification of dystonias

- Generalized dystonia
- Primary torsion dystonia (PTD)
- Dopamine-responsive dystonia (DRD)
- Drug-induced dystonia (e.g. metoclopramide)
- Symptomatic dystonia (e.g. after encephalitis lethargica or in Wilson's disease)
- Paroxysmal dystonia (very rare, familial, with marked fluctuation)
- Focal dystonia
- Spasmodic torticollis
- Writer's cramp
- Oromandibular dystonia
- Blepharospasm
- Hemiplegic dystonia, e.g. following stroke
- Multiple sclerosis – rare

- **Heredo-degenerative dystonia** – as part of a wider neurodegenerative disorder
- **Paroxysmal dystonias** – rare, mostly genetic, attacks of sudden involuntary movements with elements of dystonia and chorea.

Primary dystonias

Young onset. Mutations in the DYT1 gene locus, seen particularly in the Ashkenazi Jewish population, cause limb-onset dystonia (usually foot), before age 28. Most patients have a 3 base-pair GAG deletion in the torsinA endoplasmic reticulum ATPase protein encoded by the DYT1 gene. Penetrance is low (autosomal dominant) and phenotype very variable, but it often spreads over years to become generalized dystonia, and can result in severe disability. Cognitive function remains normal. The condition is rare and the definitive form of treatment for severe cases is now deep brain stimulation (electrodes inserted into globus pallidus).

Adult onset. Much the commonest type of primary dystonia. Onset is usually around 55 and dystonia is usually focal (restricted to one body part), particularly affecting the head and neck unlike DYT1 dystonia. Various patterns are recognized:

Torticollis

Dystonic spasms gradually develop in neck muscles causing the head to turn (torticollis) or to be drawn backwards (retrocollis). There may also be a jerky head tremor. A gentle touch with a finger tip at a specific site may relieve the spasm temporarily (sensory trick or 'geste').

Writer's cramp and task-specific dystonias

A specific inability to perform a previously highly developed repetitive skilled movement, e.g. writing. The movement provokes dystonic posturing. Other functions of the hand remain normal. Overuse may lead to task-specific dystonias in certain occupations, e.g. musicians, typists and even golfers.

Blepharospasm and oromandibular dystonia

These consist of spasms of forced blinking or involuntary movement of the mouth and tongue (e.g. lip-smacking and protrusion of the tongue and jaw). Speech may be affected.

Dopa-responsive dystonia (DRD)

In this rare dystonia is completely abolished by small doses of levodopa. Typically dystonic walking begins in childhood and may resemble a spastic paraparesis or even present as cerebral palsy. Dominantly inherited mutations in the GTP cyclohydrolase gene on chromosome 14q21.3 (necessary for synthesis of a co-factor – tetrahydrobiopterin – needed for dopamine synthesis) lead to brain dopamine deficiency. Patients with dystonic gaits are sometimes given test doses of levodopa.

Neuroleptics and movement disorders

Neuroleptics (antipsychotic drugs used to treat schizophrenia) and related drugs used as antiemetics (e.g. metoclopramide) can cause a variety of movement disorders.

- **Akathisia.** This is a restless, repetitive and irresistible need to move
- **Parkinsonism.** Due to D₁ and D₂ dopamine receptor blockade – see above
- **Acute dystonic reactions.** Spasmodic torticollis, trismus and oculogyric crises (episodes of sustained

FURTHER READING

Tarsy D, Simon DK. Dystonia. *N Engl J Med* 2006; 355:818–829.

upward gaze) develop, dramatically and unpredictably, after single doses

- **Tardive dyskinesia.** These mouthing and lip-smacking grimaces occur after several years of neuroleptic use. They often become temporarily worse when the drug is stopped or the dose reduced. Even if treatment ceases, resolution seldom follows. Atypical neuroleptics are less prone to cause this complication.

Treatment

Targeted injection of botulinum toxin into affected muscles is now the principal form of treatment for all focal dystonias. Antimuscarinics (e.g. trihexyphenidyl) are sometimes helpful.

MULTIPLE SCLEROSIS (MS)

MS is a chronic autoimmune T-cell mediated inflammatory disorder of the CNS. Multiple plaques of demyelination occur throughout the brain and spinal cord, occurring sporadically over years (dissemination in space and time which is crucial for diagnosis).

MS is a major cause of disability in young adults but recent therapeutic advances mean that it is no longer an 'untreatable' disease.

Epidemiology

Prevalence: MS is a common neurological disorder in the UK with prevalence of 1.2/1000. Approximately 80 000 people in the UK have MS.

Gender: women outnumber men by 2:1. There is evidence that this ratio is widening with an increasing proportion of women being affected.

Age: presentation is typically between 20 and 40 years of age. Presentation after age 60 is rare although diagnosis may sometimes be much delayed, occurring years after initial symptoms.

Prevalence varies widely in different geographic regions and ethnic groups. This probably reflects both genetic and environmental influences in pathogenesis. It is much commoner in white populations and with increasing distance from the equator. Even within the UK there is a north-south divide with prevalence being higher in Scotland than southern England. Migration studies show that children moving from a low risk to a high risk area (e.g. the UK) develop a higher risk of MS, similar to the population of the country to which they migrate, indicating that environmental factors are a factor in pathogenesis.

Other autoimmune disorders occur with increased frequency in patients with MS and their relatives, indicating a genetic predisposition to autoimmunity.

Aetiology and pathogenesis

MS is a T-cell mediated autoimmune disease causing an inflammatory process mainly within the white matter of the brain and spinal cord. The aetiology of MS is complex and not yet fully understood.

Genetic susceptibility

Multiple genes interact to confer increased risk of MS, giving a complex polygenic inheritance pattern. Genetic differences between different populations probably account for part of the observed variation in MS incidence around the world.

Family studies show that there is a much increased risk of MS in 1st-degree relatives of affected patients (approx. 3–5% lifetime risk of developing MS). Twin studies confirm a major

genetic component to susceptibility with 30% of monozygotic twins being concordant for MS versus 5% of dizygotic twins.

Genes. Variations in some 60 different genes have been identified so far as conferring an increased risk of MS; 80% of these are genes relating to immune system function and regulation, including HLA and MHC polymorphisms.

Environmental factors

Migration studies (see above) and twin studies indicate that environmental factors play a role in the development of MS but these factors are still largely unknown. Viral infections can precipitate MS relapses and exposure to infectious agents at critical times in development may trigger MS in genetically susceptible individuals. There is evidence that exposure to EBV may be linked to MS; EBV seropositivity is higher in patients with MS than the general population. Human herpesvirus 6 (HHV-6) has also been implicated. Exposure to infectious agents in childhood may reduce risk of developing MS and other autoimmune disorders (the 'Hygiene Hypothesis'). There is also some evidence that low levels of vitamin D and lack of sunlight exposure may be a risk factor for MS.

Pathology (Fig. 22.44)

Plaques of demyelination, 2–10 mm in size, are the cardinal features. Plaques occur anywhere in CNS white matter (and sometimes grey matter) but have a predilection for distinct CNS sites: optic nerves, the periventricular region, the corpus callosum, the brainstem and its cerebellar connections and the cervical cord (corticospinal tracts and posterior columns). MRI studies show that most inflammatory plaques are asymptomatic. Peripheral myelinated nerves are not directly affected in MS.

Acute relapses are caused by focal inflammation causing myelin damage and conduction block. Recovery follows as inflammation subsides and remyelination occurs. When damage is severe, secondary permanent axonal destruction occurs. Progressive axonal damage is the pathological basis of the progressive disability seen in progressive forms of MS. The exact relationship between the inflammatory lesions seen in early relapsing-remitting forms of MS and the progressive axonal loss of chronic forms of MS is disputed.

Clinical features

No single group of signs or symptoms is diagnostic. A wide variety of possible symptoms may occur depending on the

Figure 22.44 Multiple sclerosis. Cross-section of spinal cord showing MS plaques in posterior column and lateral corticospinal tracts. (Courtesy of the late Professor Ian Macdonald.)

Figure 22.45 Clinical patterns of multiple sclerosis.

anatomical site of lesions; MS has been described as the modern 'great imitator'. The clinical time course of attacks and tempo of evolution of symptoms are as good as the symptoms themselves in making the diagnosis of MS.

Types of MS

There are three main clinical patterns (Fig. 22.45):

- Relapsing-remitting MS (RRMS) (85–90%). The commonest pattern of MS. Symptoms occur in attacks (relapses) with a characteristic time course: onset over days and typically recovery, either partial or complete, over weeks. On average patients have one relapse per year but occasionally many years may separate relapses (benign MS – 10% of patients). Patients may accumulate disability over time if relapses do not recover fully.
- Secondary progressive MS – this late stage of MS consists of gradually worsening disability progressing slowly over years. 75% of patients with relapsing-remitting MS will eventually evolve into a secondary progressive phase by 35 years after onset. Relapses may sometimes occur in this progressive phase (relapsing-progressive MS).
- Primary progressive MS (10–15%). The least common form of MS, characterized by gradually worsening disability without relapses or remissions. Typically presents later and is associated with fewer inflammatory changes on MRI.

Clinical presentations

Three characteristic common presentations of MS are optic neuropathy (neuritis), brainstem demyelination and spinal cord lesions, described below.

Optic neuritis (ON)

See 'Inflammatory optic neuropathy', page 1073.

Brainstem demyelination

A relapse affecting the brainstem causes combinations of diplopia, vertigo, facial numbness/weakness, dysarthria or dysphagia. Pyramidal signs in the limbs occur when the corticospinal tracts are involved. A typical picture is sudden diplopia, and vertigo with nystagmus, but without tinnitus or deafness. Bilateral internuclear ophthalmoplegia (INO, in this chapter) is pathognomonic of MS.

Spinal cord lesions

Paraparesis developing over days or weeks (Box 22.27) is a typical result of a plaque in the cervical or thoracic cord,

causing difficulty in walking and limb numbness with tingling, often asymmetric. Lhermitte's sign may be present (p. 1087). Arms are sometimes also involved in high cervical cord lesions. A tight band sensation around the abdomen or chest is common with thoracic cord lesions.

Common symptoms in MS

Disability and neurological impairments accumulate gradually over the years. Several symptoms are common and many can be improved with symptomatic treatments.

- Visual changes (see p. 1073).
- Sensory symptoms – often unusual, e.g. sensation of water trickling down skin. The presenting feature in 40% of patients. Reduced vibration sensation and proprioception in the feet are among the commonest abnormalities on examination but examination may be normal despite significant sensory symptoms.
- Clumsy/useless hand or limb – due to loss of proprioception (often a dorsal column spinal plaque).
- Unsteadiness or ataxia.
- Urinary symptoms – bladder hyper-reflexia causing urinary urgency and frequency. Treat with antimuscarinics or intravesical botulinum toxin injections.
- Pain – neuropathic pain is common.
- Fatigue – a common and often debilitating symptom which can occur in patients with otherwise mild disease. This sometimes responds to amantadine or modafinil or a fatigue management programme.
- Spasticity – may require baclofen or other muscle relaxants. Occasionally botulinum toxin injections for focal spasticity.
- Depression.
- Sexual dysfunction.
- Temperature sensitivity – temporary worsening of pre-existing symptoms with increases in body temperature, e.g. after exercise or a hot bath, is known as Uhthoff's phenomenon.

Unusual presentations

Epilepsy and trigeminal neuralgia (p. 1110) occur more commonly in MS patients than in the general population. Tonic spasms (frequent brief spasms of one limb) are rare but pathognomonic of MS.

Late stage multiple sclerosis

Late MS causes severe disability with spastic tetraparesis, ataxia, optic atrophy, nystagmus, brainstem signs (e.g. bilateral INO), pseudobulbar palsy and urinary incontinence. Cognitive impairment, often with frontal lobe features, may occur in late stage disease. In a proportion of patients, disability eventually becomes severe with median time to requiring walking aids of 15 years and time to wheelchair use 25 years from onset.

Diagnosis of MS

Few other neurological diseases have a similar relapsing and remitting course. The diagnosis of MS requires two or more attacks affecting different parts of the CNS, i.e. dissemination in time and space, and exclusion of other possible causes. History and support from investigations, particularly MR imaging, make the diagnosis. The McDonald criteria formalize the diagnostic criteria but are designed mainly for research purposes and rarely used in clinical practice.

When taking a history at the time of initial presentation it is essential to ask about previous episodes of neurological

FURTHER READING

Polman CH, Reingold SC, Banwell B et al. Diagnostic criteria for multiple sclerosis: 2010 Revisions to the McDonald criteria. *Ann Neurol* 2011; 69:292–302.

symptoms, often years previously, that may represent episodes of unrecognized demyelination. For example a severe episode of vertigo lasting weeks or loss of vision in one eye that gradually recovered.

Investigations

The purpose of investigations is to provide supportive evidence of dissemination in time and space (i.e. to show scattered demyelinating lesions which evolve over time), to exclude other diseases and to provide evidence of immunological disturbance.

- **MRI of brain and cord** is the definitive investigation as it demonstrates areas of demyelination with high sensitivity.

Multiple scattered plaques are usually seen, demonstrating dissemination in space.

Typical lesions are oval in shape, up to 2 cm in diameter, and often orientated perpendicular to the lateral ventricles. Occasionally, large 'tumefactive' (swelling) lesions are seen.

Acute lesions show gadolinium enhancement for 6–8 weeks.

Although a sensitive technique to demonstrate plaques (normal MRI in MS is possible but distinctly rare), it is limited by lower specificity. Over the age of 50, small ischaemic lesions may be difficult to distinguish from demyelination and in younger patients other neuro-inflammatory disorders such as sarcoidosis, Behçet's syndrome and vasculitis may produce similar imaging appearances.

The presence of spinal cord lesions is quite specific for inflammatory disorders such as MS rather than ischaemic lesions so cord imaging is often useful where there is diagnostic difficulty.

Plaques are rarely visible on CT.

- **CSF examination** is often unnecessary with suggestive MR imaging and a compatible clinical picture. CSF analysis shows oligoclonal IgG bands in over 90% of cases but these are not specific for MS. The CSF cell count may be raised (5–60 mononuclear cells/mm³).
- **Evoked responses**, e.g. visual evoked responses in optic nerve lesions, may demonstrate clinically silent lesions. However since the advent of MRI they are less important in diagnosis.
- **Blood tests** are used to exclude other inflammatory disorders such as sarcoidosis or SLE or other causes of paraparesis, e.g. adrenoleucodystrophy, HIV, HTLV-1 and B₁₂ deficiency.

The clinically isolated syndrome (CIS)

In patients presenting with a first ever episode of neurological symptoms suggestive of neuro-inflammation, termed a 'clinically isolated syndrome', a diagnosis of MS cannot be made by definition. In up to 70% of such patients MRI shows multiple clinically silent lesions. An abnormal brain MRI at presentation, with multiple inflammatory type lesions, confers an 85% chance of developing MS over subsequent years (50% if presenting with optic neuritis). Patients need to be made aware of this possibility.

A second clinical event indicative of a new lesion in a different anatomical location allows the diagnosis of MS to be confirmed. Alternatively, a repeat MRI brain scan at least 1 month later showing either a new lesion or a gadolinium enhancing lesion is sufficient to show dissemination in time and space and confirm the diagnosis even in the absence of new symptoms.

Treatment

There is no cure for MS but in recent years several immunomodulatory treatments for MS have been introduced that have dramatically altered the ability to modify the course of the inflammatory relapsing-remitting phase of MS. It is hoped that these will translate into reduced long-term disability but this has yet to be proven.

- **General measures.** Education, provision of appropriate written materials and support from a multidisciplinary team including an MS nurse specialist are essentials. Treatments are available for various symptoms, e.g. pain and urinary symptoms. Physiotherapy and occupational therapy are helpful where there is persisting impairment between relapses. Infections should be treated early as they may precipitate relapses or lead to worsening of existing symptoms. Immunizations are safe.
- **Acute relapses.** Short courses of steroids, such as i.v. methylprednisolone 1 g/day for 3 days or high-dose oral steroids, are used for severe relapses. They speed recovery but do not influence long-term outcome.
- **Disease modifying drugs (DMDs)** (Table 22.19). Immunomodulatory drugs such as β -interferon (both INF- β 1b and 1a) and glatiramer acetate reduce relapse rate by one-third and serious relapses by up to half in RRMS. They also significantly reduce development of new MRI lesions and may reduce accumulation of disability over the short term. They are self-administered by s.c. or i.m. injection and are generally well tolerated apart from flu-like side-effects and injection site irritation. From a health economics point of view cost is an issue as these drugs are very expensive.

Current recommendations in the UK are that DMDs are offered to ambulant patients with RRMS where there have been two or more *significant* relapses over a 2-year period or after one major disabling relapse. When used after CIS the conversion rate to definite MS is reduced from 50% to 30% over 3 years, but in the UK treatment with DMDs after CIS is rarely recommended. DMDs are not effective in primary progressive or secondary progressive MS.

- **Treatment of aggressive RRMS.** Immunomodulatory drugs and biological agents (monoclonal antibodies) such as *natalizumab*, *alemtuzumab* and oral *fingolimod* have shown high efficacy in preventing relapses and may reduce accumulation of disability significantly (Table 22.19). Their exact place in MS treatment is not yet established but they have the potential to cause serious adverse effects and are generally used only in very aggressive disease or where relapses are not reduced by β -interferon or glatiramer acetate. Recently, oral teriflunomide which reversibly inhibits dihydroorotate dehydrogenase (an enzyme involved in pyrimidine synthesis) has been shown in a phase III study to reduce relapses and MRI evidence of disease activity

Prognosis

The clinical course of MS is unpredictable: a high MR lesion load at initial presentation, high relapse rate, male gender and late presentation are poor prognostic features but not invariably so. There is wide variation in severity. Many patients continue to live independent, productive lives; a minority become severely disabled. Life expectancy is reduced by 7 years on average.

Table 22.19 Disease modifying drugs used in RRMS

Drug	Mode of action	Administration	Reduction in relapse rate	Effect on disability	Adverse effects/ comments
β-interferon. INF-β1b and 1a	Immunomodulatory	s.c. alternate days or i.m. weekly	33%	?	Few
Glatiramer acetate	Unknown	s.c. daily	33%	?	Few
Natalizumab	MCA blocks α-4 integrin vascular adhesion molecule. Prevents T cells entering CNS	i.v. monthly	68%	+	Rarely PML (fatal) Hypersensitivity reactions
Fingolimod	Sphingosine-1-phosphate receptor (S1- PR) ligand. Prevents T cells leaving lymph nodes	Orally daily	60%	?+	Bradycardia and increased infection rate
Alemtuzumab	MCA. Anti-CD52. Depletes T > B cells	i.v. once and repeat at 1 year	65% relapse free at 4 years	++	Autoimmune disorders – Graves' disease and ITP
Mitoxantrone	Cytotoxic agent	i.v. every 3 months	?>60%	?	Cardiotoxicity and secondary malignancy. Sometimes used in relapsing progressive MS

MCA, Monoclonal antibody; PML, Progressive multifocal leucoencephalopathy. ITP, immune thrombocytopenic purpura.

NERVOUS SYSTEM INFECTION AND INFLAMMATION

Meningitis

Meningitis usually implies serious *infection* of the meninges (Box 22.25). Bacterial meningitis is fatal unless treated. Microorganisms reach the meninges either by direct extension from the ears, nasopharynx, cranial injury or congenital meningeal defect, or by bloodstream spread. Immuno-compromised patients are at risk of infection by unusual organisms. Non-infective causes of meningeal inflammation include malignant meningitis, intrathecal drugs and blood following subarachnoid haemorrhage.

Pathology

In acute bacterial meningitis, the pia-arachnoid is congested with polymorphs. A layer of pus forms. This may organize to form adhesions, causing cranial nerve palsies and hydrocephalus.

In chronic infection (e.g. TB), the brain is covered in a viscous grey-green exudate with numerous meningeal tubercles. Adhesions are invariable. Cerebral oedema occurs in any bacterial meningitis.

In viral meningitis there is a predominantly lymphocytic inflammatory CSF reaction without pus formation, polymorphs or adhesions; there is little or no cerebral oedema unless encephalitis develops.

Clinical features

The meningitic syndrome

This is a simple triad: headache, neck stiffness and fever. Photophobia and vomiting are often present. In acute bacterial infection there is usually intense malaise, fever, rigors, severe headache, photophobia and vomiting, developing within hours or minutes. The patient is irritable and often prefers to lie still. Neck stiffness and positive Kernig's sign usually appear within hours.

In less severe cases (e.g. many viral meningitides), there are less prominent meningitic signs. However, bacterial infection may also be indolent, with a deceptively mild onset.

- *Streptococcus* Group B
- *Listeria monocytogenes*
- Gram-negative bacilli, e.g. *E. coli*
- *Mycobacterium tuberculosis*
- *Treponema pallidum*

Viruses

- Enteroviruses:
 - ECHO
 - Coxsackie
- (Poliomyelitis – mainly eradicated worldwide)
- Mumps
- Herpes simplex
- HIV
- Epstein-Barr virus

Fungi

- *Cryptococcus neoformans*
- *Candida albicans*
- *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis* (USA)

^aThese organisms account for 70% of acute bacterial meningitis outside the neonatal period. A wide variety of infective agents are responsible for the remaining 30% of cases. *Haemophilus influenzae b* (Hib) has been eliminated as a cause in many countries by immunization. Malaria often presents with cerebral symptoms and a fever.

In uncomplicated meningitis, consciousness remains intact, although anyone with high fever may be delirious. Progressive drowsiness, lateralizing signs and cranial nerve lesions indicate complications such as venous sinus thrombosis (p. 1107), severe cerebral oedema, hydrocephalus, or an alternative diagnosis such as cerebral abscess (p. 1130) or encephalitis (p. 1128).

Specific varieties of meningitis

Clinical clues point to the diagnosis (Table 22.20). If there is access to the subarachnoid space via skull fracture

(recent or old) or occult *spina bifida*, bacterial meningitis can be recurrent, and the infecting organism is usually pneumococcus.

Acute bacterial meningitis

Onset is typically sudden, with rigors and high fever. Meningococcal meningitis is often heralded by a petechial or other rash, sometimes sparse (see [Emergency Box 22.1](#)). The meningitis may be part of a generalized meningococcal

septicaemia (p. 127). Acute septicaemic shock may develop in viral bacterial meningitis.

Viral meningitis

This is almost always a benign, self-limiting condition lasting 4–10 days. Headache may follow for some months. There are no serious sequelae, unless an encephalitis is present (p. 1128).

Chronic meningitis (see below)

For further discussion on chronic meningitis, see below.

Differential diagnosis

It may be difficult to distinguish between the sudden headache of subarachnoid haemorrhage, migraine and acute meningitis. Meningitis should be considered seriously in anyone with headache and fever and in any sudden headache. Neck stiffness should be looked for – it may not be obvious. Chronic meningitis sometimes resembles an intracranial mass lesion, with headache, epilepsy and focal signs. Cerebral malaria can mimic bacterial meningitis.

Management (Emergency Box 22.1)

Recognition and immediate treatment of acute bacterial meningitis is vital. Minutes save lives. Bacterial meningitis is lethal. Even with optimal care, mortality is around 15%. The following applies to adult patients; management is similar in children.

When meningococcal meningitis is diagnosed clinically by the petechial rash, immediate i.v. antibiotics should be given and blood cultures taken; lumbar puncture is unnecessary. In other causes of meningitis, a lumbar puncture is performed if there is no clinical suspicion of a mass lesion (p. 1091). If the latter is suspected an immediate CT scan must be performed because coning of the cerebellar tonsils may follow LP. Typical CSF changes are shown in [Table 22.21](#). CSF pressure is characteristically elevated. If a presumptive diagnosis of the organism can be made (e.g. pneumococcus is likely with skull fracture or sinus infection), targeted treatment should be started immediately. Immediate antibiotic treatment in acute bacterial meningitis is shown in [Table 22.22](#).

Blood should be taken for cultures, glucose and routine tests. Chest and skull films should be obtained if appropriate.

CSF stains demonstrate organisms (e.g. Gram-positive intracellular diplococci – pneumococcus; Gram-negative cocci-meningococcus). Ziehl-Neelsen stain demonstrates acid-fast bacilli (TB), though TB organisms are rarely numerous. Indian ink stains fungi.

Meticulous attention should focus on microbiological studies in suspected CNS infection with close liaison between clinician and microbiologist. Specific techniques (e.g. polymerase chain reaction for meningococci and other bacteria) are invaluable. Syphilitic serology should always be carried out.

Nervous system infection and inflammation

Rash of meningococcal septicaemia with meningitis.

Table 22.20 Clinical clues in meningitis

Clinical feature	Possible cause
Petechial rash	Meningococcal infection
Skull fracture	Pneumococcal infection
Ear disease	
Congenital CNS lesion	
Immunocompromised patients	HIV opportunistic infection
Rash or pleuritic pain	Enterovirus infection
International travel	Malaria
Occupational (work in drains, canals, polluted water, recreational swimming)	Leptospirosis
Clinical: myalgia, conjunctivitis, jaundice	

Emergency Box 22.1

Meningococcal meningitis and meningococcaemia: emergency treatment

Suspicion of meningococcal infection is a medical emergency requiring treatment immediately.

Clinical features:

- Petechial or nonspecific blotchy red rash
- Fever, headache, neck stiffness.

All these features may not be present – and meningococcal infection may sometimes begin like any apparently non-serious infection.

Immediate treatment for suspected meningococcal meningitis at first contact before transfer to hospital or investigation:

- Benzylpenicillin 1200 mg (adult dose) slow i.v. injection or intramuscularly
- Alternative if penicillin allergy – cefotaxime 1 g i.v.

In meningitis, minutes count: delay is unacceptable. On arrival in hospital:

- Routine tests including blood cultures immediately
- Watch out for septicaemic shock.

For further management and prophylaxis, see text.

Table 22.21 Typical CSF changes in viral, pyogenic and TB meningitis

	Normal	Viral	Pyogenic	Tuberculosis
Appearance	Crystal clear	Clear/turbid	Turbid/purulent	Turbid/viscous
Mononuclear cells	<5/mm ³	10–100/mm ³	<50/mm ³	100–300/mm ³
Polymorph cells	Nil	Nil ^a	200–300/mm ³	0–200/mm ³
Protein	0.2–0.4 g/L	0.4–0.8 g/L	0.5–2.0 g/L	0.5–3.0 g/L
Glucose	$\frac{2}{3}$ – $\frac{1}{2}$ blood glucose	> $\frac{1}{2}$ blood glucose	< $\frac{1}{2}$ blood glucose	< $\frac{1}{2}$ blood glucose

^aSome CSF polymorphs may be seen in the early stages of viral meningitis and encephalitis.

Table 22.22 Antibiotics in acute bacterial meningitis

Organism	Antibiotic	Alternative (e.g. allergy)
Unknown pyogenic	Cefotaxime	Benzylpenicillin and chloramphenicol
<i>Meningococcus</i>	Benzylpenicillin	Cefotaxime
<i>Pneumococcus</i>	Cefotaxime	Penicillin
<i>Haemophilus</i>	Cefotaxime	Chloramphenicol

The clinical picture and CSF examination should thus yield a presumptive cause for acute meningitis within hours. Antibiotics, however, must be started before the actual organism is identified.

If bacterial meningitis is diagnosed, further discussion with the microbiologist should include antibiotics, drug resistance, recent infections in the locality, barrier nursing and prophylaxis.

In adults with pneumococcal meningitis, dexamethasone should be given first with the initial antibiotics.

Intrathecal antibiotics are no longer used.

Local infection (e.g. paranasal sinus) should be treated surgically if necessary. Repair of a depressed skull fracture or meningeal tear may be required.

Prophylaxis

Meningococcal infection should be notified to public health authorities, and advice sought about immunization and prophylaxis of contacts, e.g. with rifampicin or ciprofloxacin. MenC, a meningococcal C conjugate vaccine, is part of many countries' immunization programme and often given to case contacts. A combined A and C meningococcal vaccine is sometimes used prior to travel from the UK to endemic regions, e.g. Africa, Asia; and a quadrivalent ACWY vaccine for specific events, e.g. the Hajj and Umrah in Mecca. There is no vaccine for Group B.

A polyvalent pneumococcal vaccine is used after recurrent meningitis, e.g. after a CSF leak following skull fracture.

Hib (*Haemophilus influenzae*) vaccine is given routinely in childhood in the UK and other countries, e.g. Gambia, virtually eliminating a common cause of fatal meningitis.

Chronic meningitis

Tuberculous meningitis (TBM) and *cryptococcal meningitis* commence typically with vague headache, lassitude, anorexia and vomiting. Acute meningitis can occur but is unusual. Meningitic signs often take some weeks to develop. Drowsiness, focal signs (e.g. diplopia, papilloedema, hemiparesis) and seizures are common. Syphilis, sarcoidosis and Behçet's also cause chronic meningitis. In some cases of chronic meningitis, an organism is never identified.

Management of tuberculous meningitis

TBM is a common and serious disease worldwide. Brain imaging, usually with MRI, may show meningeal enhancement, hydrocephalus and tuberculomas (in this chapter), although it may remain normal (see Table 22.21 for CSF changes). In many cases the sparse TB organisms cannot be seen on staining and PCR testing should be performed, although results may be negative. Repeated CSF examination is often necessary and it will be some weeks before cultures are confirmatory. Treatment with antituberculosis drugs (p. 842) – rifampicin, isoniazid and pyrazinamide – must commence on a presumptive basis and continue for at least 9 months. Ethambutol should be avoided because of its eye complications. Adjuvant corticosteroids, e.g. prednisolone 60 mg for 3 weeks, are now recommended (often tapered

Box 22.26 Causes of sterile CSF pleocytosis

- Partially treated bacterial meningitis
- Viral meningitis
- TB or fungal meningitis
- Intracranial abscess
- Neoplastic meningitis
- Parameningeal foci, e.g. paranasal sinus
- Syphilis
- Cerebral venous thrombosis
- Cerebral malaria
- Cerebral infarction
- Following subarachnoid haemorrhage
- Encephalitis, including HIV
- Rarities, e.g. cerebral malaria, sarcoidosis, Behçet's syndrome, Lyme disease, endocarditis, cerebral vasculitis

off). Relapses and complications (e.g. seizures, hydrocephalus) are common in TBM. The mortality remains over 60% even with early treatment.

Malignant meningitis

Malignant cells can cause a subacute or chronic non-infective meningitic process. A meningitic syndrome, cranial nerve lesions, paraparesis and root lesions are seen, often in confusing and fluctuating patterns. The CSF cell count is raised, with high protein and low glucose. Treatment with intrathecal cytotoxic agents is rarely helpful.

Cells in a sterile CSF (pleocytosis)

A raised CSF cell count is present without an evident infecting organism. CSF pleocytosis, i.e. a mixture of lymphocytes and polymorphs, is the usual situation (Box 22.26).

Encephalitis

Encephalitis means acute inflammation of brain parenchyma, usually viral. In viral encephalitis fever (90%) and meningism are usual, but in contrast to meningitis the clinical picture is dominated by brain parenchyma inflammation. Personality and behavioural change is a common early manifestation which progresses to a reduced level of consciousness and even coma. Seizures (focal and generalized) are very common and focal neurological deficits, e.g. speech disturbance, often occur (especially in herpes simplex encephalitis).

Viral encephalitis

The viruses isolated from adult UK cases are usually herpes simplex, VZV and other herpes group viruses, HHV-6, 7, enteroviruses and adenovirus. HSV encephalitis (HSVE) typically affects the temporal lobes initially, often asymmetric. Often, the virus is never identified. Outside the UK in endemic regions different pathogens cause encephalitis including Flaviviruses (Japanese encephalitis, West Nile virus, tick-borne encephalitis) and rabies.

Local epidemics can occur. For example, in New York in the 1990s, West Nile virus caused an epidemic and

Venezuelan equine virus was isolated from encephalitis cases in South America.

Investigations

- MR imaging shows areas of inflammation and swelling, generally in the temporal lobes in HSV encephalitis. Raised intracranial pressure and midline shift may occur leading to coning.
- EEG shows periodic sharp and slow wave complexes.
- CSF shows an elevated lymphocyte count (95%).
- Viral detection by CSF PCR is highly sensitive for several viruses such as HSV and VZV. However, a false negative result may occur within the first 48 h after symptom onset. Serology (blood and CSF) is also helpful.
- Brain biopsy is rarely required since the advent of MRI and PCR.

Treatment

Suspected HSV and VZV encephalitis is treated immediately with i.v. aciclovir (10 mg/kg 3 times a day for 14–21 days), even before investigation results are available. Early treatment significantly reduces both mortality and long-term neurological damage in survivors. Seizures are treated with anticonvulsants. Occasionally decompressive craniectomy is required to prevent coning but coma confers a poor prognosis.

Long-term complications are common including memory impairment, personality change and epilepsy.

Post-infectious encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) follows many infections (e.g. measles, mycoplasma, mumps and rubella) and rarely follows immunization after 1–2 weeks. There is a monophasic illness with multifocal brain, brainstem and often spinal cord inflammatory lesions in white matter, with demyelination. ADEM is caused by an immune mediated host response to infection and occurs principally in children and young adults. Mild cases recover completely. Survivors often have permanent brain damage. Treatment is supportive, with steroids and anticonvulsants.

Autoimmune encephalitis

This group of disorders have been described in recent years and are increasingly recognized. Autoantibodies directed against neuronal epitopes cause a subacute encephalitic illness – limbic encephalitis or panencephalitis. Limbic encephalitis presents over weeks or months with memory impairment, confusion, psychiatric disturbance, and seizures – usually temporal lobe seizures reflecting involvement of the hippocampus and mesial temporal lobes.

Paraneoplastic limbic encephalitis (PLE). Seen particularly with small cell lung cancer and testicular tumours and associated with a variety of antibodies including anti-Hu and anti-Ma2. Antibodies can be detected in 60% of cases. MRI usually shows a hippocampal high signal. PLE precedes the diagnosis of cancer in most cases and should prompt investigation to identify the tumour.

Voltage gated potassium channel (VGKC) limbic encephalitis. VGKC antibodies (which can be tested for) produce a variety of disorders including limbic encephalitis, characteristic faciobrachial dystonic seizures, neuromyotonia and peripheral nerve hyperexcitability syndromes. This usually occurs in patients older than 50 but is rarely associated with cancer (thymoma).

Anti NMDA receptor antibody panencephalitis. Presents as limbic encephalitis followed by coma and often status epilepticus. Orofacial dyskinesias are characteristic. Usually younger patients, some have ovarian teratomas.

Patients may respond to immunotherapy – i.v. immunoglobulin or plasma exchange initially followed by steroids, rituximab or cyclophosphamide. PLE responds less well to treatment.

Herpes zoster (shingles)

This is caused by reactivation of varicella zoster virus (VZV), usually within dorsal root ganglia. Primary infection with VZV causes chickenpox following which the virus remains latent in sensory ganglia. Development of shingles may indicate a decline in cell mediated immunity, e.g. due to age or malignancy.

Clinical patterns and complications

Dermatomal shingles. Thoracic dermatomes are most commonly affected. Tingling or painful dysaesthesias precede the vesicular rash by a few days (p. 81). Motor radiculopathy can occur (usually lumbar or cervical, as thoracic involvement is often clinically silent). It rarely occurs without the rash – *zoster sin herpete*. Antiviral drugs such as aciclovir, famciclovir or valaciclovir reduce the incidence of postherpetic neuralgia.

Postherpetic neuralgia. Defined as pain lasting more than 4 months after developing shingles; occurs in 10% of patients (often elderly). Burning, intractable pain responds poorly to analgesics. Response to treatment is unsatisfactory but there is a trend towards gradual recovery over 2 years. Amitriptyline or gabapentin are commonly used and topical lidocaine patches may help.

Cranial nerve involvement. Only cranial nerves with sensory fibres are affected, particularly the trigeminal and facial nerves. Ophthalmic herpes is due to involvement of V₁. This can lead to corneal scarring and secondary panophthalmitis. Involvement of the geniculate ganglion of the facial nerve is also called Ramsay Hunt syndrome (p. 1098).

Myelitis may occur in the context of shingles when the inflammatory process spreads from the dorsal root ganglion to the adjacent spinal cord.

Immunization. The Centers for Disease Control and Prevention (CDC) in America have suggested that all adults over 60 years old should be vaccinated against herpes zoster (even those who have had shingles previously), as it reduces the incidence of shingles by about 50%.

Neurosyphilis

Many neurological symptoms occur, sometimes mixed (see also syphilis, p. 166).

Asymptomatic neurosyphilis

This means positive CSF serology without signs.

Meningovascular syphilis

This causes:

- Subacute meningitis with cranial nerve palsies and papilloedema
- A gumma – a chronic expanding intracranial mass
- Paraparesis – a spinal meningovasculitis.

Tabes dorsalis

Demyelination in dorsal roots causes a complex deafferentation syndrome. The elements of tabes:

- Lightning pains (p. 1086)
- Ataxia, stamping gait, reflex/sensory loss, wasting
- Neuropathic (Charcot) joints
- Argyll Robertson pupils (p. 1074)
- Ptosis and optic atrophy.

General paralysis of the insane (GPI)

The grandiose title describes dementia and weakness. GPI dementia is typically similar to Alzheimer's (p. 1138). Progressive cognitive decline, seizures, brisk reflexes, extensor plantar reflexes and tremor develop. Death follows within 3 years. Argyll Robertson pupils are usual. GPI and tabes are rarities in the UK.

Other forms of neurosyphilis

In *congenital* neurosyphilis (acquired *in utero*), features of combined tabes and GPI develop in childhood – taboparesis.

Secondary syphilis can be symptomless or cause a self-limiting subacute meningitis.

Treatment

Benzylpenicillin 1 g daily i.m. for 10 days in primary infection eliminates any risk of neurosyphilis. Allergic (Jarisch–Herxheimer) reactions can occur; steroid cover is usually given with penicillin (p. 1129). Established neurological disease is arrested but not reversed by penicillin.

Neurocysticercosis

The pork tapeworm, *Taenia solium*, is endemic in Latin America, Africa, India and much of South-east Asia (p. 159). Epilepsy is the commonest clinical manifestation of neurocysticercosis and one of the commonest causes of epilepsy in endemic countries. Most infected people remain asymptomatic.

Brain CT and MRI show ring-enhancing lesions with surrounding oedema when the cyst dies and later calcification. Multiple cysts are often seen in both brain and skeletal muscle. Serological tests indicate infection but not activity. Biopsy of a lesion is rarely necessary. Management is primarily the control of seizures and the anthelmintic agent albendazole is often also given (usually with steroid cover).

HIV and neurology

HIV-infected individuals frequently present with or develop neurological conditions. The HIV virus itself is directly neuroinvasive and neurovirulent. Immunosuppression leads to indolent, atypical clinical patterns (p. 176). HIV patients also have a high incidence of stroke. The pattern of disease is changing where antiretroviral (ARV) therapy is available.

CNS and peripheral nerve disease in HIV

HIV seroconversion can cause meningitis, encephalitis, Guillain–Barré syndrome and Bell's palsy (the commonest cause of Bell's palsy in South Africa).

Chronic meningitis occurs with fungi (e.g. *Cryptococcus neoformans* or *Aspergillus*), TB, listeria, coliforms or other organisms. Raised CSF pressure is common in cryptococcal meningitis.

AIDS-dementia complex (ADC). A progressive, HIV-related dementia, sometimes with cerebellar signs, is still seen where antiretroviral therapy is unavailable.

Encephalitis and brain abscess. Toxoplasma, cytomegalovirus, herpes simplex and other organisms cause severe

encephalitis. Multiple brain abscesses develop in HIV infection, usually due to toxoplasmosis.

CNS lymphoma. This is typically fatal (Chapter 9).

Progressive multi-focal leucoencephalopathy (PML) is due to JC virus and occurs with very low CD4 counts (p. 191).

Spinal vacuolar myelopathy occurs in advanced disease.

Peripheral nerve disease. HIV related peripheral neuropathy is common (70%) and can be difficult to distinguish from the effects of ARV treatment which is also toxic to peripheral nerves.

Other infections

Many other infections involve the CNS and are discussed in Chapter 4, e.g. rabies, tetanus, botulism, Lyme disease and leprosy.

Other inflammatory conditions

Subacute sclerosing panencephalitis (SSPE)

Persistence of measles antigen in the CNS is associated with this rare late sequel of measles. Progressive mental deterioration, fits, myoclonus and pyramidal signs develop, typically in a child. Diagnosis is made by high measles antibody titre in blood and CSF. Measles immunization protects against SSPE, which has now been almost eliminated in the UK.

Progressive rubella encephalitis

Some 10 years after primary rubella infection, this causes progressive cognitive impairment, fits, optic atrophy, cerebellar and pyramidal signs. Antibody to rubella viral antigen is produced locally within the CNS. It is even rarer than SSPE.

Mollaret's meningitis

This is recurrent self-limiting episodes of aseptic meningitis (i.e. no bacterial cause is found) over many years. Viral (possibly herpes simplex) infection is postulated.

Whipple's disease

CNS Whipple's disease, due to *Tropheryma whippelii* infection is characterized by myoclonus, dementia and supranuclear ophthalmoplegia (p. 268). Diagnosis of CNS involvement is made by CSF PCR (only 50% sensitivity) or brain biopsy.

Neurosarcoidosis

Neurosarcoid with or without systemic sarcoid causes chronic meningoencephalitis, cord lesions, cranial nerve palsies, particularly bilateral VIIth nerve lesions, polyneuropathy and myopathy (p. 845).

Behçet's syndrome (see also p. 544)

Behçet's principal features are recurrent oral and/or genital ulceration, inflammatory ocular disease (uveitis, p. 1062) and neurological syndromes. Brainstem and cord lesions, aseptic meningitis, encephalitis and cerebral venous thrombosis occur.

Brain and spinal abscesses

Brain abscess (Fig. 22.46)

Focal bacterial infection behaves as any expanding mass. Typical bacteria found are *Streptococcus anginosus* and *Bacteroides* species (paranasal sinuses and teeth) and staphylococci (penetrating trauma). Mixed infections are common. Multiple abscesses develop, particularly in HIV infection. Fungi also cause brain abscesses. A parameningeal infective focus (e.g. ear, nose, paranasal sinus, skull fracture) or a distant source of infection (e.g. lung, heart,

Figure 22.46 Pyogenic cerebral abscess: CT. There is a ring enhancing lesion with adjacent oedema.

abdomen) may be present. Frequently no underlying cause is found. An abscess is more than 10 times rarer than a brain tumour in the UK.

Clinical features and management

Headache, focal signs (e.g. hemiparesis, aphasia, hemianopia), epilepsy and raised intracranial pressure develop. Fever, leucocytosis and raised ESR are usual although not invariable.

Urgent imaging is essential. MRI shows a ring-enhancing mass, usually with considerable surrounding oedema. The search for a focus of infection should include a detailed examination of the skull, ears, paranasal sinuses and teeth, and distant sites such as heart and abdomen. Lumbar puncture is dangerous and should not be performed. Neurosurgical aspiration with stereotactic guidance allows the infective organism to be identified. Treatment is with high-dose antibiotics and sometimes surgical resection/decompression. Despite treatment, mortality remains high at approximately 25%. Epilepsy is common in survivors.

Brain tuberculoma

TB causes chronic caseating intracranial granulomatous masses – tuberculomas. These are the commonest intracranial masses in countries where TB is common, e.g. India. Brain tuberculomas either present as mass lesions *de novo* or develop during tuberculous meningitis; they are also found as symptomless intracranial calcification on imaging. Spinal cord tuberculomas also occur. Treatment is described on page 842.

Subdural empyema and intracranial epidural abscess

Intracranial subdural empyema is a collection of subdural pus, usually secondary to local skull or middle ear infection. Features are similar to those of a cerebral abscess. Imaging is diagnostic.

In **intracranial epidural abscess** a layer of pus, 1–3 mm thick, tracks along the epidural space causing sequential cranial nerve palsies. There is usually local infection, e.g. in the middle ear. MRI shows the collection; CT is typically normal. Drainage is required, and antibiotics.

Spinal epidural abscess

Staphylococcus aureus is the usual organism, reaching the spine via the bloodstream, e.g. from a boil. Fever and back pain are followed by paraparesis and/or root lesions.

Figure 22.47 Bilateral cerebellar metastases: MR T1.

Table 22.23 Common brain tumours

Tumour	Approximate frequency
Metastases	50%
Bronchus	
Breast	
Stomach	
Prostate	
Thyroid	
Kidney	
Primary malignant tumours of neuroepithelial tissues	35%
Astrocytoma	
Oligodendroglioma	
Mixed (oligoastrocytomas) gliomas	
Ependymoma	
Primary cerebral lymphoma	
Medulloblastoma	
Benign	15%
Meningioma	
Neurofibroma	

Emergency imaging and antibiotics are essential and surgical decompression is often necessary.

BRAIN TUMOURS

Primary intracranial tumours account for some 10% of neoplasms. The most common tumours are outlined in Table 22.23. **Metastases** are the commonest intracranial tumours (Fig. 22.47). Symptomless meningiomas (benign) are found quite commonly on imaging or at autopsy.

Gliomas (Fig. 22.48)

These malignant tumours of neuroepithelial origin are usually seen within the hemispheres, but occasionally in the cerebellum, brainstem or cord. Their cause is unknown. Gliomas are occasionally associated with neurofibromatosis. They tend to spread by direct extension, virtually never metastasizing outside the CNS.

- Astrocytomas are gliomas that arise from astrocytes. They are classified histologically into grades I–IV. Grade I astrocytomas grow slowly over many years, while grade IV tumours (*glioblastoma multiforme*) cause death within several months. Cystic astrocytomas of childhood are relatively benign, and usually cerebellar.
- Oligodendrogliomas arise from oligodendrocytes. They grow slowly, usually over several decades. Calcification is common.

Meningiomas

These benign tumours (Figs 22.49–22.51) arise from the arachnoid and may grow to a large size, usually over years. Those close to the skull erode bone or cause local hyperostosis. They often occur along the intracranial venous sinuses, which they may invade. They are unusual below the tentorium. Common sites are the parasagittal region, sphenoidal ridge, subfrontal region, pituitary fossa and skull base.

Neurofibromas (Schwannomas)

These solid benign tumours arise from Schwann cells and occur principally in the cerebellopontine angle, where they

arise from the VIIIth nerve sheath (acoustic neuroma, p. 1070). They may be bilateral in neurofibromatosis type 2 (p. 1143).

Other neoplasms

Other less common neoplasms include cerebellar haemangioblastoma, ependymomas of the IVth ventricle, colloid cysts of the IIIrd ventricle, pinealomas, chordomas of the skull base, glomus tumours of the jugular bulb, medulloblastomas (a cerebellar childhood tumour), craniopharyngiomas (p. 937) and primary CNS lymphomas (p. 468). For pituitary tumours, see page 946.

Clinical features

Mass lesions within the brain produce symptoms and signs by three mechanisms:

- By direct effect – brain is infiltrated and local function impaired
- By secondary effects of raised intracranial pressure and shift of intracranial contents (e.g. papilloedema, vomiting, headache)
- By provoking generalized and/or partial seizures.

Although neoplasms, either secondary or primary, are the commonest mass lesions in the UK, cerebral abscess, tuberculoma, neurocysticercosis, subdural and intracranial haematomas can also produce features that are clinically similar.

Direct effects of mass lesions

The hallmark of a direct effect of a mass is local progressive deterioration of function. Tumours can occur anywhere within the brain. Three examples are given:

- **A left frontal meningioma** caused a frontal lobe syndrome over several years with vague disturbance of personality, apathy and impaired intellect. Expressive aphasia developed, followed by progressive right hemiparesis as the corticospinal pathways became involved. As the mass enlarged further, pressure headaches and papilloedema developed.
- **A right parietal lobe glioma** caused a left homonymous field defect (optic radiation). Cortical sensory loss in the left limbs and left hemiparesis followed over 3 months. Partial seizures (episodes of tingling of the left limbs) developed.
- **A left VIIIth nerve sheath neurofibroma (an acoustic neuroma, Schwannoma)** in the cerebellopontine angle caused, over 3 years, progressive deafness (VIII), left facial numbness (V) and weakness (VII), followed by cerebellar ataxia on the same side.

With a hemisphere tumour, epilepsy and the direct effects commonly draw attention to the problem. The rate of progression varies greatly, from a few days or weeks in a highly malignant glioma, to several years with a slowly enlarging mass such as a meningioma. Cerebral oedema surrounds mass lesions: its effect is difficult to distinguish from that of the tumour itself.

Raised intracranial pressure

Raised intracranial pressure causing headache, vomiting and papilloedema is a relatively unusual presentation of a mass lesion in the brain. These symptoms often imply hydrocephalus – obstruction to CSF pathways. Typically this is produced early by posterior fossa masses that obstruct the aqueduct and IVth ventricle but only later with lesions above the tentorium. Shift of the intracranial contents produces features that co-exist with the direct effects of any expanding mass:

FURTHER READING

Bredel M, Scholtens DM, Yadav AK et al. NFKBIA deletion in glioblastomas. *N Engl J Med* 2011; 364: 627–637.

Figure 22.48 Cerebral glioblastoma multiforme: MR T1.

Figure 22.49 Frontal meningioma: CT.

Figure 22.50 Falx meningioma (occipital): MR T1.

Figure 22.51 Meningioma within sella and suprasellar extension: MR T1.

- **Distortion of the upper brainstem**, as midline structures are displaced either caudally or laterally by a hemisphere mass (Fig. 22.48). This causes impairment of consciousness progressing to coning and death as the medulla and cerebellar tonsils are forced into the foramen magnum.
- **False localizing signs** – false only because they do not point *directly* to the site of the mass.
Three examples of false localizing signs are:
 - **A Vth nerve lesion**, first on the side of a mass and later bilaterally as the Vth nerve is compressed or stretched during its long intracranial course.
 - **A IIIrd nerve lesion** develops as the temporal lobe uncus herniates caudally, compressing III against the petroclinoid ligament. The first sign is ipsilateral pupil dilatation as parasympathetic fibres are compressed.
 - **Hemiparesis** on the same side as a hemisphere tumour, i.e. the side you might not expect, from compression of the contralateral cerebral peduncle on the edge of the tentorium.

Seizures

Seizures are a common presenting feature of malignant brain tumours. Partial seizures, simple or complex, that may evolve into generalized tonic-clonic seizures, are characteristic of many hemisphere masses, whether malignant or benign. The pattern of partial seizure is of localizing value (p. 1112).

Investigations

Imaging

Both CT and MRI are useful in detecting brain tumours; MRI is superior for posterior fossa lesions. Benign and malignant tumours, brain abscess, TB, neurocysticercosis and infarction have characteristic, but not entirely reliable, appearances and refined imaging techniques and biopsy are often necessary. MR angiography is used occasionally to define blood supply and MR spectroscopy to identify patterns typical of certain gliomas. PET is sometimes helpful to locate an occult primary tumour with brain metastases.

Routine tests

Since metastases are common, routine tests, e.g. chest X-ray, should be performed.

Lumbar puncture

This is contraindicated when there is any possibility of a mass lesion as withdrawing CSF may provoke immediate coning. CSF examination is rarely helpful and has been superseded by imaging.

Biopsy and tumour removal

Stereotactic biopsy via a skull burr-hole is carried out to ascertain the histology of most suspected malignancies. With a benign tumour, e.g. a symptomatic, accessible meningioma, craniotomy and removal is usual.

Management

Cerebral oedema surrounding a tumour responds rapidly to steroids: i.v. or oral dexamethasone. Epilepsy is treated with anticonvulsants.

While complete surgical removal of a tumour is an objective, it is often not possible, nor is surgery always necessary. Follow-up with serial imaging is sometimes preferable in low-grade gliomas. At exploration, some benign tumours can be entirely removed (e.g. acoustic neuromas, some parasagittal meningiomas). With a malignant tumour it is not possible to

entirely remove an infiltrating mass. Biopsy and debulking are performed.

Within the posterior fossa, tumour removal is often necessary because of raised pressure and danger of coning. Overall mortality for posterior fossa exploration remains around 10%.

For gliomas and metastases, radiotherapy is usually given and improves survival, if only slightly. Solitary metastases can often be excised successfully. Chemotherapy has little real value in the majority of primary or secondary brain tumours. Vincristine, procarbazine and temozolomide (an oral alkylating agent) can be used. Most malignant gliomas have a poor prognosis despite advances in imaging, surgery, chemotherapy and radiotherapy – <50% survival for grade IV gliomas at 2 years. Surgical debulking and radiotherapy improve survival by 4–5 months.

Stereotactic radiotherapy (gamma knife)

Only available in selected centres, a collimated radiotherapy beam can deliver high doses of radiation to small targets up to 3 cm in diameter with precision. It may be used to target small metastases, and inaccessible skull base tumours such as meningiomas or schwannomas. It may also be used to treat intracerebral AVMs.

HYDROCEPHALUS

Hydrocephalus is an excessive accumulation of CSF within the head caused by a disturbance of formation, flow or absorption. High pressure and ventricular dilatation result (Fig. 22.52).

Infantile hydrocephalus

Head enlargement in infancy occurs in 1 in 2000 live births. There are several causes:

- **Arnold–Chiari malformations**. Cerebellar tonsils descend into the cervical canal. Associated spina bifida is common. *Syringomyelia* may develop (p. 1137).
- **Stenosis of the aqueduct of Sylvius**. Aqueduct stenosis is either congenital (genetic) or acquired following neonatal meningitis/haemorrhage.
- **Dandy–Walker syndrome**. There is cerebellar hypoplasia and obstruction to IVth ventricle outflow foramina.

Hydrocephalus in adults

Hydrocephalus is sometimes an unsuspected finding on imaging. Stable childhood hydrocephalus can become

Figure 22.52 Hydrocephalus with gross IIIrd, IVth and lateral ventricle enlargement: MR T1.

Hydrocephalus

apparent in adult life ('arrested hydrocephalus') but can suddenly decompensate. Combinations of headache, cognitive impairment, features of raised intracranial pressure, and ataxia develop depending on how high the CSF pressure rises and rapidity of onset. Elderly patients with more compliant brains may present with gradual onset gait apraxia and subtle cognitive slowing.

Hydrocephalus may be caused by:

- **Posterior fossa and brainstem tumours** obstructing the aqueduct or IVth ventricular outflow
- **Subarachnoid haemorrhage**, head injury or meningitis (particularly tuberculous), causing obstruction of CSF flow and reabsorption
- **A third ventricle colloid cyst** causing intermittent hydrocephalus – recurrent prostrating headaches with episodes of lower limb weakness
- **Choroid plexus papilloma** (rare) secretes CSF.

Frequently, the underlying cause for hydrocephalus remains obscure.

Treatment

Ventriculoperitoneal shunting is necessary when progressive hydrocephalus causes symptoms. Removal of tumours is carried out when appropriate. Endoscopic third ventriculostomy may be performed.

Normal pressure hydrocephalus (NPH)

NPH describes a syndrome of enlarged lateral ventricles in elderly patients with the clinical triad of:

- A gait disorder – gait apraxia
- Dementia
- Urinary incontinence.

The term is a misnomer, as it is a low-grade hydrocephalus with intermittently raised ICP. Ventriculoperitoneal shunting may be required. A trial of prolonged drainage of lumbar CSF over several days predicts response to shunt insertion.

TRAUMATIC BRAIN INJURY

In most western countries head injury accounts for about 250 hospital admissions per 100 000 population annually. Traumatic brain injury (TBI) describes injuries with potentially permanent consequences. For each 100 000 people, 10 die annually following TBI; 10–15 are transferred to a neurosurgical unit – the majority of these require rehabilitation for a prolonged period of 1–9 months. The prevalence of survivors with a major persisting handicap is around 100/100 000. Road traffic accidents and excessive alcohol use are the principal aetiological factors in this major cause of morbidity and mortality, in many countries.

Skull fractures

Linear skull fracture of the vault or base is one indication of the severity of a blow, but is itself not necessarily associated with any brain injury. Healing of linear fractures takes place spontaneously. **Depressed** skull fracture is followed by a high incidence of post-traumatic epilepsy. Surgical elevation and debridement are usually necessary.

Principal local complications of skull fracture are:

- **Meningeal artery rupture** – causing extradural haematoma
- **Dural vein tears** – causing subdural haematoma (p. 1106)
- **CSF rhinorrhoea/otorrhoea** and consequent meningitis.

Mechanisms of brain damage

Older classifications attempted to separate *concussion*, transient coma for hours followed by apparent complete clinical recovery, from brain *contusion*, i.e. bruising, with prolonged coma, focal signs and lasting damage. Pathological support for this division is poor. Mechanisms of TBI are complex and interrelated:

- Diffuse axonal injury – shearing and rotational stresses on decelerating brain, sometimes at the site opposite impact (the *contrecoup* effect)
- Neuronal and axonal damage from direct trauma
- Brain oedema and raised intracranial pressure
- Brain hypoxia
- Brain ischaemia.

Clinical course

In a mild TBI, a patient is stunned or dazed for a few seconds or minutes. Following this the patient remains alert without post-traumatic amnesia. Headache can follow; complete recovery is usual. In more serious injuries duration of unconsciousness and particularly of post-traumatic amnesia (PTA) helps grade severity. PTA of >24 hours defines severe TBI. The Glasgow Coma Scale (GCS, p. 1092) is used to record the degree of coma; this has prognostic value. A GCS below 5/15 at 24 hours implies a serious injury; 50% of such patients die or remain in a vegetative or minimal conscious state (p. 1096). However, prolonged coma of up to some weeks is occasionally followed by good recovery.

Recovery after severe TBI takes many weeks or months. During the first few weeks, patients are often intermittently restless or lethargic and have focal deficits such as hemiparesis or aphasia. Gradually they become more aware, though they may remain in post-traumatic amnesia, being unable to lay down any continuous memory despite being awake. This amnesia may last some weeks or more, and may not be obvious clinically. PTA is one predictor of outcome. PTA over a week implies that persistent organic cognitive deficit is almost inevitable, although return to unsupported paid work may be possible.

Late sequelae

Sequelae of TBI are major causes of morbidity and can have serious social and medicolegal consequences. They include:

- **Incomplete recovery**, e.g. cognitive impairment, hemiparesis
- **Post-traumatic epilepsy** (p. 1113)
- **The post-traumatic (post-concussional) syndrome**. This describes the vague complaints of headache, dizziness and malaise that follow even minor head injuries. Litigation is frequently an issue. Depression is prominent. Symptoms may be prolonged
- **Benign paroxysmal positional vertigo** (BPPV, Chapter 21)
- **Chronic subdural haematoma** (p. 1071)
- **Hydrocephalus** (p. 1133)
- **Chronic traumatic encephalopathy**. This follows repeated and often minor injuries. It is known as the 'punch-drunk syndrome' and consists of cognitive impairment, extrapyramidal and pyramidal signs, seen typically in professional boxers.

Immediate management

Attention to the airway is vital. If there is coma, depressed fracture or suspicion of intracranial haematoma, CT imaging and discussion with a neurosurgical unit are essential.

Indications for CT imaging vary from imaging all minor head injuries in some US centres to more stringent criteria elsewhere.

In many severe TBI cases, assisted ventilation will be needed. Intracranial pressure monitoring is valuable. Hypothermia lowers intracranial pressure when used early after a TBI; an effect on outcome has only been seen in specialized neurotrauma centres. Care of the unconscious patient is described on [page 1096](#). Prophylactic antiepileptic drugs have been shown to be of no value in prevention of late post-traumatic epilepsy.

Rehabilitation

TBI cases require skilled, prolonged and energetic support. Survivors with severe physical and cognitive deficits require rehabilitation in specialized units. Rehabilitation includes care from a multidisciplinary team with physiotherapeutic, psychological and practical skills. Many survivors are left with cognitive problems (amnesia, neglect, disordered attention and motivation) and behavioural/emotional problems (temper dyscontrol, depression and grief reactions). Long-term support for both patients and families is necessary.

SPINAL CORD DISEASE

The cord extends from C1, the junction with the medulla, to the lower vertebral body of L1, where it becomes the conus medullaris. Blood supply is from the anterior spinal artery and a plexus on the posterior cord. This network is supplied by the vertebral arteries, and several branches from lumbar and intercostal vessels including the artery of Adamkiewicz.

Spinal cord compression

Principal features of chronic and subacute cord compression are spastic paraparesis or tetraparesis, radicular pain at the level of compression, and sensory loss below the compression ([Box 22.27](#)).

For example, in compression at T4 ([Fig. 22.15](#)) a band of pain radiates around the thorax, characteristically worse on coughing or straining. Spastic paraparesis develops over months, days or hours, depending upon underlying pathology. Numbness commencing in the feet rises to the level of compression. This is called the *sensory level* and is usually 2–3 dermatome levels below the level of anatomical compression. Retention of urine and constipation develop.

Causes

Disc and vertebral lesions. Central cervical disc and thoracic disc protrusion cause cord compression ([p. 1148](#)).

Box 22.27 Causes of spinal cord compression

- Spinal cord tumours
- Extradural, e.g. meningioma or neurofibroma
- Intramedullary, e.g. ependymoma or glioma
- Vertebral body destruction by bone metastases, e.g. prostate primary
- Disc and vertebral lesions:
 - Chronic degenerative and acute central disc prolapse
 - Trauma
- Inflammatory:
 - Epidural abscess
 - Tuberculosis
 - Granulomatous
- Epidural haemorrhage/haematoma

Chronic compression due to cervical spondylotic myelopathy is frequently seen in clinical practice and is the commonest cause of a spastic paraparesis in an elderly person.

Trauma. Stabilize the neck and back and move patient with extreme caution in trauma. Any trauma to the back is potentially serious and the patient should be immobilized until the extent of the injury can be determined.

Spinal cord tumours. Extradural tumours, e.g. meningiomas and neurofibromas, cause cord compression ([Fig. 22.53](#) and [Box 22.28](#)) gradually over weeks to months, often with root pain and a sensory level ([p. 1087](#)). Vertebral body destruction by bony metastases, e.g. in prostate or breast cancer, is a common cause of spinal cord compression.

Intramedullary tumours (e.g. ependymomas) are less common and typically progress slowly, sometimes over many years. Sensory disturbances similar to syringomyelia may develop ([p. 1137](#)).

Tuberculosis. Spinal TB is the commonest cause of cord compression in countries where TB is common. There is destruction of vertebral bodies and disc spaces, with local spread of infection. Cord compression and paraparesis follow, culminating in paralysis – Pott's paraplegia.

Spinal epidural abscess. This is described on [page 1131](#).

Epidural haemorrhage and haematoma. These are rare sequelae of anticoagulant therapy, bleeding disorders or trauma and can follow lumbar puncture when clotting is abnormal. A rapidly progressive cord or cauda equina lesion develops.

Management

Acute spinal cord compression is a medical emergency. Early diagnosis and treatment is vital. MRI is the imaging technique of choice.

Routine tests (e.g. chest X-ray) may indicate a primary neoplasm or infection. Surgical exploration is frequently necessary; if decompression is not performed promptly, irreversible cord damage results. Results are excellent if benign tumours and haematomas are removed early. Radiotherapy is used to treat cord malignancies, or compression due to inoperable malignant vertebral body disease causing cord compression.

Other spinal cord disorders

Inflammatory cord lesions (transverse myelitis)

This is one of the commoner causes of a non-compressive spinal cord syndrome. MS is the commonest cause of a spastic paraparesis in a young adult. Typically 1 or 2 spinal segments are affected with part or all of the cord area at that level involved. Clinically a myelopathy evolves over days and recovery (often partial) follows over weeks or months. MR is sensitive and shows cord swelling and oedema with gadolinium enhancement at the affected level(s). CSF may be inflammatory with an excess of lymphocytes. Causes include:

- Parainfectious autoimmune inflammatory response is the commonest cause, e.g. after viral infection or immunization or in the context of MS (sometimes the presenting feature of MS)
- Systemic inflammatory disorders, e.g. SLE, Sjögren's, sarcoidosis
- Infection: viruses including herpesviruses such as VZV or EBV, HIV, HTLV-1&2 (tropical spastic paraparesis), mycobacteria-TB, syphilis, Lyme or schistosomiasis
- Neuromyelitis optica (Devic's disease) causes long cord lesions (≥ 3 segments) and optic nerve demyelination. Diagnosis is made by testing for aquaporin-4 antibodies.

Treatment is usually with high-dose steroids or other immunosuppression or antimicrobial therapy in the case of specific infections.

Anterior spinal artery (ASA) occlusion

There is acute paraplegia and loss of spinothalamic (pain and temperature) sensation, with infarction of the anterior two-thirds of the spinal cord. It may result from aortic atherosclerosis, dissection, trauma or cross-clamping in surgery. Vasculitis, emboli, haematological disorders causing thrombosis and severe hypotension are also causes. Occlusion of the artery of Adamkiewicz, which supplies the thoracic ASA, causes watershed infarction of the cord typically at the T8 level where perfusion is relatively poor.

Arteriovenous malformations (AVMs) of the cord

Although rare, spinal AVMs may be difficult to diagnose but are potentially curable. The two main types seen are dural AV fistulas (acquired) and true intramedullary AVMs (probably congenital but gradually enlarge). Dural AV fistulas occur mainly in middle aged men due to formation of a direct connection between an artery and vein in a dural nerve root sleeve. This causes arterialization of veins with venous hypertension and thus oedema and congestion of the spinal cord at and below the affected level. Presentation is with a gradually progressive myelopathy over months or a few years, often with thoracic back pain. MRI usually shows cord swelling and may show the enlarged arterialized veins over the surface of the cord. Spinal angiography demonstrates the fistula and allows endovascular ablation with glue, often with complete resolution of

symptoms if permanent neuronal damage has not already occurred.

Genetic disorders – hereditary spastic paraparesis (HSP)

Several genetic disorders may present with a gradually evolving upper motor neurone syndrome resembling a myelopathy. Typically spasticity and stiffness dominate the clinical picture rather than weakness especially in HSP. Muscle relaxants such as baclofen improve gait. There are 28 known genes associated with HSP, some causing 'pure' spasticity and others with associated neurological features, e.g. thinning of the corpus callosum.

Other genetic disorders such as adrenoleucodystrophy may cause a slowly progressive spastic paraparesis (including in manifesting female carriers) as can the spinocerebellar ataxias (p. 1143) or presenilin-1 mutations (p. 1140).

Vitamin B₁₂ deficiency

Subacute combined degeneration of the cord resulting from vitamin B₁₂ deficiency (p. 382) is the most common example of metabolic disease causing spinal cord damage. Abuse of nitric oxide may precipitate functional B₁₂ deficiency with normal serum B₁₂ levels.

Other causes of a spastic paraparesis

Motor neurone disease may present initially with a spastic paraparesis before lower motor neurone features develop (p. 1141). Paraneoplastic disorders, radiotherapy, copper deficiency, liver failure and rare toxins (e.g. lathyrism) may cause spinal cord damage. Not all causes of paraparesis relate to spinal cord pathology – beware a parasagittal cerebral meningioma presenting with a paraparesis due to bilateral compression of the leg area of the motor cortex.

Care of the patient with paraplegia

Where patients are left with a severe paraplegia there are several issues in long-term care and specialist nursing is vital.

Bladder management. The bladder does not empty and urinary retention results. Patients self-catheterize, or develop reflex bladder emptying, helped by abdominal pressure. Early treatment of urine infections is essential. Chronic kidney disease is a common cause of death.

Bowel function. Constipation and impaction must be avoided. Following acute paraplegia, manual evacuation is necessary; reflex emptying develops later.

Skin care. Risks of pressure sores and their sequelae are serious. Meticulous attention must be paid to cleanliness and regular turning. The sacrum, iliac crests, greater trochanters, heels and malleoli should be inspected frequently (p. 1227). Pressure relieving mattresses are useful initially until patients can turn themselves. If pressure sores develop, plastic surgical repair may be required. Pressure palsies, e.g. of ulnar nerves, can occur.

Lower limbs. Passive physiotherapy helps to prevent contractures. Severe spasticity, with flexor or extensor spasms, may be helped by muscle relaxants such as baclofen or by botulinum toxin injections.

Rehabilitation. Many patients with traumatic paraplegia or tetraplegia return to self-sufficiency (especially if the level is at C7 or below). A specialist spinal rehabilitation unit is necessary. Lightweight, specially adapted wheelchairs provide independence. Tendon transfer operations may allow functional grip if hands are weak. Autonomic dysreflexia may be a problem. Patients with paraplegia have substantial practical, psychological and sexual needs.

a

b

Dural arteriovenous fistulas.

Figure 22.54 Cervical syrinx – cavity within cord: MR T2.

Syringomyelia and syringobulbia

A syrinx is a fluid-filled cavity within the spinal cord. Syringobulbia means a cavity in the brainstem. Syringomyelia is frequently associated with the Arnold–Chiari malformation (p. 1133). The abnormality at the foramen magnum probably allows normal pulsatile CSF pressure waves to be transmitted to fragile tissues of the cervical cord and brainstem, causing secondary cavity formation. The syrinx is in continuity with the central canal of the cord. Syrinx formation may also follow spinal cord trauma and lead to secondary damage years later and can also be caused by intrinsic cord tumours.

Pathological anatomy

The expanding cavity in the cord gradually destroys spinothalamic neurones, anterior horn cells and lateral corticospinal tracts. In the medulla (syringobulbia), lower cranial nerve nuclei are affected.

Clinical features

Cases associated with the Arnold–Chiari malformation usually develop symptoms around the age of 20–30. Upper limb pain exacerbated by exertion or coughing is typical. Spinothalamic sensory loss – pain and temperature – leads to painless upper limb burns and trophic changes. Paraparesis develops. The following are typical signs of a substantial cervical syrinx (Fig. 22.54):

- **‘Suspended’ area of dissociated sensory loss**, i.e. spinothalamic loss in the arms and hands without loss of light touch.
- **Loss of upper limb reflexes**.
- **Muscle wasting** in the hand and forearm.
- **Spastic paraparesis** – initially mild.
- **Brainstem signs** – as the syrinx extends into the brainstem (syringobulbia) there may be tongue atrophy and fasciculation, bulbar palsy, Horner’s syndrome and impairment of facial sensation.

Investigation and management

MRI demonstrates the cavity and herniation of cerebellar tonsils. Syringomyelia is gradually progressive over several decades. Sudden deterioration sometimes follows minor trauma, or occurs spontaneously. Surgical decompression of the foramen magnum often causes the syrinx to collapse.

NEURODEGENERATIVE DISEASES

An umbrella term for disorders characterized by progressive neuronal cell loss with distinct patterns in different disorders.

These disorders are increasing in an ageing population. Understanding of the molecular pathogenesis of these disorders has advanced rapidly and common themes are emerging, including genetic causes, protein misfolding disorders and disorders of protein degradation by the proteosome system.

Dementia

Dementia is a clinical syndrome with multiple causes, defined by:

- An acquired loss of higher mental function, affecting two or more cognitive domains including:
 - Episodic memory – usually (but not always) involved
 - Language function
 - Frontal executive function
 - Visuospatial function
 - Apraxia or agnosia
- Of sufficient severity to significantly cause social or occupational impairment
- Occurring in clear consciousness (to distinguish it from delirium).

Although dementia is usually progressive it is not invariably so and may even be reversible in some cases. Dementia robs patients of their independence, is a serious burden on carers and a major socioeconomic challenge for society as a whole.

Epidemiology

Dementia is common and becoming commoner as a result of an ageing population and better case ascertainment. Age is the main risk factor followed by family history. Over age 65 there is a 6% prevalence and over age 85 the prevalence increases to 20%.

Clinical assessment

There are two main considerations:

- Does the patient have dementia?
- Is the pattern of cognitive deficits, tempo of progression, or associated features suggestive of a distinct cause?
